Study population. Sixteen pregnant women from the University of Washington and Harborview Medical Center antepartum clinics or patients referred by community obstetricians for this study were enrolled. In addition, we recruited 16 nonpregnant women from volunteers at the University of Washington women's clinics and at Puget Sound Blood Center blood drives. All study subjects met the following enrollment criteria: (1) reproductive age (18 to 40 years) with regular menses; (2) no history of vascular, renal, endocrine, or hematologic disease; (3) no vasoactive medication (including oral contraceptive) use or substance (including tobacco) abuse; (4) prephlebotomy fingerstick hemat-

ocrit ≥34%; (5) American Association of Blood Banks standards for autologous or homologous blood donation met[13]; and (6) informed consent obtainable. All pregnant subjects met the following additional criteria: (1) singleton pregnancy at 24 to 36 weeks' gestation; (2) normotensive at first prenatal visit and at enrollment; (3) no premature labor or abnormal placentation; and (4) normal fetal growth with no fetal anomalies.

Instrumentation. The maternal and volunteer donor circulation were studied by A- and B-mode ultrasonography. With the UltraCOM cardiac output monitor and the methods described by Easterling et al.[14] ultrasonographic measurements of the aortic root diameter were obtained; these measurements were used to calculate the aortic cross-sectional area. A time-velocity profile of blood flow in the ascending aorta was generated with continuous wave Doppler ultrasonography through a suprasternal window. Cardiac stroke volume was calculated by $SV = CSA \int v\,(t)\,dt$, where SV is stroke volume, CSA is aortic cross-sectional area, v is velocity, and t is ejection time. Maternal cardiac output was then calculated by CO = SV (HR, where CO is cardiac output and HR is heart rate. Blood pressure was measured every 5 minutes with an Accutorr (Datascope, Paramus, N.J.) automated cuff on the arm contralateral to the phlebotomy site. Systemic vascular resistance was calculated as TPR = 80 (MAP)/CO, where TPR is total peripheral vascular resistance and MAP is mean arterial pressure. All UltraCOM measurements were performed by an experienced research nurse whose proficiency in this method had previously been validated by close correlation with invasively obtained cardiac outputs in both pregnant and nonpregnant patients.[15]

The fetal umbilical artery flow velocity waveform was obtained with a Medasonics Vasculab D-10 continuous-wave Doppler with an insonating frequency of 4 MHz. During a period of fetal inactivity and apnea the umbilical artery waveform was identified and printed. The maximum systolic and minimum diastolic flow velocities were measured by hand, the systolic/diastolic ratio was calculated. Two separate measurements over a minimum of five waveforms were averaged. Fetal heart rate (FHR) and uterine activity were continuously monitored with a third-generation Hewlett Packard electronic fetal monitor (Hewlett Packard, Germany) with an external Doppler probe for FHR and a tocodynamometer strain gauge for uterine activity.

Study protocol. The initial fingerstick for the screening hematocrit and the subsequent phlebotomy for 1 U of whole blood were carried out by a certified phlebotomist. Collection, identification, transport, processing, and storage of the autologous units from the pregnant study group and the homologous units of blood from the control group were carried out in strict compliance with American Association of Blood Banks guidelines.

After the predonation history and informed consent were obtained, the subject was settled into semi-Fowler recumbent position. In pregnant subjects the external fetal monitors were applied, and the screening hematocrit was spun. Blood pressure, cardiac output, and fetal Doppler measurements were concurrently obtained with the woman in the supine position. Thereafter, the subjects were asked to rise to the standing position, fetal monitors were adjusted, and the vital signs were allowed to equilibrate for 5 minutes, at which time hemodynamic measurements were repeated. The subject was then returned to a recumbent position, and phlebotomy for 450 ml of whole blood was carried out. After a 10-minute equilibration period measurements were repeated, the subject was gradually returned to the standing position, and a final set of hemodynamic parameters was obtained.

Data analysis. The data were analyzed with a microcomputer statistical software package (StatView 512, Version 1.1, Abacus Concepts Inc., Brain Power, Cal-

abasas, Calif.) by means of a one- or two-tailed paired Student t test for comparisons of hemodynamic variables. The relative impact of position, pregnancy, and phlebotomy was analyzed by one-way factorial analysis of variance, with the hemodynamic parameters serving as the dependent variable and pregnancy, maternal position, and blood loss as the independent variables. A value of $p \leq 0.05$ was chosen to represent statistical significance.[16]

Human subjects. The study had University of Washington Institutional Review Board approval and was carried out in the Clinical Research Center of University Hospital. Informed consent for the study protocol and a standard consent for blood donation were obtained, and all subjects were made aware that the blood would be subject to screening for hepatitis and human immunodeficiency virus. Pregnant study subjects were also made aware that their autologous blood would be transfused only if clinical indications warranted it and that the blood, if unused, would not be added to the homologous donor pool. The study subjects were not financially compensated.

Results

A summary of the hemodynamic data is shown in Table I. As expected from the physiologic changes known to occur during pregnancy, pregnant subjects had significantly higher cardiac outputs ($p < 0.05$) and heart rates ($p < 0.05$) than did nonpregnant controls. Similarly, peripheral vascular resistance was significantly lower in the pregnant state ($p < 0.05$). The lower mean arterial pressure known to be associated with pregnancy ($p < 0.05$) was, however, only seen during recumbency before phlebotomy.

Orthostasis provoked significant changes in all maternal hemodynamic parameters in both the study and control groups before and after blood loss. Mean arterial pressure, peripheral vascular resistance, and heart rate increased, whereas cardiac output and stroke volume decreased ($p < 0.01$ for all parameters, one-tailed Student t test).

We analyzed the relative effects of pregnancy, orthostasis, and blood loss on the hemodynamic parameters we studied with one-way factorial analysis variance (Table II). When the effects of pregnancy ($p < 0.01$) and orthostatic stress ($p < 0.01$) were taken into account, the impact of a 450 ml blood loss became negligible ($p > 0.05$).

In both the pregnant and control group, the effect of phlebotomy on the subjects' responses to orthostatic stress was insignificant for cardiac output, peripheral vascular resistance, mean arterial pressure, and stroke volume ($p > 0.05$, paired Student two-tailed t test). Only the heart rate response to orthostasis was significantly different, in that a slightly more pronounced heart rate increase was observed after phlebotomy in both pregnant ($+5.82 \pm 2.2$ beats/min, $p < 0.05$) and control subjects ($+14.2 \pm 6.3$ beats/min, $p < 0.01$). In pregnant subjects, however, the magnitude of this change was significantly less pronounced than in controls ($p < 0.05$).

Neither phlebotomy nor orthostasis had significant effects on the fetal umbilical systolic/diastolic ratio ($p > 0.05$, analysis of variance) (Table II). No abnormal FHR patterns or excessive uterine activity were observed.

Two subjects (one pregnant and one control) had vasovagal episodes on arising after phlebotomy. Both events were self-limited and responded readily to additional recumbency. The FHR tracing remained normal throughout the episode.

Comment

The physiologic impact of acute blood loss in the context of blood donation has not previously been reported for either pregnant or nonpregnant individuals. The present study demonstrates that measurement of blood pressure and heart rate are only crude tools in

the evaluation of physiologic changes that may be present during periods of hemodynamic stress. Although there were profound and significant differences between pregnant and control groups in almost all hemodynamic parameters both in the supine and standing positions before and after blood loss, the mean arterial pressure reflected these differences only during recumbency before phlebotomy. This points to the need for a more detailed characterization of the hemodynamic effects of blood donation in both pregnant and nonpregnant subjects.

The noninvasive methods we used to study the donor circulation were first described by Huntsman et al.[17] and have been extensively compared with thermodilution-generated cardiac output measurements in both nonpregnant adults[18, 19] and pregnant women.[14] The correlation between thermodilution and Doppler ultrasonographic cardiac output determination in pregnancy is tight ($r = 0.91$).[15]

These noninvasive methods have previously been used to study the maternal hemodynamic effects of postural change in normal pregnancies.[20] In a study of 15 nonpregnant reproductive aged women, 14 pregnant women in the first trimester, and 16 pregnant women in the third trimester Easterling et al.[20] demonstrated a mean fall in cardiac output of 1.7 to 1.8 L/min with change from the recumbent to the standing position. Systemic vascular resistance rose in each of the groups. The most marked rise was observed in the nonpregnant group, with the smallest rise occurring during the third trimester of pregnancy.

The current study again demonstrates the increase in peripheral vascular resistance and the decline in cardiac output with orthostatic stress. The loss of 1 U of blood had no significant effect on the relative magnitude of these orthostatic responses in either pregnant women or in control subjects. Except for a small increase in the heart rate response, there appears to be no significant hemodynamic (mean arterial pressure, total peripheral resistance or cardiac output) impact on the orthostatic responses to phlebotomy in either pregnant or nonpregnant subjects.

Although pregnant and nonpregnant individuals responded similarly to both orthostatic stress and phlebotomy, some quantitative differences were observed. The increase in total peripheral vascular resistance in response to orthostatic stress both before and after phlebotomy was more pronounced in the control group. The same was true for the enhanced tachycardia seen in response to orthostatic stress after phlebotomy. These data and the absence of significant symptoms during and after blood donation in the pregnant study group support the notion that the maternal vasculature in healthy pregnancy, presumably because of its decreased reactivity to adrenergic stresses and volume loading, is relatively protected from hemodynamic changes, such as increases in vascular resistance, that are observed in nonpregnant individuals and that could conceivably pose a hazard to the developing fetus.

We recognize that the umbilical systolic/diastolic ratio, which was used to study the potential hemodynamic consequences or orthostasis and phlebotomy on the fetal circulation, permits only very limited conclusions about acute changes occurring in the fetal circulation as a result of maternal hemodynamic interventions. However, others have described measurable changes in the umbilical flow velocity waveform after maternal afterload reduction from lumbar epidural analgesia,[21] and after maternal bed rest and medical therapy in hypertensive pregnancies.[22, 23] We thus consider the absence of any consistent increase in the umbilical artery systolic/diastolic ratio in response to orthostasis or phlebotomy to be reassuring. It is further encouraging that continuous electronic fetal monitoring failed to show any abnormalities of the FHR tracing or increases in maternal uterine activity.

We thus conclude that in uncomplicated pregnancies during the third trimester the quality of the maternal hemodynamic response to the loss of 1 U of blood is similar to the response of healthy nonpregnant women and that the magnitude of this hemodynamic response appears to be somewhat less pronounced than in nonpregnant individuals. Although we cannot suggest that pregnant women are the ideal blood donors, it appears that ordinary periods of orthostatic stress, to which all pregnant women are subjected, have significantly more hemodynamic consequences than does the loss of 1 U of blood. No adverse fetal consequences resulted from the maternal hemodynamic changes that were observed as a result of blood donation. Continuous electronic fetal monitoring may thus be unnecessary if autologous blood donation is planned in a healthy near-term pregnancy.

First-trimester diagnosis of cystic hygroma—Course and outcome

Rieteke M. van Zalen-Sprock, MD, John M.G. van Vugt, MD, PhD, and Herman P. van Geijn, MD, PhD

Amsterdam, The Netherlands

OBJECTIVE: We studied the outcomes of fetuses in whom cystic hygroma was diagnosed in the first trimester of pregnancy through the application of transvaginal ultrasonography.

STUDY DESIGN: In the period 1990 to 1991 22 fetuses with cystic hygroma were found. All fetuses had karyotyping and a complete ultrasonographic search for associated anomalies.

RESULTS: Aneuploidy was found in seven of 22 fetuses: four trisomy 21, two trisomy 18, and one translocation. Monosomy X was absent in this series. In 15 of 22 cases there was a normal karyotype. In 10 of 15 euploid fetuses the small nonseptated hygroma resolved spontaneously. In four of 15 euploid fetuses other malformations were detected with ultrasonography (i.e., polycystic kidneys, coarctation of the aorta, bladder outlet obstruction, and fetal hydrops).

CONCLUSION: Whenever a cystic hygroma is suspected in the antenatal period, even if of small size, a structured and detailed ultrasonographic examination and fetal karyotyping are recommended. (Am J Obstet Gynecol 1992;167:94-8.)

Key words: Cystic hygroma, nuchal structures, transvaginal ultrasonography, first-trimester diagnosis, aneuploidy

High-frequency ultrasonography, especially through transvaginal application, allows early detection of fetal anomalies. Diagnosis in the first trimester of pregnancy has been reported for several fetal defects (e.g., gastroschisis, omphalocele, spina bifida, and cystic hygroma).[1-3] Other anomalies such as omphalocele cannot always be definitely diagnosed in the first trimester of pregnancy. Protrusion of fetal intestines anterior to the abdominal wall may reflect normal physiologic herniation.[4]

Although cystic hygromas are commonly found in first trimester abortuses,[5] the incidence at birth is rare (1/6000).[3] The introduction of transvaginal ultrasonography has dramatically increased the frequency of detection of first trimester cystic hygromas. Association of cystic hygromas with other structural defects and chromosomal abnormalities has been reported, although, on the other hand, regression of the hygroma has been observed with a good neonatal outcome.[3, 6]

This report describes the outcome of 22 fetuses with cystic hygroma diagnosed in the first trimester of pregnancy.

Subjects and methods

Ultrasonographic scans were performed with a 5.0 or 7.5 MHz transvaginal sector scanner (Acuson 128, Mountain View, Calif.). In each case ultrasonographic examination was done for obstetric reasons such as pregnancy dating or vaginal blood loss. Cystic hygromas, which originated in the soft tissue with an intact skull and spinal column, were identified as single or multiloculated, fluid-filled cavities in the lateral or pos-

terior cervical region. They all measured >3 mm in diameter and were either septated or nonseptated.[7] Whenever a cystic hygroma was suspected, a careful search for associated malformations was performed.[8-10]

Karyotype analysis was available from all patients through either chorionic villus (four transcervical, 16 transabdominal) or amniotic fluid (two) sampling. Autopsy was performed in all cases of elective abortion. In cases of small nonseptated cystic hygromas with a normal karyotype the patients had regular weekly ultrasonographic controls until the anatomic finding had resolved. An ultrasonographic examination was performed to detect or exclude additional (cardiac) anomalies at 16 to 18, 22 to 24, and 31 to 32 weeks of pregnancy.

Results

The malformations were detected in all 22 cases between 10 and 16 weeks of gestation, as listed in Table I. The mean gestational age at detection was 13.1 weeks (SD ± 1.6 weeks). Chromosome analysis was available from all 22 cases; seven fetuses (32%) had an abnormal and 15 fetuses (68%) a normal karyotype. In 10 of the euploid cases (67%) the posterior nonseptated hygromas could no longer be detected with ultrasonography after 16 weeks of gestation, and no signs of a disturbance in lymphatic drainage or other nuchal malformations such as webbed neck could be detected after birth (Fig. 1). Two of these fetuses had a single umbilical artery. Both infants were born at term and did not show any morphologic abnormality. In four euploid fetuses associated malformations were detected. One fetus had a cardiac anomaly, consisting of a small atrial and ventricular septal defect and a coarctation of the aorta, detected in the third trimester of pregnancy and confirmed after delivery. In this case the hygroma was partially absorbed. The ultrasonographic appearance changed during pregnancy from a translucent structure to a thick echogenic nuchal fold. The child was born with a webbed neck. Noonan's syndrome was considered, although the cardiac anomaly originally described with this single gene disorder consists of pulmonary stenosis. One pregnancy with a euploid fetus in which the hygroma had resolved showed later on severe oligohydramnios. At 22 weeks polycystic kidneys and absence of bladder filling were detected. The malformations in the third fetus consisted of bladder outlet obstruction and deformation of the legs. In the fourth case there was a serious progressive septated hygroma in the neck and axillary region in association with fetal hydrops. One pregnancy with a euploid fetus was terminated on the patient's request.

Septation of the hygroma was found in six of 22

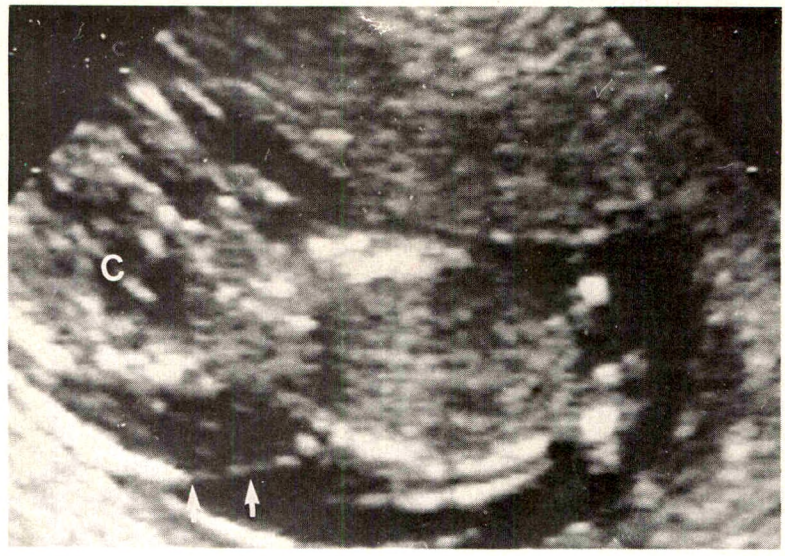

Fig. 2. Large sonolucent hygroma *(arrows)* in fetus with trisomy 18. *C*, Caput.

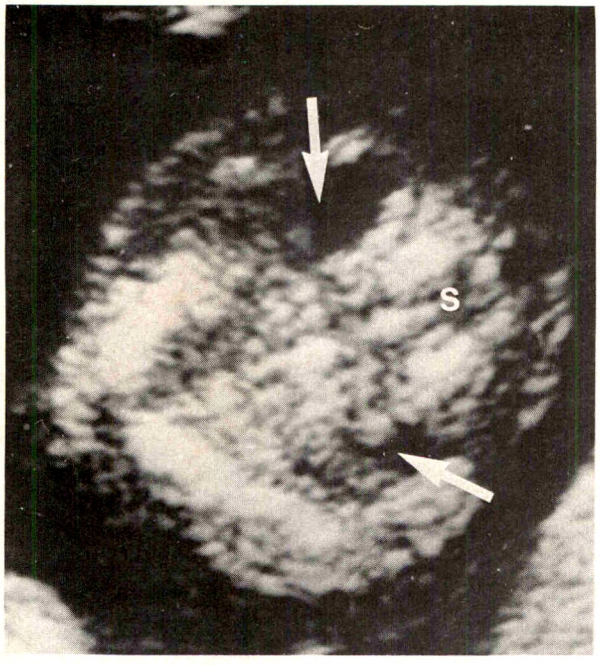

Fig. 3. Transverse scan through cervical spine *(S)*, with lateral localized translucent cysts *(arrows)* in fetus with trisomy 21.

fetuses, whereas 16 of 22 were nonseptated. Three fetuses with a septated hygroma had aneuploidy and two fetuses had a normal karyotype but demonstrated associated anomalies. One fetus with a septated hygroma was euploid and had no associated malformations. Of the 16 cases with a nonseptated hygroma four were aneuploid (one with associated anomalies), two had associated anomalies with a normal karyotype, and 10 fetuses were euploid and showed no other malformations.

In 21 of the 22 cases the hygroma was located posterior in the neck area (Fig. 2). In one case the malformation was lateral in the cervical region. Trisomy 21 was diagnosed (Fig. 3). All pregnancies with abnormal karyotypes (seven cases) were electively aborted as were four euploid pregnancies, three because of the associated anomalies and one because of serious mental instability in the mother. Autopsy results were available from all terminated pregnancies. The small nonseptated hygromas ultrasonographically detected in four of the seven aneuploid cases could not be identified by the pathologist at autopsy, probably due to lytic processes of the fetal material. The septated hygromas could all be identified by the pathologist at autopsy.

Comment

Fetal cystic hygromas are congenital malformations of the lymphatic system manifested as single or multiloculated fluid-filled cavities in the neck region. The posterior or lateral position and cystic appearance are characteristic.[11] The lymphatic vessels normally drain into two large sacs lateral to the jugular vein.[12] In case of a defect in the formation of the lymphatic vessels, the jugular sacs enlarge and lymph accumulates in tissues. The hygroma may regress and resolve if collateral routes develop or the jugular veins connect.[13, 14] Larger hygromas are often divided by a midline septum in the nuchal region. Extension to the fetal skull may be present. This feature has to be differentiated from other craniocervical masses such as encephalocele or meningomyelocele, teratoma, hemangiomas, and familial nuchal bleb.[15-17] Furthermore, one should be aware of diagnostic errors, i.e., a segment of the umbilical cord behind the neck, prominent fetal hair (later in pregnancy), an adjacent subchorionic cyst, or a part of the amnion not yet merged with the chorion in the first

trimester. Cystic structures in the neck region have been described in various sizes. Cullen et al.[3] refer to nuchal blebs if the size is <3 mm. In that case the cystic structure is always nonseptated and disappears before the eleventh week.

If a small cystic hygroma in the nuchal region has been detected there is also the possibility of a pseudomembrane,[18] especially when the suspected structure is not found in follow-up sonograms. Either the small cystic hygroma has absorbed or a dorsal specular reflection originating from the surface of the skin had been identified during the first examination.

Larger hygromas have often been described as caused by Turner's syndrome.[19] Besides monosomy X, which is often associated with generalized edema and coarctation of the aorta, several other chromosomal disorders have been reported, such as trisomy 21, 18, and 13.[20, 21] All these syndromes have a low recurrence risk. Other syndromes with a normal karyotype such as familial pterygium colli, Robert's syndrome, and Noonan's syndrome have been described with cystic hygroma.[11, 22, 23] The main features of Noonan's syndrome are very similar to monosomy X but are easily distinguished after birth facially, cytogenetically, and gonadally. Noonan's syndrome is often associated with hypertelorism, ptosis, dental malocclusion, lowset ears, broad nasal base, webbed neck, and low posterior hairline, and the affected children have normal ovaries 46,XX, or testis 46,XY. The associated congenital heart disease in Noonan's syndrome usually consists of pulmonary stenosis. This syndrome is caused by a single gene disorder and has a recurrence risk that may be much higher than in Turner's syndrome; it has a familial predilection and is probably transmitted in an autosomal dominant manner with incomplete penetrance. An extensive ultrasonographic examination is still the diagnostic choice in future pregnancies.[24]

In the current series monosomy X was not diagnosed. Several authors describe 50% association of Turner's syndrome with cystic hygroma. It always concerned large septated cystic hygromas, often in combination with fetal hydrops. Transvaginal application and modern high-resolution equipment makes it possible to visualize smaller cystic hygromas early in pregnancy, structures often not detectable with abdominal ultrasonography. More embyros and fetuses will be identified with a cystic hygroma in the first trimester of pregnancy than before. Early detection enlarges the group with these findings drastically. Cytogenetic analysis on villus material obtained from retained abortions in the first trimester revealed an abnormal chromosome constitution in 77%.[25] The relative proportion of chromosome abnormalities in retained abortions is higher for trisomies (61%) than for 45,XO (7.5%).[25] This eight-times-higher proportion may explain the absence of a monosomy X in our series.

Not all pregnant women have an ultrasonographic examination in the first or early second trimester of pregnancy. A cystic hygroma may have resolved if the sonogram is made in the second or third trimester. It is possible that some cases of Down syndrome obvious at birth could have been diagnosed early in pregnancy if the nuchal region had been inspected ultrasonographically in the first trimester. Hygromas can also be associated with trisomy 18 or 13, but the majority of these cases will be detected by ultrasonography either in the first trimester or later in pregnancy because of associated anomalies. In most of these cases the diagnosis can be suspected prenatally and confirmed by chromosome analysis.

In conclusion, the following recommendations can be made. A close look at the nuchal region should be part of every thorough investigation for congenital anomalies, especially in the first trimester. The finding—even if of limited size—has to be followed by a detailed ultrasonographic examination, and fetal karyotyping should be offered.[7] In case of euploidy and a resolving cystic hygroma, or if the aspect of the hygroma changes during pregnancy, a close look for cardiac anomalies is advisable.

We thank Nico Leschot, MD, PhD, Institute of Anthropogenetics, University of Amsterdam, for the chromosome analysis done at his institute; Hans van der Harten, MD, PhD, Department of Pathology, Free University Amsterdam, for the autopsy results; and Veronique Karsdorp, MD, Marianne Cortenraad, MD, Sacha Amitai, and Joke van der Ouderaa for their contributions in the ultrasonographic examinations.

Baking powder pica mimicking preeclampsia

John R. Barton, MD,[a] Caroline A. Riely, MD,[b] and Baha M. Sibai, MD[a]
Memphis, Tennessee

We report a case of baking powder pica during pregnancy that was associated with maternal hypertension, hypokalemia, and elevated liver function tests. After discontinuation of baking powder ingestion and correction of electrolyte abnormalities, the blood pressure and the liver function tests normalized. (AM J OBSTET GYNECOL 1992;167:98-9.)

Key words: Pica, preeclampsia, pregnancy

Pica is an eating disorder manifested by the abnormal desire to ingest substances not generally considered for normal consumption. Previous investigations of the association of pica and toxemia of pregnancy noted a significant correlation with geophagia but not amylophagia.[1] Presented is a report of a woman who, while consuming large quantities of baking powder during her pregnancy, developed hypertension, hypokalemia, and elevated liver function tests.

Case report

A 23-year-old black woman, gravida 3, para 2, was seen at 19.5 weeks' gestation with a 3-day history of headaches, dizziness, nausea, and vomiting. Blood pressure was 144/90 mm Hg with a first-trimester blood pressure of 110/50 mm Hg. Laboratory data included serum aspartate aminotransferase 144 U/L, lactic dehydrogenase 359 U/L, platelet count 226,000/mm^3, hematocrit 21.8%, and serum potassium 3.1 mEq/L. A urine drug screen was negative. During hospitalization, after transfusion of packed red blood cells for anemia and correction of hypokalemia, the blood pressure and liver function tests normalized. The patient was discharged home, but on a return clinic

visit at 33 weeks' gestation the blood pressure was 170/86 mm Hg and proteinuria (2+) was revealed. The patient was hospitalized and placed on a regimen of magnesium sulfate for seizure prophylaxis. Laboratory data included serum aspartate aminotransferase 308 U/L, lactic dehydrogenase 962 U/L with an increased LD_4 and LD_5 fraction, total bilirubin 1.7 mg/dl, serum potassium 1.4 mEq/L, platelet count 214,000/mm^3, and hematocrit 27.5%. Blood gas studies noted a pH of 7.49. A 24-hour urine collection noted a creatinine clearance of 177 mg/min with 991 mg protein. A human immunodeficiency virus antibody screen was negative.

A computed tomographic scan of the liver was performed, which showed a normal liver size and no focal hypodensities within the liver. Hounsfield unit measurements noted the same density as the spleen. A liver biopsy was performed, which demonstrates diffuse hepatocellular swelling accompanied by portal venous dilatation and low-grade acute and chronic nonspecific portal triaditis. There was no necrosis, cholestasis, or hemorrhage. This was not consistent with the pathologic findings of preeclampsia, acute fatty liver of pregnancy, or viral hepatitis.

Although previously denying pica, on further questioning the patient admitted to a 1½ year history of ingesting Calumet (General Foods, White Plains, N.Y.) baking powder in quantities up to one can (7 ounces) per day. The patient related that this was a family remedy for the relief of gas discomfort. Again during hospitalization, after correction of hypokalemia and discontinuation of baking powder ingestion, the blood pressure and liver function tests normalized.

The patient returned in active labor at 40 weeks' gestation, at which time she admitted to continued baking powder pica. Admission blood pressure was 138/102 mm Hg with a serum potassium level of 2.4 mEq/L and hematocrit of 23.3%. A primary cesarean section was performed for secondary arrest of dilatation with delivery of a 4235 gm male infant with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. The umbilical cord blood gas noted a pH of 7.63, P_{CO_2} 19 mm Hg, and P_{O_2} 27 mm Hg with a base excess of 1.7 mEq/L.

Comment

Pica is a persistent compulsive ingestion of substances not generally considered for normal consumption. Pica is more common in black women and those women with a positive childhood and family history of pica. The most common forms of pica include consumption of clay (geophagia) or starch (amylophagia) but may include ice, coal, or soap. Although the prevalence of pica among pregnant women in high-risk groups declined between the 1950s and the 1970s, Horner et al.[2] reported that pica now affects about one fifth of high-risk women. Nutritional assessment and counseling are indicated in those patients with pica.

Baking powder is composed of 30% sodium bicarbonate with cornstarch, sodium aluminum sulfate, calcium acid phosphate, and calcium sulfate. The main effect of ingestion and chronic abuse is a hypokalemic-hypochloremic metabolic alkalosis. Other metabolic abnormalities, including hypernatremia and hypocalcemia, are possible. Transient albuminuria, neuromuscular irritability including hyperreflexia, and elevations in blood urea nitrogen may occur with metabolic alkalosis. Ingestion of baking powder has been described to cause an increase in blood pressure, but liver dysfunction seems to be an unusual finding. Acute withdrawal from baking powder may cause a hypoaldosterone-like state.

Treatment of electrolyte abnormalities associated with baking powder pica should begin with the diagnosis. Correction of chloride and potassium deficit may allow for renal excretion of bicarbonate. If severe alkalemia persists, intravenous ammonium chloride in normal saline solution may be used.

Presacral neurectomy for the treatment of pelvic pain associated with endometriosis: A controlled study

Giovanni Battista Candiani, MD, Luigi Fedele, MD, Paolo Vercellini, MD, Stefano Bianchi, MD, and Giuliana Di Nola, MD
Milan, Italy

OBJECTIVE: Our objective was to evaluate the efficacy of presacral neurectomy combined with conservative surgery for the treatment of pelvic pain associated with endometriosis.
STUDY DESIGN: In a randomized, controlled study performed in a tertiary institution 71 patients with moderate or severe endometriosis and midline dysmenorrhea were randomly assigned to conservative surgery alone (n = 36) or conservative surgery and presacral neurectomy (n = 35). Main outcome measures were relief of dysmenorrhea, pelvic pain, and deep dyspareunia after surgery according to a multidimensional and an analog pain scale.
RESULTS: Presacral neurectomy markedly reduced the midline component of menstrual pain, but no statistically significant differences were observed between the two groups in the frequency and severity of dysmenorrhea, pelvic pain, and dyspareunia in the long-term follow-up. After presacral neurectomy, constipation developed or worsened in 13 patients and urinary urgency occurred in three and a painless first stage of labor in two.
CONCLUSION: Presacral neurectomy should be combined with conservative surgery for endometriosis only in selected cases. (Am J Obstet Gynecol 1992;167:100-3.)

Key words: Endometriosis, presacral neurectomy, pelvic pain

Presacral neurectomy first described by Jaboulay[1] and Ruggi[2] in 1899, is widely used, in addition to removal of adhesions and ovarian and peritoneal endometriotic implants, in the treatment of pelvic pain associated with endometriosis. This surgical procedure is considered useful by many authors,[3-6] although it is not without intraoperative risks and side effects. Moreover, almost all studies completed so far have been retrospective and have evaluated pain without an adequate investigation of the symptom itself or without the use of a pain scale.[7] In a recent prospective study Tjaden et al.[8] observed that midline dysmenorrhea was abolished in 100% of patients undergoing presacral neurectomy in addition to conservative surgery for endometriosis. However, their series was small, and the reported benefit exclusively concerned the midline component of dysmenorrhea, whereas no favorable effect was seen in the other components.

We performed a prospective study of a larger series to evaluate the efficacy of presacral neurectomy in addition to conservative surgery in the relief of pelvic pain associated with moderate and severe endometriosis.

Material and methods

We recruited 78 consecutive patients with laparotomic or laparoscopic diagnosis of endometriosis stage III or IV of the revised American Fertility Society classification[9] undergoing conservative surgery at the First Department of Obstetrics and Gynecology, University of Milan, from June 1986 to January 1990. All the women reported moderate or severe midline or midline plus lateral menstrual pelvic pain, associated in some with intermenstrual pain or deep dyspareunia. Thirty-four were infertile. None had previously undergone surgery for gynecologic disease or received medical treatment in the 6 months before the operation. We obtained informed consent from each patient and approval from the institution.

The women were assigned to conservative surgery alone (n = 40) or to conservative surgery and presacral neurectomy (n = 38) according to a randomization list. Clinical and demographic data of the patients are shown in Table I. The sample size was based on the assumption that dysmenorrhea would resolve in 50% of the women who did not undergo presacral neurectomy and in 80% to 90% of those who did. The number of patients included gave the study a power of 80% for a difference of 30% and a power of 90% for a difference of 40% at a level of statistical significance of 0.05.

Before surgery all patients underwent gastroenterologic, urologic, and orthopedic evaluation to exclude other causes of pelvic pain. In addition, they all completed a questionnaire that requested information on

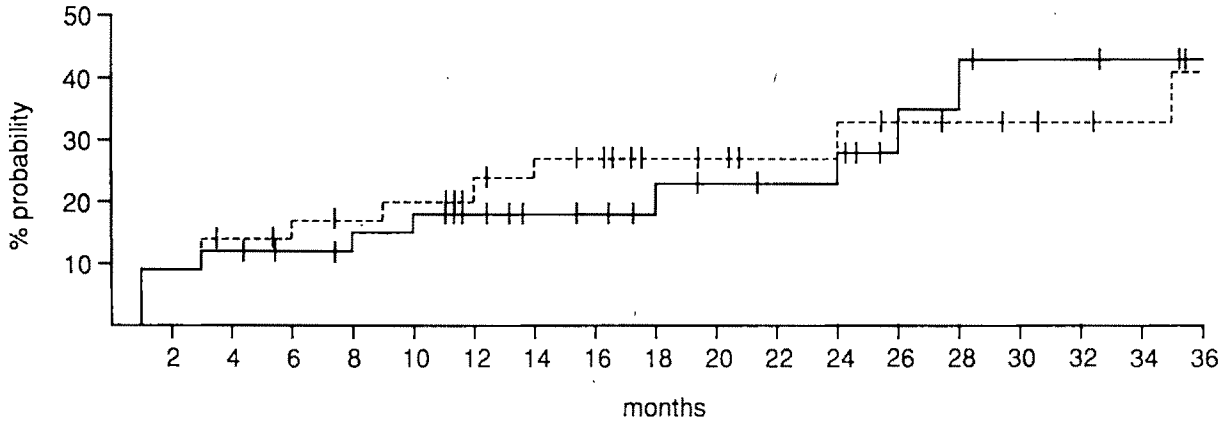

Fig. 1. Probability of recurrence of moderate or severe dysmenorrhea, according to linear pain scale, after presacral neurectomy in association with conservative surgery *(continuous line)* and after conservative surgery alone *(dotted line)*.

the presence, severity, and site of menstrual and pelvic pain and the presence and severity of deep dyspareunia. The severity of dysmenorrhea and pelvic pain was evaluated by means of a multidimensional scoring system, which is a modification of that proposed by Andersch and Milsom.[10] This system defines pain according to limitation of working ability (unaffected = 0, rarely affected = 1, moderately affected = 2, clearly inhibited = 3), coexistence of systemic symptoms (absent = 0, present = 1), and need for analgesics (no = 0, rarely = 1, regularly = 2, inefficacious = 3) and ranks their simple sum in three groups (0 to 3 = mild, 4 to 5 = moderate, 6 to 7 = severe). The women were also asked to specify the severity of dysmenorrhea and pelvic pain according to a 10-point linear pain scale in which 0 indicated the absence of pain, 1 to 5 mild pain, 6 to 7 moderate pain and 8 to 10 severe pain. The severity of deep dyspareunia was evaluated as described by Biberoglu and Behrman.[11] The women were asked to record monthly any pain symptoms after surgery. Every 6 months they underwent a clinical examination and the pain diary was checked. The follow-up was carried out in all patients for at least 1 year.

Conservative surgery was performed with the techniques described by Buttram and Reiter[12] and presacral neurectomy in accordance with Malinak's suggestions.[13] All adhesions and ovarian and peritoneal endometriotic implants were removed during surgery.

The pattern of dysmenorrhea in the postoperative follow-up was analyzed with the life-table method.[14] The patients with persistent or renewed, moderate, or severe pain were considered as treatment failures; the curve represents the cumulative probability rate of recurrence of moderate or severe dysmenorrhea.

We used the *t* test for unpaired data to compare the means and the χ^2 test to analyze the frequencies.

Table I. Characteristics of patients

	Conservative surgery (n = 36)	*Conservative surgery plus presacral neurectomy (n = 35)*
Age (yr, mean ± SD)	31.1 ± 3.6	32.5 ± 4.2
No. of parous women	5	6
No. of infertile women	19	15
Endometriosis stage		
III	26	23
IV	10	12

Results

Seven patients did not accept randomization, leaving 36 in the group for conservative surgery (group A) and 35 in that for conservative surgery plus presacral neurectomy (group B). According to the multidimensional and analog scales, dysmenorrhea before operation was moderate in 13 (36.2%) and eight (23%) of group A and in 10 (28.6%) and six (17.2%) of group B and severe in 23 (63.8%) and 28 (77%) of group A and in 25 (71.4%) and 29 (82.8%) of group B, respectively. In addition to midline dysmenorrhea, lateral menstrual pain was reported by 27 (75%) patients in group A and 24 (68.6%) in group B.

The mean time (±SD) taken to perform presacral neurectomy was 23 ± 8 minutes. No complications occurred during the operation, and no significant differences in postoperative morbidity (fever, days in hospital after surgery) were observed between the two groups. One patient underwent a second laparotomy 2 days after presacral neurectomy for a retroperitoneal presacral hematoma. Eleven subserous myomas (mean diameter 1.6 cm, range 0.6 to 3.5 cm) were enucleated or cauterized in eight patients of group A and 14 (mean diameter 1.7 cm, range 0.5 to 4 cm) in 10 patients of group B.

Figs. 1 and 2 show the pattern of dysmenorrhea during follow-up in the two groups, according to the two

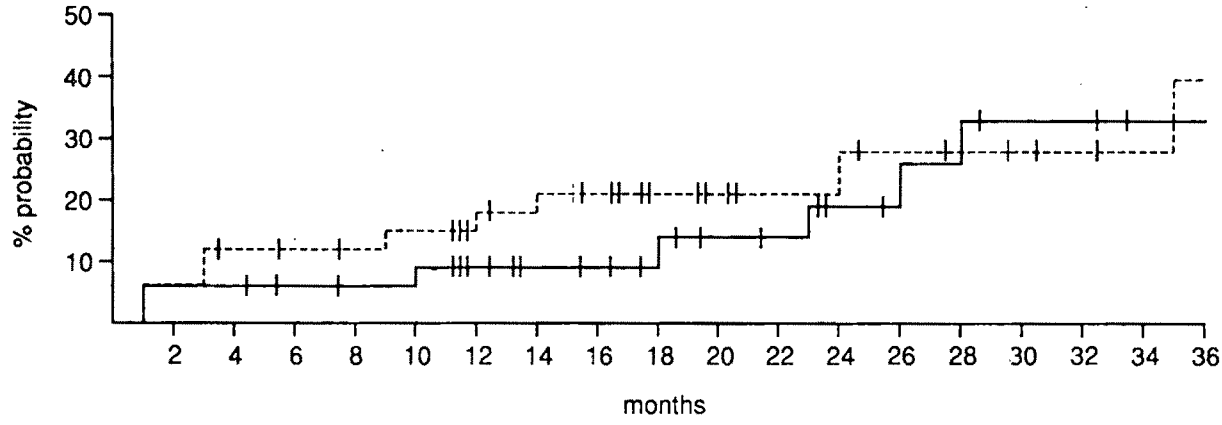

Fig. 2. Probability of recurrence of moderate or severe dysmenorrhea, according to multidimensional pain scale, after presacral neurectomy in asscciation with conservative surgery *(continuous line)* and after conservative surgery alone *(dotted line)*.

Table II. Frequency and severity of dysmenorrhea according to analog and multidimensional pain scale before and 12 months after surgery

	Conservative surgery (n = 36)		*Conservative surgery plus presacral neurectomy (n = 35)*

Severe	6 (17%)	3 (8%)	9 (26%)	2 (6%)

pain scales. Table II shows the frequency and severity of dysmenorrhea 12 months after surgery. In this period dysmenorrhea recurred in 15 patients in group A and in 12 in group B. Recurrent menstrual pain had a midline component in 15 (100%) group A women and in eight (66.7%) group B subjects (median = 3.525, p = 0.06) and a lateral one in nine (60%) and 10 (83%) (p = not significant), respectively. The frequency and severity of intermenstrual pain and deep dyspareunia in the two groups before and 12 months after surgery are reported in Table III. Presacral neurectomy was associated with different side effects in the follow-up. Moderate or severe constipation developed or worsened in 13 patients. One had recurrent subocclusive crises due to the formation of fecal masses in the rectal ampulla. Three patients reported the appearance of urinary urgency. Two women who delivered after presacral neurectomy had a painless first stage of labor. One of them arrived at the hospital at 36 weeks of gestation, already in the second stage, with a breech presentation, and vaginal delivery was achieved without complications.

Comment

In our study the addition of presacral neurectomy to conservative surgery for moderate or severe endometriosis did not result in a greater reduction of pelvic pain than did conservative surgery alone. In fact, 1 year after the operation 80% of the patients who underwent presacral neurectomy did not have moderate or severe dysmenorrhea, compared with 75% of the controls. Af-

ter conservative surgery plus presacral neurectomy deep dyspareunia resolved or improved in 84% of patients and intermenstrual pain in 82%, compared with 67% and 80% of women who underwent conservative surgery alone.

Because of the relatively small size of our series, we cannot exclude the possibility that a small beneficial effect of presacral neurectomy on pain went unrecognized. However, our study had the power to demonstrate differences of ≥40%. Because presacral neurectomy may have important complications and side effects are frequent, an advantage of <40% should not, in our opinion, justify its routine performance.

After surgery the patients were informed whether they had undergone presacral neurectomy. It was not possible to make our study a blind one for organizational and medicolegal reasons. Knowledge of the surgical procedure performed could have influenced the patients' perception of pelvic pain. However, it has been demonstrated that in dysmenorrhea the placebo effect disappears within 3 months.[15]

In our analysis of the pattern of dysmenorrhea we used the life-table method to correct for variations in follow-up and the occurrence of pregnancy. The pattern of recurrence of dysmenorrhea was very similar in the two treatment groups.

Midline recurrent menstrual pain was reported by eight women (23%) who underwent presacral neurectomy and 15 (42%) who did not. Although the difference reaches the limit of statistical significance ($p = 0.06$), these data indicate that after presacral neurectomy recurrent dysmenorrhea could also have a midline component.

To date few clinical studies have evaluated the efficacy of conservative laparotomic surgery for endometriosis specifically in terms of pain relief.[7] Some retrospective nonrandomized studies have demonstrated that combining presacral neurectomy with conservative surgery offers a better resolution of dysmenorrhea and pelvic pain than simple excision of the endometriotic lesions.[3-6] However, in most reports the sample size was limited and the extent of endometriosis poorly defined, other pelvic diseases were often included, the length of follow-up was variable, and a pain scale was almost never used prospectively.

Recently Tjaden et al.[8] performed a randomized study to evaluate the efficacy of conservative surgery with and without presacral neurectomy in patients with moderate or severe endometriosis and chronic pelvic pain. They found that midline menstrual pain was completely abolished in 100% of the four patients who underwent presacral neurectomy with respect to the 0% of the four who did not. Similar findings were also observed in the 18 patients who refused randomization. However, the resolution of deep dyspareunia and acyclic pain was not greater in the cases versus the controls.

We conclude that there is still insufficient evidence showing that presacral neurectomy is indicated in the treatment of pelvic pain in all women undergoing conservative surgery for endometriosis. Endometriosis rarely provokes exclusively midline pain. Consequently, because presacral neurectomy markedly reduces only the midline component of dysmenorrhea, overall it cannot modify the subjective and social impact of the symptom. Thus presacral neurectomy for endometriosis should be performed only by skillful surgeons after a careful selection of the patients with mainly midline pain. Another probably useful criterion to determine the expectation of pain relief could be selective hypogastric nerve block performed before the operation.[16]

OBJECTIVE: Our objective was to evaluate a self-administered cervicovaginal irrigation apparatus (MY-PAP, Medtech, Bohemia, N.Y.) for the detection of cervicovaginal human papillomavirus infection.
STUDY DESIGN: Twenty-five women referred to a colposcopy clinic because of a recent abnormal Papanicolaou smear were studied. Human papillomavirus infection test results detected by Southern blot hybridization and polymerase chain reaction from physician-administered and MY-PAP self-administered cervicovaginal lavage were paired for comparison.
RESULTS: Seventeen (68%) patients returned home samples by mail a mean of 13 days after the clinic visit. All clinic samples and 16 of 17 (94%) home samples yielded adequate deoxyribonucleic acid for human papillomavirus infection analyses. Human papillomavirus infection was detected by polymerase chain reaction in 14 of 16 (88%) samples with complete concordance of viral detection in paired samples from the clinic and home. Southern blot detected human papillomavirus infection in 13 of 25 clinic samples (52%) and 7 of 16 home samples (44%), with concordance in 12 of 16 paired samples (75%). Specific viral type was the same in all positive paired samples (6/6). Concordance was high when the initial sample had a strong (2+ to 4+) human papillomavirus infection signal (5/6, 83%) or a negative result (5/6) or when a dysplastic (cervical intraepithelial neoplasia grade 1 to 3) lesion (9/11, 82%) was seen on cervical biopsy.
CONCLUSION: Self-administered lavage represents an extremely promising technique for obtaining cervicovaginal lavage samples for human papillomavirus infection analyses. (Am J Obstet Gynecol 1992;167:104-7.)

Key words: Cervicovaginal lavage, human papillomavirus infection, polymerase chain reaction, Southern blot

Human papillomavirus (HPV) infection has been implicated as an etiologic agent in the development of cervical neoplasia and cancer.[1] However, diagnosis of HPV infection has been hampered by the inability to culture the virus and the lack of reliable serologic tests. Diagnosis has required the use of molecular biologic techniques that identify the viral genome in cellular material from the lower genital tract.

Collection of samples for HPV analysis has been accomplished by cervical biopsy, scrape, swab, brush, or cervicovaginal lavage. Of the noninvasive methods, cervicovaginal lavage has proved superior in obtaining adequate samples for Southern blot analysis.[2, 3] However, significant limitations continue to impair the screening of large populations, including the availability of trained medical personnel, time requirements, patient inconvenience, or noncompliance, expense, and inability to reach medically underserved populations.

The recent development of MY-PAP (Medtech, Bohemia, N.Y.), a self-administered cervicovaginal irrigation device designed to obtain cellular material for cervical cytologic studies, offers promise for studies of genital HPV infection and cervical cancer screening. This study was undertaken to compare the results of HPV detection in cervicovaginal lavage samples collected in the clinic with those obtained at home by the patient using MY-PAP. Results of paired clinic and home samples were compared, thereby allowing each patient to serve as her own control.

Material and methods

Patient protocol. Twenty-five new patients from the colposcopy clinic of Bronx Municipal Hospital gave in-

formed consent and were enrolled in this Institutional Review Board–approved study. All subjects had recent abnormal Papanicolaou smears. Gynecologic examination included Papanicolaou smear, cervicovaginal lavage, colposcopy, and directed cervical biopsy.

Patients were requested to obtain a self-administered cervicovaginal lavage sample with the MY-PAP kit approximately 10 days after the colposcopic examination. MY-PAP is designed and used like a douche. The device contains 21 ml of a physiologic saline solution in a small plastic bellows attached to a collection cup and a douchelike polypropylene tip with multiple openings designed to spray the irrigation solution outward in an omnidirectional pattern. After irrigation, release of the bellows apparatus causes the saline solution to be reaspirated through the tip, into the collection cup and bellows. Patients were provided with an ethanol-carbowax preservative and a preaddressed, postage-paid mail container to return the sample. No attempts were made to contact participants who failed to return the sample.

Cytology and histopathology. Cytologic slides were stained with the Papanicolaou stain, examined by a cytotechnologist, and reviewed by an experienced pathologist. Cervical cytologic results were reported with the Bethesda classification.[4] Biopsy specimens were formalin fixed, paraffin embedded, and stained with hematoxylin and eosin. Results were classified with the World Health Organization criteria for mild dysplasia (koilocytotic atypia, grade 1 cervical intraepithelial neoplasia), moderate dysplasia (grade 2 cervical intraepithelial neoplasia), or severe dysplasia (grade 3 cervical intraepithelial neoplasia–carcinoma in situ).[5]

Detection of HPV deoxyribonucleic acid (DNA). DNA was isolated from cellular material by proteinase K–sodium dodecyl sulfate digestion, followed by phenol-chloroform extraction and ethanol precipitation. Polymerase chain reaction was performed with the Manos L1 consensus primers.[6] Simultaneous amplification of HPV and a 110 bp cellular β-globin DNA fragment,[7] which served as an internal control of amplification efficacy, were performed as described by Bauer et al.[8] Polymerase chain reaction products were separated by electrophoresis in 3% NuSieve and 0.5% SeaKem agarose (FMC, Rockland, Me.) and transferred to nylon filters. A digoxigenin-labeled generic HPV probe was generated by the amplification of HPV 11, 16, and 18 with internal nested primers[6] in reactions that contained 200 μmol/L deoxyadenosine triphosphate, 200 μmol/L deoxyguanosine triphosphate, 200 μmol/L deoxycytidine triphosphate, 130 μmol/L deoxythymidine triphosphate, and 70 μmol/L digoxigenin-11-deoxyuridine triphosphate.[9] The probes were gel purified, denatured, and, together with a digoxigenin-11-deoxyuridine triphosphate end-labeled β-globin oligonucleotide probe,[6] added directly to filters that had been prehybridized in 5× saline sodium citrate, 0.02% sodium dodecyl sulfate, 0.5% blocking reagent (Boehringer Mannheim, Germany), and 0.1% *N*-lauryolsarcosine sodium salt. After overnight hybridization the filters were washed in 2× saline sodium citrate and 0.1% sodium dodecyl sulfate at 55° C, and the probe was detected by chemiluminescence with the Genius (Boehringer Mannheim) protocol.

Polymerase chain reaction products that were positive with the HPV generic probe were hybridized with type-specific oligonucleotide probes[8] for HPV 6/11, 16, 18, 31, 33, 35, 39, 45, 51, and 52. Aliquots of 3 μl of the initial polymerase chain reaction were denatured in 0.4 mol/L sodium hydroxide, and 25 mmol/L ethylenediaminetetraacetic acid, and applied to replicate filters with a 96-well dot blot apparatus. Filters were individually hybridized with the digoxigenin-11-deoxyuridine triphosphate end-labeled type-specific probes, and the blots were read blinded to other data. Samples that were positive by the generic probe mix but negative by all type-specific probes were considered to represent uncharacterized HPV types.

For Southern blot analyses approximately 5 to 10 μg DNA was digested by *Pst* I, separated by electrophoresis in an agarose gel, and transferred to a nylon filter. Low-stringency hybridization was performed with a mixed probe of phosphorus 32–labeled HPV 11, 16, and 18 DNA. Filters were washed under conditions of low stringency (TM − 40° C, 40° C below the DNA duplex melting temperature) and exposed to radiographic film at −70° C for 36 hours, followed by high-stringency (TM −10° C) washing and autoradiography for 10 days.

Southern blots were interpreted in a blinded manner. HPV typing was determined by the *Pst* I restriction enzyme pattern and the hybridization specificity.[10, 11] When distinct hybridization bands were present but the HPV type could not be determined, the virus was classified as "uncharacterized,"[12] and the approximate molecular weights of the DNA fragments were noted to allow later comparison of results from the clinic and home HPV samples. HPV hybridization signal strength was graded from weak to 4+ for each positive sample.[13]

Results

Seventeen (68%) patients returned samples they had obtained at home a mean of 13 (range 10 to 36) days after the clinic visit. There were no significant differences between the patients who returned the samples and those who did not with regard to age, initial HPV positivity, or cervical histopathologic findings (data not shown).

Cellular pellets from the home samples were somewhat bulkier and required longer digestion with proteinase K–sodium dodecyl sulfate than did samples ob-

14	High-grade lesion	Grade 2 cervical intraepithelial neoplasia	18	2+	6,11,16,18	18	2+	6,11,16,18
15	Negative	Squamous metaplasia	U	1+	18,31,33	U	1+	18,31,33
16	High-grade lesion	Grade 1 cervical intraepithelial neoplasia, cervicitis	0		U	0		16
17	Technically inadequate	Not performed	0		U	0		U

U, Positive for uncharacterized HPV type; *0*, negative for HPV.

*All subjects had a history of abnormal Papanicolaou results. Papanicolaou results shown are from the last smear obtained before cervical biopsy and clinic cervicovaginal lavage. HPV was detected by Southern blot and polymerase chain reaction followed by type-specific probing. Home samples were obtained a mean of 13 (range 10 to 36) days after the clinic visit and biopsy. Southern blot signal strength was scored on a weak+ to 4+ scale as previously described.[13]

tained in the clinic. This may have been partially attributable to the carbowax in the MY-PAP preservative. Nevertheless, all clinic samples and 94% (16/17) of the home samples yielded DNA that was quantitatively and qualitatively adequate for Southern blot and polymerase chain reaction analyses. The one sample judged to be inadequate (Table I, patient 12) contained no visible cellular pellet, and attempts to amplify the β-globin fragment were unsuccessful, suggesting that the sample was devoid of amplifiable genomic DNA.

Polymerase chain reaction followed by hybridization with the generic probe mixture detected HPV in 88% (14/16) of the amplified samples from both clinic and home, demonstrating complete concordance as to the presence or absence of virus in paired samples (Table I). Although the results of type-specific probing after

polymerase chain reaction suggested that many patients were infected with multiple HPV types, the paired samples yielded the same results on all but three instances. One patient (No. 2) had positive results for HPV types 6/11, 16, 18, and 31 in the clinic and HPV types 16, 18, and 31 in the home sample. Another patient (No. 6) had HPV 35 and 52 detected in the clinic sample and an uncharacterized type detected in the home sample. The third patient (No. 16) had an uncharacterized HPV initially but was HPV 16 positive in the home sample.

HPV was detected by Southern blot in 52% (13/25) of the clinic samples and 44% (7/16) of the home samples ($p = 0.85$, χ^2). Seventy-five percent (12/16) of the paired samples (Table I) were concordant for the presence of HPV DNA. In addition, concordance was highest when the initial sample yielded a strong (2+ to 4+) HPV signal (83% or five of six) or a negative result (5/6). Concordant results were also observed more frequently in those patients who had dysplastic lesions (cervical intraepithelial neoplasia grades 1 to 3) on cervical biopsy (82% or 9/11) than those who had inflammatory changes or normal biopsy specimens (50%, 2/4). All positive paired samples (6/6) yielded the same viral type from both lavage specimens.

Comment

Seventeen of 25 patients returned home cervicovaginal lavage samples. The 68% compliance rate observed in this inner-city, municipal hospital population was judged to be quite acceptable, particularly since no reimbursement was offered for study participation and no attempt was made to contact those individuals who failed to return samples.

Samples obtained at home and preserved in ethanol-carbowax fixative were qualitatively and quantitatively adequate for Southern blot and polymerase chain reaction analyses. Polymerase chain reaction, the more sensitive diagnostic modality, demonstrated that the same viral types were present in both clinic and home samples. Indeed, the agreement in results on paired samples was striking. Furthermore, many patients tested positive for multiple viral types with polymerase chain reaction. Potentially, some of these patients may have been infected with uncharacterized viral types that cross hybridized with one or several type-specific probes.

The results of HPV detection by Southern blot demonstrated highest concordance in paired samples when the initial samples yielded either a strong signal or a negative result and in those patients who had dysplastic lesions on cervical biopsy. This suggests that discordant results occurred most often in patients with quantitatively less virus and in patients who lacked evidence of viral cytopathic effect or dysplasia on biopsy. Factors that may have contributed to discordant results include the elapsed time (averaging 2 weeks) between samples, day-to-day variation in viral shedding, or the intervening cervical biopsy, which may have decreased detectable virus.

We conclude the MY-PAP offers an easy, relatively inexpensive method of obtaining cervicovaginal lavage samples for HPV analysis. Patient compliance and acceptability of the device were high. This method offers great promise in clinical and epidemiologic studies of HPV infection and cervical neoplasia and may be particularly useful in studies that involve repetitive sampling or in the evaluation of medically underserved populations.

Cold therapy in the management of postoperative cesarean section pain

Soheil Amin-Hanjani, MD, Joseph Corcoran, DO, and Ashwin Chatwani, MD
Philadelphia, Pennsylvania

Sixty-two patients were randomized to receive either localized cold therapy to the cesarean section incision or routine postoperative care. Evaluation of the amount of analgesia requested, infection rate, and length of hospital stay did not show a significant difference between the two groups. There is no objective evidence to show that the use of cold therapy in postoperative cesarean section pain relief is beneficial. (Am J Obstet Gynecol 1992;167:108-9.)

Key words: Cold therapy, cesarean section, postoperative analgesia

Postoperative use of cold therapy is said to result in a quicker, less painful recovery from surgery and a decrease in the need for analgesic medications. It has been widely used after orthopedic procedures[1] but has not been studied in abdominal surgery. It acts by causing constriction of the cutaneous blood vessels, by diminishing bleeding and edema, and by raising the pain threshold and causing localized muscle relaxation.[2]

We carried out a prospective study to evaluate the efficacy of cold therapy in postcesarean wound analgesia. The Dual Temp localized cold therapy unit by Seabrook Medical Systems, Inc., was used. Sixty-two consecutive patients undergoing cesarean section at Temple University Hospital were enrolled for the study. Half were randomized to receive the cold therapy (group 1) whereas the other half had routine postoperative care (group 2). The disposable Dual Temp pad was applied to the operative incision after routine closure, wound cleansing, and application of a nonadhesive dressing. The unit, which circulates chilled water through its channels, has two self-sealing hoses that are left outside the bandages. The desired surface temperature is maintained by the central unit, thereby avoiding the problem of overcooling and damage to superficial structures. The temperature of the fluid is set at 43° F, and the unit is run continuously for 48 hours. However, the unit can be disconnected and reconnected for intermittent interruptions as required. Patients receiving epidural analgesics for long-term pain control postoperatively were excluded from the study.

Comparison of the two groups with regard to age, gravidity and parity, racial background, and prenatal care did not reveal a significant difference. Likewise there was no significant difference in the indications for cesarean section in the two groups. The majority of cesarean sections were performed with the patient under epidural anesthesia, with spinal or general anesthesia used in the rest of the cases. Postoperative parenteral analgesia was with meperidine hydrochloride and promethazine hydrochloride, followed by oxycodone or acetaminophen with codeine when bowel function returned. No significant difference was noted between the two groups in relation to the amount and duration for which postoperative analgesia was required. Patients with group 1 required an average of

6/1/36678

Table I. Comparison of two patient groups

	Cold therapy (n = 31)	*Control (n = 31)*	*p*
Postoperative analgesia			
Parenteral (mean)	3.09 (range 0-8)	3.08 (range 1-7)	NS
Total oral (mean)	2.68 (range 0-9)	3.16 (range 1-5)	NS
Return of gastrointestinal function (mean No. days to passing flatus)	1.9 (range 1-6)	2.0 (range 1-5)	NS
Postpartum endomyometritis	11 (35.4%)	13 (41.9%)	NS
Length of hospital stay (mean days)	4.58 (range 3-7)	4.83 (range 3-8)	NS

NS, Not significant.

3.09 injections followed by 2.68 oral doses of analgesia as compared with patients in group 2, who required 3.08 injections followed by 3.16 doses of oral analgesia. One patient in group 1 did not require any analgesia postoperatively. There was also no significant difference between the two groups in relation to the time to return of bowel activity, postoperative infection rate, and length of hospital stay (Table I).

This preliminary study fails to show a significant difference in requirement for postoperative analgesia or postoperative recovery when cold therapy is used in cesarean section patients. Experience in orthopedic surgery has shown cold therapy to be an effective means of reducing postoperative pain, especially in knee surgery and hip replacement, but this study failed to show similar outcome in the treatment of postoperative pain in abdominal surgery. It has been suggested that direct application of the cooling pad over the incision, as opposed to applying it over the surgical dressing, might enhance the physiologic effect, and this might warrant further study. In summary, it should be noted that at the present there is no objective evidence to show that the use of cold therapy in postoperative cesarean section pain relief is beneficial.

Cyclooxygenase products do not modulate angiotensin II–induced contractions of human chorionic plate arteries

Grigory Sorokin, BS,[a] Nancy M. Grant, BS,[a] Brent M. Egan, MD,[b] and Julian H. Lombard, PhD[a]

Milwaukee, Wisconsin

OBJECTIVE: This study sought to determine whether cyclooxygenase products modulate angiotensin II–induced contractions of human placental arteries.

STUDY DESIGN: Ring segments of chorionic plate arteries (3 to 5 mm inner diameter) were obtained after normal vaginal deliveries. Active force n response to 10^{-6} mol/L angiotensin II or 10^{-4} mol/L arachidonic acid was measured in the presence or absence of 10^{-6} mol/L indomethacin to inhibit cyclooxygenase. The response of K^+ contracted arteries to the stable prostacyclin analog iloprost was also tested to determine whether prostacyclin relaxes these vessels. Statistical differences were assessed by analysis of variance, Wilcoxon sign rank test, or Student *t* test with Bonferroni correction for multiple comparisons.

RESULTS: Successive applications of angiotensin II produced significantly less contraction than the original dose (angiotensin II tachyphylaxis). Angiotensin II tachyphylaxis was unaffected by indomethacin. Arachidonic acid caused an indomethacin-sensitive contraction and iloprost failed to relax the arteries.

CONCLUSIONS: These results suggest that cyclooxygenase products do not mediate angiotensin II tachyphylaxis in these vessels. (AM J OBSTET GYNECOL 1992;167:110-4.)

Key words: Angiotension tachyphylaxis, prostaglandins, pregnancy-induced hypertension, prostacyclin, preeclampsia

Eicosanoids and vasoactive peptides have an important role in controlling blood flow in a number of different tissues, including the umbilicoplacental circulation.[1-5] These compounds appear to interact in many organs to regulate arterial tone, tissue blood flow, and vascular resistance. For example, vasodilator products of the cyclooxygenase pathway have been proposed to modulate angiotensin II–induced contractions in some peripheral blood vessels[5-7] (but not others[8-9]).

Alterations in the interactions between eicosanoids and other vasoactive stimuli may contribute to morbidity and mortality in some pathophysiologic states. For example, Minuz et al.[10] reported that the excretion of prostaglandin and thromboxane metabolites was altered in pregnancy–induced hypertension and concluded that an imbalance between constrictor and dilator influences in pregnancy-induced hypertension might produce vasoconstriction and potentiate the hypertensive effects of catecholamines and angiotensin II. Other authors[11, 12] have reported that vessels of preeclamptic individuals exhibit an enhanced responsiveness to angiotensin II and a diminished production of prostacyclin (PGI_2), which may be responsible for reduced blood flow and defective fetal nutrition[11] and could lead to the clinical manifestations of preeclampsia.[12]

To evaluate the potential role of altered angiotensin II responsiveness and reduced production of PGI_2 (or other cyclooxygenase products) in preeclampsia, it is essential to determine if these blood flow controllers interact in the normal placental vasculature. In the current study, we performed a series of experiments to test the hypothesis that the release of vasodilator products of the cyclooxygenase pathway modulates angiotensin II–induced contractions of the chorionic plate arteries on the fetal side of the human placenta.

Material and methods

General. The present experiments on placental vessels were conducted with the approval of the Human Research Review Committee of the Medical College of Wisconsin. Medium size chorionic plate arteries (3 to 5 mm inner diameter) were carefully dissected from human placentas obtained soon after normal vaginal

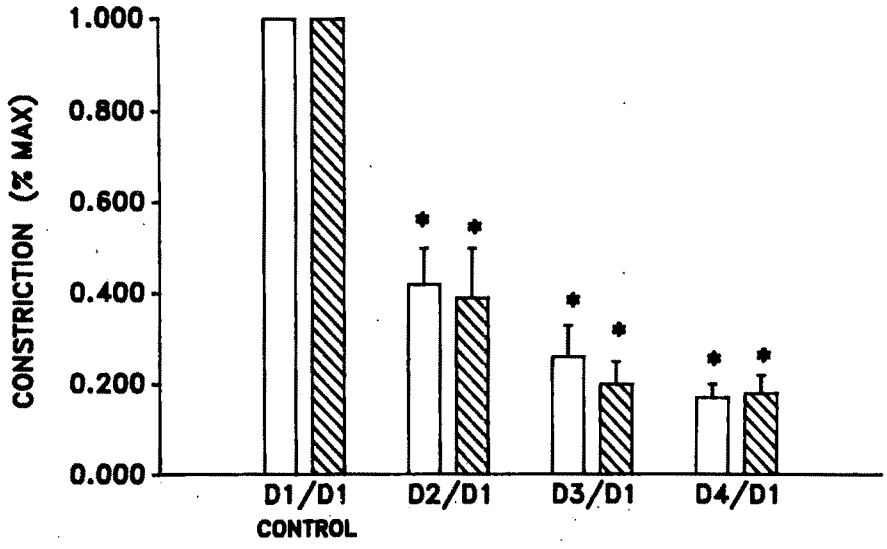

Fig. 1. Tachyphylaxis of human placental arteries to angiotensin II (10^{-6} mol/L) in presence of 10^{-6} mol/L indomethacin *(cross-hatched bars)* or vehicle *(open bars)*. Data are expressed as ratio of contractile response of vessel to given dose of angiotensin II *(D1, D2, D3, D4)* divided by the response to the first dose of angiotensin II *(D1)*. Successive applications of angiotensin II produced tachyphylaxis in both vehicle and indomethacin-treated rings. Data expressed as mean ± SEM for six arteries in each group. *Asterisk*, Significant decrease ($p < 0.05$) from initial response to angiotensin II in specific group. See text for details.

deliveries. Placental vessels were cut into 3 mm rings, mounted in 25 ml jacketed tissue baths, and maintained in physiologic salt solution containing 119 mmol/L sodium chloride, 4.6 mmol/L potassium chloride, 1.5 mmol/L magnesium chloride, 1.6 mmol/L calcium chloride dihydrate, 15 mmol/L sodium bicarbonate, 1.2 mmol/L sodium phosphate, and 11 mmol/L glucose. The vessel rings were maintained at 37° C and gassed with a 93% oxygen and 7% carbon dioxide gas mixture. Vessels were maintained at 3.0*g* passive tension and allowed to equilibrate for 1 hour before any experimental protocols. Changes in contractile force in the vessel were measured with Grass model FT-03 isometric force transducers connected to a Grass model 7 polygraph (Grass Instrument Co., Quincy, Mass.) or a CODAS electronic data acquisition system (Dataq Instruments, Inc., Akron, Ohio).

Specific protocols. Studies of tachyphylaxis to angiotensin II were performed by incubating the rings with indomethacin (10^{-6} mmol/L) or vehicle ($n = 6$ for each) for 30 minutes followed by four successive applications of 10^{-6} mol/L angiotensin II. The successive applications were separated by 30-minute washout periods. After the initial incubation period, indomethacin (10^{-6} mol/L) or its vehicle was present in the tissue bath throughout the experiment. Data were expressed as the ratio of active force in response to a given dose of angiotensin II divided by the response to the first dose of angiotensin II.

The effects of exogenous arachidonic acid (10^{-4} mol/L) were also tested on unstimulated arterial rings after 30 minutes of incubation with indomethacin (10^{-6} mol/L) or its vehicle. In this series of experiments, arachidonic acid (sodium salt, Sigma Chemical Co., St. Louis) was dissolved in ethanol to produce a 0.1 mol/L stock solution. Aliquots of the arachidonic acid stock solution were then added to the tissue bath to achieve a final concentration of 10^{-4} mol/L.

In another series of experiments, the responses of the vessels to PGI_2 were tested by adding the stable PGI_2 analog iloprost to rings that were precontracted with 40 mmol/L K^+. To determine whether PGI_2 had any dilator action on the vessels, the active force in K^+-contracted vessels treated with iloprost was compared with that in control rings that had been exposed to 40 mmol/L K^+ for an equivalent time without iloprost (K^+ time controls) and K^+-contracted rings that were treated with the nitrovasodilator sodium nitroprusside (10^{-5} mol/L).

Statistical procedures. Differences between successive angiotensin II responses in the presence and absence of indomethacin or its vehicle were assessed by comparing the absolute force developed in response with each dose of angiotensin II. The presence of significant differences was detected by analysis of variance, and differences between specific group means were assessed with a multiple range test. Responses to exogenous arachidonic acid in the presence and absence of indomethacin were compared with the Wilcoxon sign rank test. Differences in active force in iloprost-treated vessels versus K^+ time controls and nitroprusside-treated vessels were compared with a

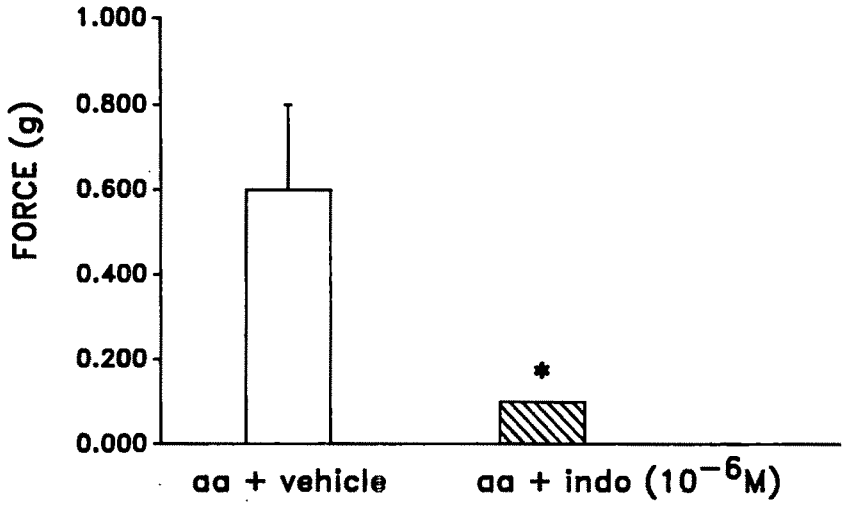

Fig. 2. Response of human chorionic plate arteries to 10^{-5} mol/L arachidonic acid *(aa)* in the presence of 10^{-6} mol/L indomethacin *(indo)* ($n = 4$) or its vehicle ($n = 7$). Data expressed as mean active force (grams) ± SEM. *Asterisk*, Significant difference ($p < 0.05$) between vehicle and indomethacin.

Student t test with a Bonferroni correction for multiple comparisons. In all comparisons, a probability value of $p < 0.05$ was considered to be statistically significant.

Results

The responses of isolated rings of human chorionic plate arteries to angiotensin II in the presence of indomethacin or its vehicle are summarized in Fig. 1. After the first exposure to angiotensin II, successive applications (second through fourth doses) produced significantly less contractile force than the original application (tachyphylaxis). Tachyphylaxis to angiotensin II was similar in the vehicle and indomethacin-treated groups.

The responses of human chorionic plate arteries to exogenous arachidonic acid in the presence of 10^{-6} mol/L indomethacin or its vehicle are summarized in Fig. 2. In these experiments, 10^{-4} mol/L arachidonic acid produced a significant contraction of the vessel, which was prevented by inhibition of cyclooxygenase with 10^{-6} mol/L indomethacin.

Fig. 3 compares the active force in K^+-contracted arteries exposed to iloprost (10^{-5} mol/L) or sodium nitroprusside (10^{-5} mol/L). In these studies arteries contracted with 40 mmol/L K^+ in the absence of iloprost or sodium nitroprusside (K^+ time controls) exhibited a pronounced reduction in active force with time, which was presumably due to stress relaxation of the vessel. Active force in vessels exposed to iloprost was not significantly different from that in K^+ time controls, whereas sodium nitroprusside caused a complete relaxation of the arteries.

Comment

Vasodilator prostaglandins, particularly PGI_2, appear to play an important role in the control of vascular reactivity, platelet aggregation, and renal and uteroplacental blood flow during normal pregnancy.[12] A major role of prostaglandins in pregnancy may be to maintain a low peripheral vascular resistance and to protect against the potential hypertensive effects of the elevated plasma angiotensin levels that occur in normal pregnancy.[13] If the interaction between vasodilator prostaglandins and angiotensin II is somehow disturbed, pregnancy-induced hypertension may develop, posing the threat of morbidity and mortality for the patient and her fetus.[14]

A number of studies have suggested that angiotensin II stimulates the synthesis and release of PGI_2 and other prostanoids[6, 7, 15-19] and that endogenous prostaglandins may modulate the response of vascular smooth muscle to angiotensin II.[5-7] However, other studies[8, 9] suggest that vasodilator eicosanoids do not contribute to angiotensin tachyphylaxis. In the current experiments, we compared successive angiotensin II–induced contractions of human chorionic plate arteries in the presence and absence of indomethacin to determine whether the release of cyclooxygenase products from the vessel modulates angiotensin II–induced contractions of these arteries.

In these experiments the contractile response of the arteries to successive applications of the same concentration of angiotensin II was significantly less than the initial response (angiotensin II tachyphylaxis). Vessel responses were virtually identical in the presence and absence of indomethacin. The latter observation is con-

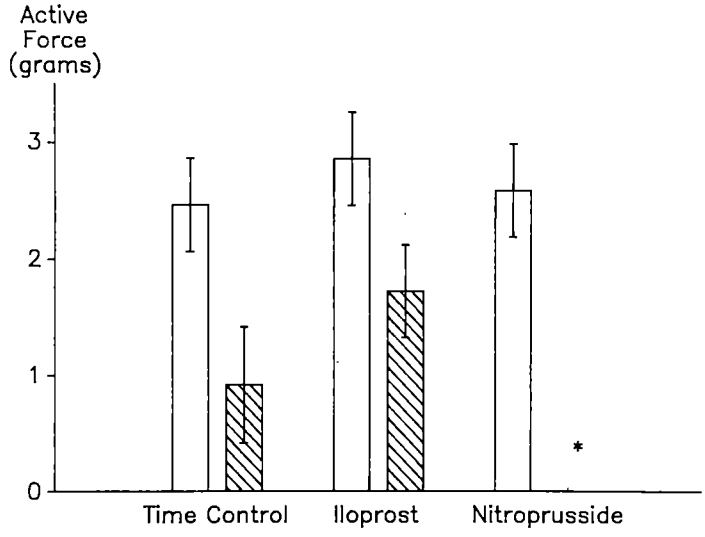

Fig. 3. Response of K^+-contracted human chorionic plate arteries to stable prostacyclin analog iloprost (10^{-6} mol/L) and sodium nitroprusside (10^{-5} mol/L). *Open bars*, Active force developed during initial activation of vessel with 40 mmol/L K^+; *cross-hatched bars*, active force during exposure to iloprost ($n = 11$), nitroprusside ($n = 5$), or 40 mmol/L K^+ with no vasodilator agent *(Time control)* ($n = 7$). Data are expressed as mean active force (grams) ± SEM. *Asterisk*, significant difference ($p < 0.05$) from active force measured in presence of iloprost. See text for details.

sistent with the view that liberation of vasodilator products of the cyclooxygenase pathway does not modulate angiotensin II–induced contractions of these fetal vessels.

Our observation that iloprost did not relax K^+-contracted chorionic plate arteries suggests that PGI_2 would not contribute to angiotensin II tachyphylaxis of these vessels, even if it is liberated from the arteries in response to angiotensin II. The lack of a dilator response to iloprost that we observed in the current experiments is consistent with the results of several animal studies, which have demonstrated that prostacyclin does not relax sheep[20-22] or rabbit[23] placental vessels and does not reverse angiotensin II–induced constriction in the sheep placental vasculature.[24, 25]

Finally, we observed that exogenous arachidonic acid caused a contraction of the arteries. This contraction was blocked by indomethacin. Although vasoconstrictor responses to arachidonic acid have been reported in some blood vessels (predominantly veins),[26, 27] arachidonic acid produces a relaxation of most arteries,[26-28] apparently as a result of the production of PGI_2 by the vascular endothelium.[28] Our observation that human chorionic plate arteries exhibit contractile responses to arachidonic acid is consistent with Tulenko's report that this compound causes constriction of resistance arteries supplying the exchange villi of the human fetal placenta.[1] Taken together, these observations indicate that the cyclooxygenase pathway in these vessels produces vasoconstrictor substances rather than vasodilator compounds.

Likely candidates for cyclooxygenase-dependent constrictor substances include thromboxane A_2,[3, 12, 29, 30] prostaglandins that have constrictor actions on chorionic plate arteries, e.g., prostaglandin E_2 or $F_{2\alpha}$,[1-4, 31] prostaglandin endoperoxides,[32] and superoxide anions generated by the hydroperoxidase activity of prostaglandin H synthase.[33, 34] Regardless of the specific compounds produced, our observation that exogenous arachidonic acid produces an indomethacin-sensitive constriction of chorionic plate arteries provides additional support for the hypothesis that angiotensin II tachyphylaxis in these vessels is not due to the production of vasodilator products by the cyclooxygenase pathway.

Although the results of the present study are consistent with the hypothesis that vasodilator products of the cyclooxyenase pathway are not direct modulators of angiotensin II–induced contractions of human chorionic plate arteries, our observations do not preclude the possibility that a reduced production of PGI_2 from other sources, e.g., uterus[35] or fetal vessels,[5] may indirectly enhance the reactivity of maternal vessels to angiotensin II in pregnancy-induced hypertension by reducing the overall level of vasodilator influences operating on these vessels. Further studies designed to identify the mechanisms of angiotensin tachyphylaxis and vascular control in the maternal and umbilicoplacental circulations should provide valuable insight into

circulatory control during normal pregnancy and pregnancy-induced hypertension.

We thank Ruth Scherkenbach and Amartyadeb Goswami for their technical assistance. Special thanks are extended to Jack A. Klieger, MD, Roland M. Pattillo, MD, and the obstetric nurses of St. Joseph's Hospital, Milwaukee, and the Milwaukee County Medical Complex for their outstanding support during these studies.

Perihepatic adhesions: Not necessarily pathognomonic of pelvic infection

Soheil Amin-Hanjani, MD, Thomas Neely, MD, and Ashwin Chatwani, MD
Philadelphia, Pennsylvania

Perihepatic adhesions are often considered to be associated with pelvic inflammatory disease and subsequent infertility. Seventeen patients out of 100 undergoing elective laparoscopic sterilization had evidence of perihepatic adhesions. Four of the 17 showed evidence of old pelvic inflammatory disease, but only two gave a history of sexually transmitted disease. All patients had a negative gonorrhea culture and 50 also had a negative chlamydia culture before the procedure. These data suggest that perihepatic adhesions may be observed in otherwise normal fertile women, and its presence does not necessarily imply pelvic inflammatory disease or poor fertility. (Am J Obstet Gynecol 1992;167:115-6.)

Key words: Perihepatic adhesions, Fitz-Hugh–Curtis syndrome, pelvic inflammatory disease, laparoscopic tubal ligation

Perihepatic adhesions are a well known sequelae of pelvic inflammatory disease. Curtis[1] in 1930 and Fitz-Hugh[2] in 1934 put forth the popular concept of a perihepatitis syndrome associated with gonococcal pelvic inflammatory disease; the syndrome is not well known under the eponym combining their names. *Neisseria gonorrhoeae* and chlamydia are considered to be the principal agents involved in the pathogenesis of Fitz-Hugh–Curtis syndrome.[1-3]

In this article we present a series of patients who at the time of laparoscopic tubal ligation were also assessed for the presence of perihepatic adhesions. A study of operative findings presents a unique new subgroup of patients with Fitz-Hugh–Curtis syndrome.

Material and methods

One hundred consecutive patients undergoing elective laparoscopic tubal ligation were enrolled in this study. All patients had a negative *N. gonorrhoeae* culture, and the last 50 also had a negative chlamydia culture within 6 weeks of the surgery. A standard history included questions concerning history of sexually transmitted diseases, pelvic inflammatory disease, liver disease, or gastrointestinal diseases. All patients underwent routine laparoscopic tubal ligation. After evaluation of the pelvis for evidence of pelvic inflammatory disease and tubal ligation, evaluation of the liver capsule and anterior abdominal wall was carried out.

6/1/36861

Table I. Perihepatic adhesions: historic factors and operative findings

	Adhesions (n = 17)	*No adhesions (n = 83)*
History of sexually transmitted disease	2 (11.8%)	12 (14.5%)
History of pelvic infection	0	2 (2.4%)
Evidence of chronic pelvic infection	4 (23.5%)	5 (6.0%)

The patients were divided into two groups on the basis of the operative findings: those with and those without perihepatic adhesions.

Results

All patients were clinically asymptomatic and had normal results of abdominal and pelvic examinations before surgery. There was no statistically significant difference in age or parity in the two groups of patients.

Seventeen patients had evidence of perihepatic adhesions. Two of the patients in the adhesion group (11.8%) and 12 of the patients in the no-adhesion group (14.5%) gave a history of sexually transmitted diseases. No patient with adhesions had a documented episode of pelvic inflammatory disease (Table I). Four of the 17 patients (23.5%) with adhesions also had evidence of old pelvic infection. This was much higher than the patients who had no perihepatic adhesions but had similar pelvic findings (five of 83 or 6%). Two patients with a history of sexually transmitted disease and perihepatic adhesions also had evidence of old pelvic infection.

Comment

Our study documents the presence of perihepatic adhesions in a new group of patients, namely, fertile asymptomatic patients with no laparoscopic evidence of old pelvic infection. None of the patients had a history of pelvic infection, and only two had a history of sexually transmitted disease. Thirteen patients had no evidence of prior infection in the pelvis, and the presence of perihepatic adhesions was a surprising finding in this group. Computer-assisted search of the literature did not reveal any documentation of such a series.

The current study suggests that perihepatic adhesions may be the only residual effect left from a pelvic infection or may occur without prior pelvic infection. It also suggests that the mere presence of perihepatic adhesions is not an indication of unfavorable outcome in patients with infertility, because all our patients were fertile women undergoing interval sterilization. A larger study to define the possible causes of perihepatic adhesions is under way.

Prophylactic amnioinfusion improves outcome of pregnancy complicated by thick meconium and oligohydramnios

Charles J. Macri, MD, CDR, MC, USN, David B. Schrimmer, MD, Anna Leung, MD, Jeffrey S. Greenspoon, MD, and Richard H. Paul, MD

Los Angeles, California

OBJECTIVE: The null hypothesis is that the use of intrapartum amnioinfusion in labors complicated by the presence of thick meconium and oligohydramios will not decrease the incidence of fetal distress, cesarean delivery, meconium aspiration, or meconium aspiration syndrome.

STUDY DESIGN: One hundred seventy term and postterm patients with thick meconium and oligohydramnios were randomly chosen to receive amnioinfusion or standard obstetric care without amnioinfusion. The frequency of fetal distress, cesarean section, meconium aspiration, and meconium aspiration syndrome were subject to χ^2 analysis, Student's t test, or Fisher's exact test.

RESULTS: The rate of fetal distress was significantly reduced in the amnioinfusion group compared with controls (three of 85 vs 19 of 85, relative risk 0.15, 95% confidence interval 0.06 to 0.42). The rate of cesarean section for fetal distress was significantly reduced in the amnioinfusion group (two of 85 vs 17 of 85, relative risk 0.118, confidence interval 0.03 to 0.49). The rates of meconium aspiration (four of 85 vs 33 of 85, relative risk 0.12, confidence interval 0.0449 to 0.327) and meconium aspiration syndrome (0 of 85 vs five of 85, relative risk 0.09, confidence interval 0.009 to 0.872) were significantly reduced by amnioinfusion.

CONCLUSIONS: Amnioinfusion improves the outcome in pregnancies complicated by thick meconium and oligohydramnios. (AM J OBSTET GYNECOL 1992;167:117-21.)

Key words: Amnioinfusion, meconium, oligohydramnios, fetal distress, prolonged pregnancy

The presence of meconium in the amniotic fluid of the fetus in a vertex presentation has been considered to be a sign of fetal stress or distress. Meconium has been associated with increased perinatal morbidity and death, especially when meconium aspiration syndrome occurs.[1-3] Meconium aspiration syndrome develops when mechanical obstruction and chemical inflammation occur as a result of aspiration of meconium into the lower respiratory tract of the fetus or the neonate. The syndrome is defined as respiratory distress in a neonate with meconium aspiration. There is a mortality rate of approximately 25%, and it accounts for 2% of all perinatal deaths.[4]

Meis et al.[3] evaluated patients with meconium passage during early and late labor and graded the presence of meconium as light or heavy. Heavy meconium passage early in labor was associated with increased fetal morbidity, including abnormal fetal heart rate (FHR) patterns (late decelerations, severe variable decelerations, and decreased variability), prolonged second stage of labor, and an increased incidence of operative intervention (including operative forceps deliveries and cesarean section). A significantly higher incidence of neonatal morbidity and mortality, particularly in association with meconium aspiration, occurred when heavy meconium was present early in labor.

In 1976 Carson et al.[5] described the combined obstetric-pediatric approach to infant tracheal suctioning at delivery. In spite of a decrease in the incidence of meconium aspiration syndrome, the neonatal mortality incidence has remained at 2%.[4]

Wenstrom et al.[6] randomly compared 85 patients with thick meconium. The study group was infused with 1000 ml of normal saline solution initially and every 6 hours until delivery. The control patients received routine management. The incidences of low 1-minute Apgar score, meconium below the cords, and operative delivery were significantly less in patients receiving amnioinfusion. The three cases of meconium aspiration syndrome occurred in patients receiving routine management. Sadovsky et al.[7] demonstrated that 19 cases of labor treated with amnioinfusion for thick meconium had a better neonatal outcome com-

pared with 21 cases treated routinely. The frequency of neonatal acidemia and positive pressure ventilation were significantly decreased in the infused group. No newborn infants in the amnioinfusion group had meconium greater than "trace" below the vocal cords.

The purpose of our prospective, randomized clinical trial was to evaluate the possible effects of amnioinfusion with respect to (1) the incidence of intrapartum fetal distress, (2) the incidence of cesarean delivery for fetal distress, (3) Apgar scores, (4) umbilical artery pH values, (5) the incidence of meconium below the vocal cords, and (6) the incidence of meconium aspiration syndrome.

Material and methods

During the 14 months from Sept. 1, 1989, through Oct. 31, 1990, women in labor with thick meconium and oligohydramnios (amniotic fluid index ≤5 cm) were evaluated for participation in the study. The study was approved by the Institutional Review Board of Los Angeles County/University of Southern California. A computer program, Epi-stat, ver 3.0 (copyright 1984) (Tracy L. Gustafson, MD, Round Rock, Tex.), was used to generate the random allocation sequence used to assign subjects to one of two groups: amnioinfusion or standard obstetric care without amnioinfusion. The assignments were placed in sealed, opaque envelopes and opened sequentially after a subject was enrolled.

Criteria for entry included singleton gestation, vertex presentation, gestational age of ≥37 weeks, estimated fetal weight of ≥2500 gm, cervical dilation of ≤5 cm, normal baseline FHR, the presence of at least one acceleration of ≥15 seconds duration and ≥15 beats above the baseline, ruptured membranes (artificial or spontaneous), thick meconium, and amniotic fluid index ≤5 cm.

Patients were excluded for any of the following reasons: abnormal FHR patterns including baseline tachycardia >160 beats/min or bradycardia <120 beats/min, persistent late decelerations, and moderate or severe variable decelerations. Other reasons for exclusion included vaginal bleeding, nonvertex presentation, chorioamnionitis, fetal anomalies, uterine anomalies, or contraindication to labor.

Patients meeting these criteria and giving informed written consent were then randomized to receive either amnioinfusion or standard obstetric care.

All participants had routine admission history, physical examination, and laboratory tests performed. Meconium, identified as thick, noted at any time, including that present on admission or noted later after spontaneous or artificial rupture of membranes, was the primary criterion for entry to the study. Meconium was clinically defined as being thick if it appeared thick, tenacious, and opaque; had a "pea soup" quality; and contained significant particulate matter, after Wenstrom and Parsons.[6] One of the authors confirmed the presence of thick meconium and performed an ultrasonographic examination with a 3.5 or 5 MHz linear-array transducer (Ultramark 4, Advanced Technology Laboratories, Bothell, Wash.). The amniotic fluid index was determined, and a singleton, vertex, anatomically normal fetus was confirmed ultrasonographically.

An intrauterine pressure catheter and fetal scalp electrode provided continuous monitoring of intrauterine pressure and the FHR. Amnioinfusion was performed in a manner that was a modification of that outlined by Miyazaki and Nevarez[8] and Strong et al.[9] A total of 500 ml of normal saline solution, warmed to 37° C, was infused by gravity flow through an intrauterine pressure catheter over 20 to 30 minutes. External uterine tocodynamometry was used during the actual infusion process.

After completion of the amnioinfusion, the amniotic fluid index was determined. If the postinfusion index was <5 cm, an additional 500 ml was infused after ensuring correct catheter placement. If the amniotic fluid index was >10 cm, the patient was observed. If the subsequent index was >5 cm and <10 cm, an additional 250 ml of normal saline solution was infused. Repeat amniotic fluid index determinations were performed hourly by the investigators until delivery.

Clinical management and FHR pattern interpretation, including the diagnosis of fetal distress, was per-

formed by the resident physicians and consultant staff. Customary obstetric management was performed in both groups of patients. DeLee suctioning of the oropharynx and nasopharynx was performed on all infants after delivery of the infant's head. Umbilical cord artery and vein blood gases were obtained in all cases. A pediatric resident attended all deliveries because of the known presence of thick meconium. The neonatal attendants were unaware if the neonate was in the amnioinfusion or control group. The presence or absence of meconium in the oropharynx and below the vocal cords was evaluated in all neonates.

Outcome parameters included (1) fetal distress, (2) operative intervention rates (cesarean delivery, forceps, or vacuum delivery), (3) operative intervention for fetal distress, (4) presence of meconium in the oropharynx or below the vocal cords, (5) meconium aspiration syndrome, (6) umbilical artery pH, (7) and Apgar scores. Fetal distress was defined as bradycardia, repetitive severe variables, or repetitive late decelerations as described by Kubli et al.[10]

A p value of 0.05 was used to establish statistical significance. Assuming a β error of 0.2, a power calculation suggested that a minimum of 79 patients should be assigned to each study group. The power calculation was based on the differential emergency cesarean delivery rate of the Wenstrom and Parsons[6] study (3% vs 16%, respectively).

Statistical comparisons were performed with the Student t test, χ^2, or Fisher's exact test and the calculation of relative risks with 95% confidence intervals.[11]

Results

Informed consent was obtained for 170 patients who met the entry criteria. Eighty-five subjects were randomized into each group. After enrollment no subject was excluded from the study or from the analysis. The treatment and control groups were similar for maternal age, parity, gestational age, and amniotic fluid index (Table I). The groups did not differ with respect to the proportions of nulliparous women, postdates pregnancies (estimated gestational age >287 days), or patients with intact membranes at the time of admission (Table II). All patients exhibiting thick meconium had an amniotic fluid index <5 cm.

The treated group required an average of 1.14 infusion sequences to attain an initial amniotic fluid index value >10 cm. Seventy-two of 85 (85%) patients required a single amnioinfusion, 12 patients received two, and one received three. The total volume required ranged from 500 to 1250 ml. The mean (±SD) was 544 ± 110 ml (Table III). Nulliparous and multiparous patients did not differ statistically with respect to the initial infusion volumes required.

Reinfusions were categorized as follows: (1) part of the initial infusion process when the initial infusion of 500 ml did not restore the amniotic fluid index to 10 cm or (2) later reinfusions when the amniotic fluid index decreased below 10 cm during the course of labor. A total of 13 of 85 (15%) required more than one amnioinfusion; six of 13 immediately after the initial amnioinfusion and seven of 13 at some point later in labor. The initial 500 ml infusion increased the amniotic fluid index to ≥10 cm in 79 of 85 (93%) patients. The initial infusion did not increase the amniotic fluid index to 10 cm in six patients, and fluid was visibly leaking from the vagina in these cases. In this situation, the correct placement of the uterine catheter was confirmed and reinfusion successfully increased the amniotic fluid index to ≥10 cm. Subsequent reinfusion was required later in labor in seven patients: two at 3 hours, three at 4 hours, one at 6 hours, and one at 7 hours (Table III). No reinfusions were required before 3 hours from the initial infusion once an amniotic fluid index of 10 had been achieved.

Table II. Distribution of high-risk patients

	Infusion group (N = 85)	*Control group (N = 85)*	*Significance*
Hypertension–pregnancy-induced hypertension	10 (12%)	13 (15%)	NS
Diabetes	5 (6%)	3 (4%)	NS
Previous cesarean delivery	11 (13%)	9 (11%)	NS
Postdates pregnancies (>287 days)	70 (82%)	76 (89%)	NS
Drug abuse	1 (1%)	0	NS
History of pyelonephritis	3 (4%)	2 (2%)	NS

NS, Not significant.

The initial 500 ml infusion increased the amniotic fluid index 8.2 ± 2.2 cm. The smaller infusion volume of 250 ml raised it 4.2 ± 1.5 cm.

The overall operative interventions were 30 of 85 (36%) in the amnioinfused group versus 47 of 85 (55%) in the control group ($p < 0.05$). The amnioinfusion group demonstrated less fetal distress in labor, three of 85 versus 19 of 85 (relative risk 0.16, 95% confidence interval 0.06 to 0.42), and a lower incidence of cesarean delivery for fetal distress, two of 85 versus 17 of 85 (relative risk 0.118, 95% confidence interval 0.03 to 0.49). Cesarean birth, for arrest disorders, were similar in the amnioinfusion group and the control group, 11 of 83 (13%) versus eight of 68 (12%) (relative risk 0.88, 95% confidence interval 0.38 to 2.08) (Table IV).

The mean birth weight of the infused and control groups, 3505 ±336 gm and 3573 ±332 gm, were not significantly different. No adverse effects of amnioin-

Vacuum	8 (9%)	11 (13%)	NS
TOTAL	30 (35%)	47 (55%)	$p < 0.05$

NS, Not significant.

fusion were observed. Specifically, no cases of cord prolapse, uterine hypertonus, or acute fetal distress during infusion were noted. The overall rate of infectious morbidity was not significantly different between the amnioinfusion and control groups. Specifically, the incidence of choricamnionitis and intrapartum fever was similar in the amnioinfusion group and control group, seven of 85 (8%) versus four of 85 (5%) (relative risk 0.68, 95% confidence interval 0.53 to 5.76). The occurrence of endoparametritis after cesarean birth was not significantly different between the amnioinfusion group and the control group, four of 13 (31%) versus seven of 25 (28%) relative risk 1.11, 95% confidence interval 0.39 to 3.08). The incidence of endoparametritis after vaginal delivery was not different when comparing the amnioinfusion group and control group, four of 72 (6%) versus two of 60 (3%), respectively (relative risk 1.67, 95% confidence interval 0.36 to 8.79).

The amnioinfusion group had a fewer neonates with meconium in the oropharynx, 29 of 85 versus 70 of 85 (relative risk 0.41, 95% confidence interval 0.31 to 0.54), and significantly fewer with meconium below the vocal cords, four of 85 versus 33 of 85 (relative risk 0.12, 95% confidence interval 0.056 to 0.26). No neonates in the amnioinfusion group had meconium aspiration syndrome compared with five neonates in the control group (relative risk 0.09, 95% confidence interval 0.09 to 0.872). All five underwent operative delivery for fetal distress, four by cesarean delivery and one by vacuum extraction. All five infants with meconium aspiration syndrome had an umbilical artery pH of <7.10 and demonstrated a mixed acidosis.

The mean (±SD) umbilical artery pH value of the infusion group was significantly higher than that of the control group, 7.27 (0.05) versus 7.22 (0.09), $p = 0.002$. The mean (±SD) umbilical arterial base deficit of the infusion group was significantly less than the control group, five (3.8) verus seven (4.8), $p < 0.01$. Furthermore, the proportion of infants with an umbilical artery pH value <7.20 was significantly less in the amnioinfusion group, seven of 85 (8%), compared with the control group, 31 of 85 (36%), $p < 0.001$.

There were seven infants in the amnioinfusion group with a umbilical artery pH value <7.20. Three of these seven (43%) had a base deficit of ≤10, consistent with a respiratory acidosis. The remaining four (57%) infants had a base deficit of ≥10, consistent with a mixed acidosis. None of the seven infants required care in the neonatal intensive care unit, and all were discharged home after an uncomplicated postnatal course.

There were 31 infants in the control group with an umbilical artery pH value <7.20. Thirteen (42%) had a base deficit of ≤10, consistent with a respiratory acidosis, and 18 (58%) had a base deficit >10, consistent with a mixed acidosis.

Nineteen patients in the control group developed fetal distress in labor. Seventeen of the 19 were delivered by cesarean section. The other two were delivered by vacuum extraction. Twelve of 17 (71%) who underwent cesarean delivery had an umbilical artery pH <7.20.

The proportion of infants with a 1-minute Apgar score <7 was significantly less in the amnioinfusion group, six of 85 (7%) compared with 26 of 85 (31%) in the control group, $p < 0.001$; the proportion of infants with a 5-minute Apgar score <7 was also significantly less, 0 of 85 compared with eight of 85 (9%) in the control group, $p < 0.001$.

Comment

In this study the presence of thick meconium in labor was 100% specific in identifying patients with oligohydramnios. The observation of thick meconium may thus be associated with decreased amniotic fluid volume, and amnioinfusion should be considered. The amnioinfusion technique used in our study was simple to accomplish, did not require special equipment, had no adverse effects, and was always successful. The effect of amnioinfusion in this study was consistent with that described by Strong et al.,[12] who demonstrated a ±SD mean increase of 4.3 ± 1.5 cm in the amniotic fluid index after the infusion of 250 ml of normal saline solution. The infusion of 500 ml of normal saline solution increased the amniotic fluid index by a mean ±SD of 8.2 ± 2.2 cm.

This study confirms that of Wenstrom and Parsons[6] in that amnioinfusion decreased the incidence of meconium below the vocal cords of infants delivered after labor complicated by thick meconium. Their study did not show a statistically significant decrease in meconium aspiration syndrome, which was likely due to a small sample size. In our study, the occurrence of meconium aspiration syndrome was significantly increased in the control group. This relatively high incidence is probably attributable to the selection process requiring the presence of both thick meconium and oligohydramnios.

Our study with amnioinfusion improved the outcome of pregnancy complicated by thick meconium and oligohydramnios by reducing operative delivery for fetal distress. Furthermore, neonatal outcome was enhanced by the use of this simple intrapartum management technique. Specifically, prophylactic use of amnioinfusion was associated with decreased fetal distress, a decreased presence of meconium below the vocal cords, and an absence of meconium aspiration syndrome.

Although we have demonstrated benefits of this treatment in a highly selected patient group, unanswered questions remain. What is the role of amnioinfusion in the fetus who has FHR pattern abnormalities and thick meconium? In our study design we purposely excluded fetuses with FHR abnormalities to better assess the single factor of thick meconium. The potential benefit of amnioinfusion in relieving severe variable decelerations is well known. Future studies should evaluate the potential role of amnioinfusion wherein multiple indications such as FHR abnormalities, thick meconium presence, and oligohydramnios are encountered.

Spontaneous ovarian hyperstimulation syndrome concomitant with spontaneous pregnancy in a woman with polycystic ovary disease

Yaron Zalel, MD, Zvi Katz, MD, Benjamin Caspi, MD, Herzel Ben-Hur, MD, Rami Dgani, MD, and Vaclav Insler, MD

Rehovot, Israel

Ovarian hyperstimulation syndrome has been described after treatment with exogenous gonadotropins, clomiphene citrate, and gonadotropin-releasing hormone. Spontaneous ovarian hyperstimulation syndrome has not been described before, except in association with hypothyroidism. We report on a case associated with spontaneous pregnancy, occurring in a woman with polycystic ovary disease. (Am J Obstet Gynecol 1992;167:122-4.)

Key words: Spontaneous hyperstimulation, pregnancy, polycystic ovary disease

A case of ovarian hyperstimulation syndrome in association with pregnancy and polycystic ovary disease is reported.

Case report

A 19-year-old woman, gravida 1, para 0, was admitted to the hospital because of abdominal pain at 10 weeks' gestation. Her medical and gynecologic history was unremarkable. Menarche occurred at the age of 14 years, and menses have subsequently been regular. Her last menstrual period occurred 10 weeks before admission. She was receiving no medication, including oral contraceptives. Physical examination revealed a lean-appearing young woman with normal blood pressure, pulse, and temperature. The abdomen was mildly distended with tenderness and palpable masses in both lower quadrants. Vaginal examination revealed a normal cervix, a uterus enlarged to 10 weeks' gestation, and ovaries on both sides enlarged 10 cm each and tender. A pelvic sonogram revealed an intrauterine sac with fetal pole and heartbeat. The Crown-rump length was 40 mm, corresponding to a 10 weeks' gestation. The ovaries were multilobulated, measured 9 and 10 cm in diameter, and contained cystic structures (Fig. 1). A significant amount of free fluid was observed in the pouch of Douglas. Laboratory results included human chorionic gonadotropin levels 52,000 mIU/ml, hemoglobin 11.0 gm/dl, hematocrit 38.0%, follicle-stimulating hormone 3.4 mIU/ml, luteinizing hormone 300 mIU/ml, prolactin 32 ng/ml, estradiol 5000 pg/ml, progesterone 48 ng/ml, testosterone 1.8 ng/ml, and cholesterol 194 mg/dl. Liver and kidney function test results were within normal limits. Elective termination of pregnancy was undertaken the day after admission. Three months later, the patient was reexamined. Results of physical examination were unremarkable. Repeat ultrasonography revealed a uterus of normal size. Both ovaries were of normal size, 3 and 4 cm in diameter, with a typical appearance of polycystic ovary disease (i.e., polymicrofollicular reactions of the ovaries). There was no fluid in the cul-de-sac (Fig. 2). Laboratory results in early follicular phase included human chorionic gonadotropin negative. Follicle-stimulating hormone 3.2 mIU/ml, luteinizing hormone 14.8 mIU/ml, prolactin 6.7 ng/ml, estradiol 90 pg/ml, testosterone 0.3 ng/ml, dehydroepiandrosterone sulfate 2.6 ng/ml, thyroxine 7.9 μg/dl, triiodothyronine resin uptake 28%, thyroid-stimulating hormone 0.9 μU/ml (within normal limits).

Comment

We report a case of grade 2 ovarian hyperstimulation syndrome (by a combination of multilobulated ovarian cysts, abdominal pain, and free fluid in the cul-de-sac), occurring spontaneously in association with a 10-week gestation. The patient was not treated with any drug, including ovulation induction. Diagnosis was further confirmed by complete resolution of the ovarian hyperstimulation, as demonstrated by clinical, ultrasonographic, and laboratory data. To the best of our knowledge spontaneous ovarian hyperstimulation syndrome has not been described before. Rotmensch and Scommegna[1] have described a case associated with hypothyroidism and suggested a causal link between both conditions. We ruled out any thyroid disturbances. However, our patient showed both laboratory and ultrasonographic characteristics of polycystic ovary disease. The etiologic and pathophysiologic characteristics of ovarian hyperstimulation syndrome are poorly un-

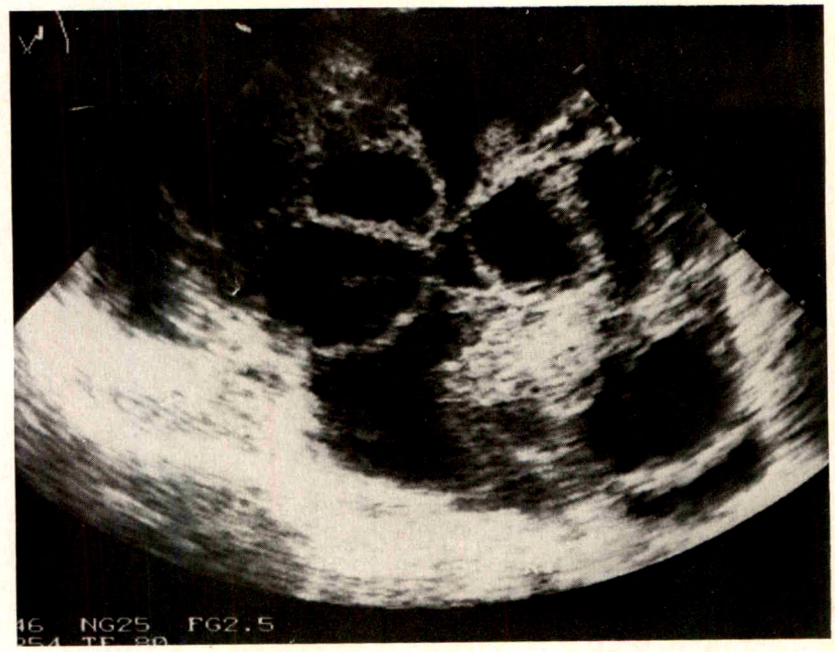

Fig. 1. Transvaginal longitudinal ultrasonographic section showing both ovaries enlarged with multiple cystic structures.

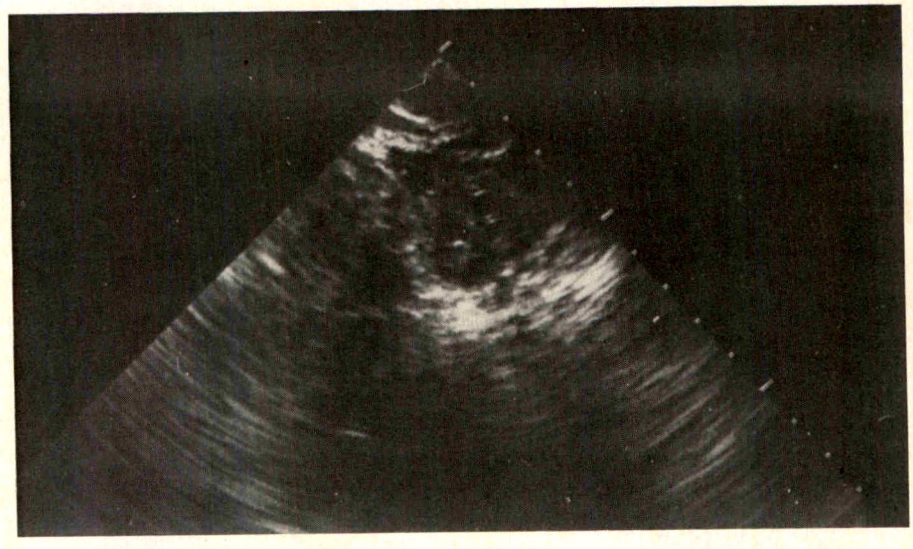

Fig. 2. Transvaginal longitudinal ultrasonographic section showing left ovary with polymicrofollicular reaction.

derstood. Various factors, including estrogen, histamine, prostaglandins, prolactin, aldosterone, and (pro)renin,[2] have been suggested to be involved in the development of the condition. Others found that treatment with a preparation with a high follicle-stimulating hormone/luteinizing hormone ratio causes less ovarian hyperstimulation, and thus ovarian hyperstimulation syndrome might be eliminated by reducing the dosage of luteinizing. Ovarian hyperstimulation syndrome is the result of massive luteinization of a large number of follicles and occurs in 1% to 5% of ovulation-induction treatment cycles. The incidence of hyperstimulation syndrome is higher in women with polycystic ovary disease, probably because of a larger number of follicles ready to respond to stimulation and a higher sensitivity of functional ovarian elements to gonadotropic stimulation. However, clinical experience showed that one of the essential conditions for the development of ovarian hyperstimulation syndrome is the administration of a relatively high dose of human chorionic gonadotropin required for ovulation induction. It has been presumed that the presence of a functioning feedback mechanism

should be adequate to prevent a spontaneous luteinizing hormone surge of height or duration sufficient for luteinizing an excessive number of follicles. Thus withholding of the ovulation-inducing human chorionic gonadotropin injection was advocated as one of the best means for preventing ovarian hyperstimulation.

The case presented suggests that, at least in patients with polycystic ovary disease, endogenous follicle-stimulating hormone is sufficient to stimulate the development of an abnormally large follicular cohort, which may then be luteinized by a spontaneous luteinizing hormone surge. Endogenous human chorionic gonadotropin, secreted by the trophoblast 7 to 8 days after fertilization, could represent an additional factor in sustaining or exacerbating the ovarian hyperstimulation in this case.

Although less common now, ovarian hyperstimulation syndrome still has a very serious impact on the patient's health and may cause severe morbidity. The purpose of our report is to emphasize that, although it is usually a complication of ovulation induction, it can also occur spontaneously.

Screening for Down syndrome with the femur length/biparietal diameter ratio: A new twist of the data

Lawrence D. Platt, MD,[a] Arnold L. Medearis, MD,[a] Dru E. Carlson, MD,[a] Rena E. Falk, MD,[b] Greggory R. DeVore, MD,[a] Janet Horenstein, MD,[a] and Catherine A. Walla, RN, MA, MN[a]

Los Angeles, California

OBJECTIVE: The purpose of this study was to determine the value of discordant morphometric measurements as identifiers of Down syndrome by evaluating the relationship of biparietal diameter, femur length, biparietal diameter/femur length ratio, and cephalic index between a group of fetuses with trisomy 21 and a control population.

STUDY DESIGN: Biometric measurements from 48 fetuses with trisomy were reviewed and compared with 107 normal fetuses of similar gestational age. Data were analyzed in 2-week gestational age intervals to determine the effect of gestational age on ultrasonographic detection of Down syndrome. Outcome measures were subject to least-squares linear regression and the *t* test for analysis.

RESULTS: A positive relationship between abnormal morphometric measurements and fetuses with Down syndrome was detected but only during specific weeks of pregnancy.

CONCLUSION: Although it appears that biometric measurements may be useful for Down syndrome, further study is needed before its widespread introduction into clinical practice. (AM J OBSTET GYNECOL 1992;167:124-8.)

Antenatal identification of congenital abnormalities in the fetus has increased over the past decade. As a new generation of ultrasonographic equipment became available, numerous publications[1-7] demonstrated its increasing ability to identify dysmorphic features of the fetus, leading to the antenatal diagnosis of specific genetic syndromes. Recent studies have also suggested

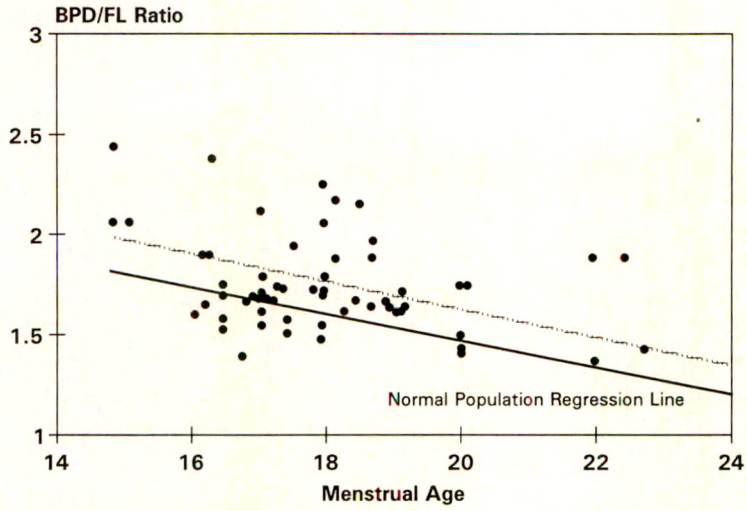

Fig. 1. Scatterplot of individual BPD/femur length *(FL)* ratio measurements versus menstrual age for trisomy 21 population. *Broken regression line*, Patients with trisomy 21; *solid line*, regression line for control population.

that discordant morphometric measurements may be useful in screening for the identification of the fetus at risk of trisomy 21. Reported characteristic features of Down syndrome include (1) brachycephaly,[8] (2) thickened nuchal skin folds,[9] (3) hypoplasia of the middle phalanx with clinodactyly,[10] (4) shortened femur length,[8, 11] (5) abnormal biparietal diameter (BPD) to femur length ratio,[12] and (6) transverse palmar crease (simian).[13]

The importance of identification of these features is potentially significant. Although standard practice dictates the offering of prenatal chromosomal diagnostic procedures to patients at risk for Down syndrome, over 80% of affected fetuses are born to women without historic risk factors. Maternal serum α-fetoprotein screening programs may help to identify 20% of these low-risk women, and potentially a greater percentage of patients will be identified with the addition of serum human chorionic gonadotropin[14-17] and estriol.[18, 19] The majority of these affected fetuses, however, go undetected until birth unless procedures for cytogenetic assessment are offered and used. In an attempt to better identify the fetus at risk for trisomy 21, a retrospective study was undertaken to evaluate the relationship of the BPD, femur length, BPD/femur length ratio, and cephalic index between a large group of fetuses with trisomy 21 and a control population.

Material and methods

Patients seen either at the Prenatal Diagnostic Program, Women's Hospital, Los Angeles County University of Southern California Medical Center, Children's Hospital of Los Angeles, or the Genetics Institute, Pasadena, California, were all eligible for entrance into this study. Medical records from patients with trisomy 21 diagnosed by amniocentesis between July 1985 and June 1988 were reviewed. The ultrasonographic examinations for each of these cases were also evaluated. Ultrasonographic data was obtained prospectively from 107 patients of similar age with normal chromosomes to develop our control population. Gestational age was determined by well-established dates, i.e., dates calculated from last menstrual periods, confirmed by early ultrasonographic examinations. Data from only a single examination were used for analysis of the affected and control populations. The examinations of the fetuses with trisomy 21 were recorded at the time of amniocentesis and before chromosomal diagnosis. The examinations were all carried out by the authors. Either a General Electric (Milwaukee) RT3000 or an ATL/ADR (Bothell, Wash.) Ultra Mark IV was used to make these measurements.

Least-squares linear regression of the menstrual age and the ultrasonographic parameters studied was performed to determine the regression lines for slope and

Table I. Results of comparison between regression lines of each of biometric measurements and overall groups

	Slope	*Intercept*	*Down syndrome vs control*
BPD	$p = 0.0001$	$p = 0.0001$	Decreased Down syndrome
Femur length	$p = 0.0001$	$p = 0.0001$	Decreased Down syndrome
Cephalic index	$p = 0.72$	$p = 0.97$	No difference
BPD/femur length ratio	$p = 0.86$	$p = 0.60$	No difference

Table II. Comparison of biometric measurements of Down syndrome group and control group stratified by 2-week intervals

Menstrual weeks	Study group	Mean				SD			
		BPD	Femur length	Cephalic index	BPD/femur length	BPD	Femur length	Cephalic index	BPD/femur length
15-16.9	Control (n = 22)	3.5	2.0	0.78	1.79	0.21	0.23	0.04	0.15
	Down syndrome (n = 14)	3.5	2.0	0.81	1.82	0.37	0.44	0.05	0.31
17-18.9	Control (n = 50)	4.0	2.5	0.78	1.66	0.23	0.25	0.04	0.12
	Down syndrome (n = 24)	4.0	2.2	0.82	1.79	0.34	0.29	0.04	0.19
19-20.9	Control (n = 22)	4.7	3.1	0.77	1.54	0.24	0.26	0.03	0.11
	Down syndrome (n = 8)	4.2	2.6	0.79	1.63	0.40	0.29	0.03	0.11
21-22.9	Control (n = 13)	5.4	3.7	0.76	1.48	0.30	0.24	0.03	0.09
	Down syndrome (n = 2)	4.9	3.0	0.78	1.66	0.57	0.07	0.07	0.23

intercept between the control and the population with Down syndrome. The two populations were further compared for statistical significance between the intercept and slope of the regression lines for the measurements studied. To further assess the possible relationships between different gestational intervals for the detection of Down syndrome, the data were also analyzed stratified by 2-week intervals from 15 to 23 weeks. A comparison of the mean values of the ultrasonographic measurements between the control and study population was performed with the t test. Statistical significance was noted if the p value was ≤ 0.05.

Results

A total of 48 fetuses with trisomy 21 were identified during this period of time. The slope and intercept for the regression lines of each of the populations is presented in Table I, with the results of the comparison between the regression lines describing the populations. Both BPD and femur length were significantly decreased downward, whereas the cephalic index and BPD/femur length ratio were not significantly different when evaluated with regression analysis. The individual data for the BPD/femur length ratio is plotted in Fig. 1 along with the mean regression lines for the normal and Down syndrome population for visual inspection.

To further delineate this data in which there appeared to be a possible menstrual age effect in a more confined time period, the data was analyzed by 2-week intervals. Table II contains number, mean, standard deviation, and statistical significance for the four measurements of this comparison between the study and control populations. Between 15 and 16.9 weeks menstrual age no significant differences were observed among any of the parameters. Although the BPD was not significantly decreased, the femur length was significantly smaller in the affected population by 17 and 18.9 weeks. The cephalic index and the BPD/femur length ratio were significantly increased. Between 19 and 20.9 weeks both the BPD and femur length were significantly smaller in the population with Down syndrome, but the cephalic index and BPD/femur length showed no significant differences. It should be noted, however, that the sample size of fetuses with Down syndrome in this gestational age range is small, numbering only 10 subjects. Between 21 and 22.9 weeks only the femur length in the Down syndrome group was significantly smaller. As in the preceding group, the sample size in this range is very small.

Comment

In contrast to the previous published reports, this study evaluated ultrasonographic parameters for screening for trisomy 21 at specific gestational ages. In general, the relationship was not equally distributed across these gestational ages. It appears that there is a relationship between ultrasonographic measurements in fetuses with Down syndrome compared with controls only during specific weeks in pregnancy. However, the difference between the mean femur lengths of the study and control fetuses represents only 3 mm at 17 to 18.9 weeks gestation. Variations in femur lengths between the two groups from 15 to 16.9 weeks gestation may be more difficult to demonstrate. This may have contributed to the failure of finding a statistical difference between this ultrasonographic measurement in the earliest group of fetuses as compared with the later ones. The usefulness of the relationship between biometric measurements and gestational age needs to be further evaluated prospectively to determine if there

is a particular gestational age that can be targeted to give patients who are not currently candidates for amniocentesis, or if amniocentesis is indicated and the patient has declined the procedure, an adjusted risk for having a fetus with trisomy 21.

From the data in this study, it is interesting to note that the femur length measurement remains short beyond a period previously reported by Lockwood et al.,[12] whereas the BPD measurement is variable. Decrease in BPD appears to occur later in the gestational ages evaluated. This may reflect selective delayed growth of the brain in fetuses with Down syndrome after 19 weeks. A decrease in growth of the head may initially be partially compensated by brachycephaly, with an increased cephalic index at 17 to 19 weeks. After this time the cephalic index was not significantly different from the control population, and a decrease in the BPD was found. These observations of the variations in head size and configuration in this cross-sectional study need to be evaluated and confirmed in a longitudinal study. This may be important if biometry is considered as a screening tool for risk for trisomy 21.

Although the patient numbers in our study are large when compared with the experience of most institutions, we believe the numbers are not, as yet, sufficient to draw the firm conclusion that an increased BPD/femur length ratio is the best screening test. Because there are a limited number of fetuses ≥19 weeks' gestation, it is difficult to draw firm conclusions about the lack of statistical significance of the BPD/femur length ratio between the Down syndrome fetuses and the controls from 19 to 20.9 weeks and 21 to 22.9 weeks. Although some reports have suggested that the BPD/femur length ratio can be used,[8, 11, 12, 20] other reports[21-25] have disputed these findings. The data presented suggest that there is indeed a benefit of looking at these ratios for the development of risk assessments for the patient scanned in the second trimester.

The intriguing part of the approach to the detection of malformations is that the measurements required are the same used in all ultrasonographic examinations performed by knowledgeable ultrasonographers. The alternative approaches of selective identification of other structural changes seen in Down syndrome, such as the wide-spaced greater toe, hypoplasia of the middle phalanx with clinodactyly, and heart defect, are clearly more difficult to recognize and will be missed in a significant number of patients at risk, even by the more experienced ultrasonographers. Identification of all markers of Down syndrome seems almost impossible unless only the most experienced sonographers perform all examinations, and the amount of time devoted to each examination is dramatically lengthened. As a manpower shortage already exists in ultrasonographic imaging, this approach would seem to preclude this from becoming a reality. Therefore, critical analysis of data readily identified becomes more important. The observation that the BPD/femur length ratio displayed abnormal trends (without significance) at most gestational ages with significance reached at specific ages provides the impetus for further study.

A further consideration of data difference between studies may be a result of either racial or ethnic variation. The data presented in this paper consist of a truly broad-based sample. Among the three centers participating, the patient populations are uniquely different. One group represents a mostly white, middle to upper socioeconomic group, whereas another center represents mostly a middle- to low-income group of patients from Anglo-American, Asian-American, and Mexican-American populations. We were unable to identify any difference in either the control or affected population between these groups.

Accumulating larger data sets also seems warranted. The early work by Lockwood et al.[12] suggested the benefit of using the method when only the BPD/femur length ratio is considered to be abnormal. In that study any measurement >1.5 SDs was considered to be abnormal, whereas most other studies use >2 SDs above the mean as their cut-off. In a later study, these same authors were unable to find a relationship between an abnormal BPD/femur length ratio and trisomy 21 in a different population group. These seemingly conflicting reports further support the need for a large collaborative study on the use of biometric screening for risk assessment for the fetus with trisomy 21. Because of increasing financial constraints being placed on most comprehensive prenatal diagnostic centers, it seems that either a statewide, regional, or national collective

effort program should be instituted to more adequately derive the data necessary to properly counsel patients.

We chose to look at an interval of 3 years of study to reduce confounding variables of different operators and equipment that may affect some of the measurements. Using this approach, we are also limited by the current tendency to reduce gestational age discrepancies between the BPD and femur length. Clearly, if this study were expanded to a large, multicenter study, interinstitutional and intrainstitutional variation in measurement technique would need to be closely monitored.

In summary, it appears that the use of biometric measurements for screening for Down syndrome appears intriguing. The distribution of data represented suggests that large numbers will be required before the widespread introduction into clinical practice. We therefore feel that a prospective, multicenter study of Down syndrome fetuses with matched controls should be instituted under the control of a central data coordinating center.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Stay at the forefront of your specialty! Subscribe today by returning the order form or by calling our toll-free number.

Rupture of uterine scar with extensive maternal bladder laceration after cocaine abuse

Chaur-Dong Hsu, MD, MPH, Serena Chen, MD, Terry I. Feng, MD, MPH, and Timothy R.B. Johnson, MD

Baltimore, Maryland

A relationship between cocaine use and extensive rupture of a uterine scar has not been reported. We report such a case with extensive laceration of the maternal urinary bladder occurring after ingestion of cocaine. (AM J OBSTET GYNECOL 1992;167:129-30.)

Key words: Cocaine abuse, uterine scar rupture, bladder laceration

Cocaine abuse in women of childbearing age has dramatically increased over the past years. Cocaine use and rupture of an unscarred uterus has recently been reported.[1] However, the incidence and severity of uterine scar rupture in cocaine users during pregnancy remains unknown. We report a case of rupture of a uterine scar with extensive laceration of the maternal urinary bladder after cocaine abuse.

From the Division of Maternal-Fetal Medicine, Department of Gynecology and Obstetrics, The Johns Hopkins University School of Medicine.

Case report

A 34-year-old unregistered black woman, para 4-0-1-4, at 36⅗ weeks' gestation was fully dilated and in active labor. Her medical history was positive for heroin and cocaine abuse. She underwent a cesarean section in 1977 at 40 weeks' gestation for an unknown reason. She had three subsequent vaginal deliveries and an elective abortion without complication. Shortly after admission the patient had a spontaneous vaginal delivery of a 3320 gm female infant with Apgar scores of 2 and 5 at 1 and 5 minutes, respectively. The umbilical cord blood gas values were as follows: pH 7.03, P_{O_2} 10 mm Hg, and P_{CO_2} 80 mm Hg. The urine toxicology screen was positive for cocaine metabolites. After delivery the patient complained of chest pain and diffuse abdominal pain. Urine output showed gross blood, and the abdomen was diffusely tender with some rebound to deep palpation. Pelvic examination revealed a

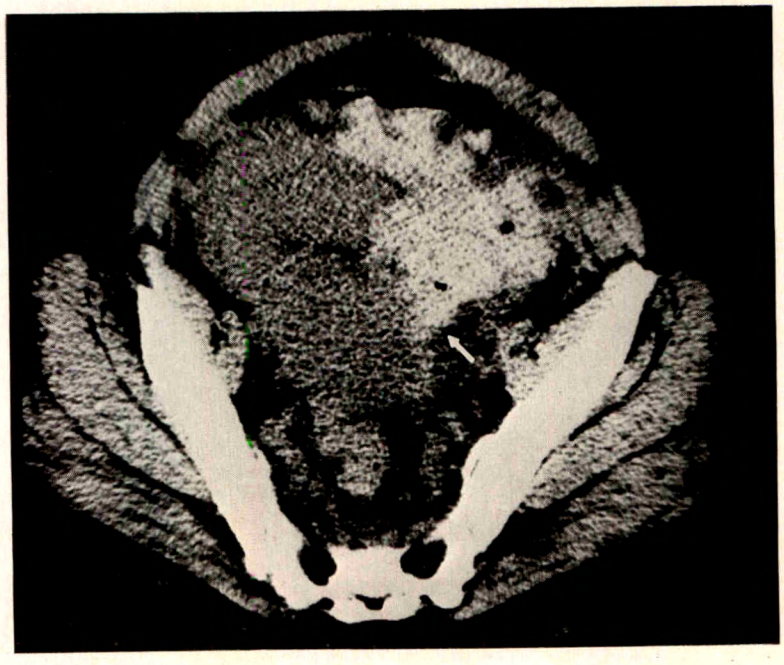

Fig. 1. Uterine rupture: disruption of uterine wall and broad ligament hematoma *(arrow)*.

slightly tender uterus. Blood gas, electrocardiogram, and chest radiographic examination were unremarkable. Ultrasonography was remarkable for a fluid collection to the left of the uterus. Computed tomographic scan (Fig. 1) revealed a large left pelvic hematoma displacing the uterus to the right with small air bubbles within it. A disruption of the wall of the lower uterine segment was suggestive of a uterine rupture. Because of the continued hematuria, a voiding cystourethrogram was obtained and showed immediate intraperitoneal extravasation from the bladder. The patient was then taken for an exploratory laparotomy. A large, left broad ligament hematoma, a large defect in the lower uterine segment, and a large defect in the bladder were noted. A total abdominal hysterectomy and repair of the large posterior bladder defect were performed. The patient did well postoperatively.

Comment

Cocaine use has been implicated in augmenting the contractile response of the pregnant uterus. It has been theorized that cocaine may block norepinephrine reuptake and stimulate the α-adrenergic contractility of uterine smooth muscle. It is possible that this response may increase the risk of uterine scar rupture in cocaine abusers during pregnancy.

Rupture of the low transverse uterine scar is reported in 0% to 2.3% of planned trials of labor. However, the incidence of rupture of a uterine scar with extensive maternal bladder laceration is unknown. Jones et al.[2] have reported eight cases of rupture of a low transverse uterine scar during a trial of labor. Three cases of maternal bladder lacerations were noted. However, seven of eight patients received either oxytocin for induction or augmentation or prostaglandin E_2 for cervical ripening. One patient had a history of three cesarean sections. These factors may explain a higher incidence of maternal bladder lacerations. Our patient did not receive prostaglandin E_2 or oxytocin during labor and delivery. Rupture of the uterine scar and the extensive maternal bladder laceration were closely related to recent cocaine abuse.

In view of increased rates of cocaine abuse during pregnancy and trials of labor and vaginal birth in recent years, the incidence and severity of rupture of uterine scars and further complications such as extensive maternal bladder laceration among recent cocaine abusers with uterine scars may also increase. Whether routine screening of cocaine abuse before a trial of labor, or other precautions, should be taken in women with cocaine abuse remains to be determined.

Comparison of the efficacy of different local anesthetics and techniques of local anesthesia in therapeutic abortions

Ellen R. Wiebe, MD
Vancouver, British Columbia, Canada

OBJECTIVES: The objectives of this study were to determine whether carbonated or plain lidocaine provides better pain control during abortions and to determine whether deep injections of lidocaine provide better pain control than regular injections of lidocaine.
STUDY DESIGN: Phase 1 was a prospective, randomized, double-blind trial comparing 10 cm^3 of 2% carbonated lidocaine with plain lidocaine. In phase 2 the plain lidocaine group in phase 1 was compared prospectively with the next group of patients, in whom a new technique of deep injection was used. A pain scale was administered by the counselor after dilatation and at the end of the procedure.
RESULTS: The improvement in pain scores with carbonated lidocaine was 8%. The improvement with the deep injection technique was 25%.
CONCLUSION: The improvement in pain scores with deep injection was clinically significant and is recommended. (Am J Obstet Gynecol 1992;167:131-4.)

Key words: Local anesthesia, therapeutic abortion, pain control

Staff working at freestanding abortion clinics are very aware of the need for better pain control during therapeutic abortions. General anesthesia is not an option for most procedures because it increases cost, morbidity, and mortality.[1-4] A review of the literature revealed no studies of the efficacy of pain managment with various types of local anesthesia or techniques used during therapeutic abortions and very few studies about the pain of therapeutic abortions.[5, 6] Before my study, one of our three clinic physicians used carbonated lidocaine and the other two used plain lidocaine. All used a technique of paracervical block involving three to six injections approximately ½ inch deep. In the first phase carbonated lidocaine was compared with plain lidocaine in a prospective, double-blind manner with pain scales administered after dilatation and after suctioning. The hypothesis was that carbonated lidocaine would work better than plain because it is rapidly absorbed and that the difference would be greatest in the dilatation phase. In September 1990 Stubblefield[7, 8] described his technique of deep injections originally described by Glick,[9] and two of our three clinic physicians decided to change to this technique. Stubblefield used 20 cm^3 1% lidocaine instead of 10 cm^3 2% lidocaine, another change that was also made. The pain scales of the plain lidocaine group of phase 1 of the study were compared with those of the two physicians using the new technique in phase 2. The hypothesis was that the deep injection technique would provide better pain control than the regular technique and that the difference would be greatest for dilatation.

Material and methods

My study was conducted at a freestanding abortion clinic. Approval for the study was obtained from the ethics committee of the University of British Columbia. All patients at the clinic were invited to participate; only those unable to understand the consent form or unwilling to sign were excluded. The three clinic physicians each had at least 10 years' experience in performing abortions. Patients who requested sedation received 1 mg of lorazepam sublingually 30 minutes before the procedure. In phase 1, 10 cm^3 2% carbonated lidocaine was compared with 10 cm^3 2% plain lidocaine. Both had 2 mg atropine/50 cm^3 added and were administered in three to six sites approximately ½–inch deep. The nurses prepared and labeled the syringes of lidocaine so that neither the physician, the patient, nor the counselor knew which local anesthetic had been used. The counselor administered the pain scale at the end of dilatation and at the end of the procedure by saying, "On a scale of 0 to 10, where 0 is no pain and 10 is the worst pain you can imagine, what was that like for you?" and recording the patient's answer on a coded form. In phase 2 the physicians changed techniques from injecting 10 cm^3 2% lidocaine (with 2 mg atropine/50 ml) in three to six sites (i.e., 12, 3, and 6 or 12, 2, 4, 6, 8, and 10 o'clock positions) approximately

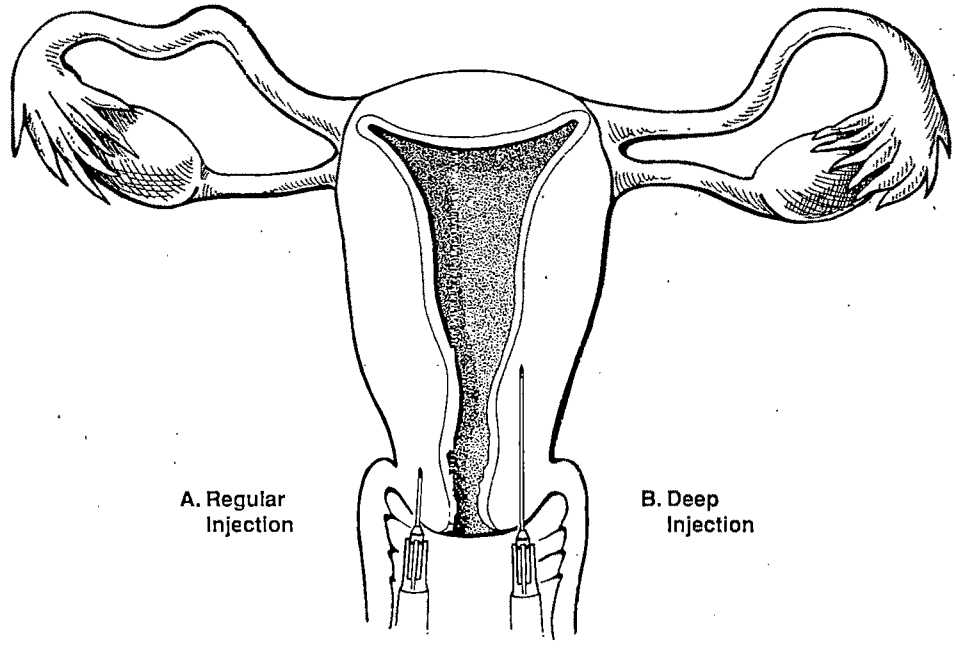

Fig. 1. Position of injections.

Table I. Comparison of pain scales: Phase 1

	Pain scale 1 (mean ± SD)	*Pain scale 2 (mean ± SD)*

½–inch deep at the reflection of the vagina off the cervix (Fig. 1, A) to injecting 20 cm³ 1% lidocaine (with 1 mg atropine/50 ml) in the following manner: 1 cm³ was injected in each of six sites (12, 2, 4, 6, 8, and 10 o'clock) superficially to blanch the mucous membrane, then 3 to 4 cm³ was injected 1 to 1.5 inches deep, that is, into the lower uterine muscle in four sites at 4, 6, 8, and 10 o'clock. The syringes were placed in the deep position and aspirated for blood; then a bolus injection was given (Fig. 1, B). Needle extenders were used. One physician used 1-inch, 25-gauge needles, and the other used 1½-inch, 25-gauge needles. There was no delay between the injections and the start of the procedure. Preoperative anxiety was assessed by the counselor in her initial interview and rated as low,[1] moderate,[3] or high.[5] Pain scales were compared with two-sample t tests of means. Two-sample t tests and χ^2 tests were also used to compare study groups on the

basis of other subject variables, including maternal age and gestational age.

Results

The pain scales with carbonated lidocaine were significantly lower than the ones with plain lidocaine ($p = 0.036$), but this difference was only 8% (Table I). The pain scales with the deep injections were 25% lower than the scales with the superficial injections ($p = 0.0001$) (Table II). There were no significant differences between the patients who received carbonated lidocaine and the patients who received plain lidocaine in terms of maternal age, gestational age, preoperative anxiety, previous abortions, or whether the patients took lorazepam preoperatively (Table III). There was no significant difference between the pain scales of the patients seen by the three different doctors (Table IV) or by the patients who had taken lorazepam compared with the ones who had not (Table V). There was no significant difference between the patients in phase 2 and phase 1 in terms of gestational age, maternal age, preoperative anxiety, or lorazepam use (Table VI). There was no difference between the pain scales of the patients of the two physicians in phase 2 (Table IV).

Comment

The improvement in pain scales with carbonated lidocaine in phase 1, although statistically significant, is probably not clinically significant or worth the extra cost. The difference with the deep injection is a big improvement clinically and has greatly enhanced pain control. There were no complications of deep injections (such as internal hemorrhage or laceration) during the study period or in the hundreds of procedures done at the clinic with that technique since the study's completion. Glick[9] and Stubblefield[7, 8] have performed thousands of procedures using this technique without incident.

Pain is a difficult parameter to measure, which may account for the lack of previous studies on the pain of abortion procedures or the efficacy of the various local anesthesias and techniques used. Studies on quantification of abortion pain,[5] topical anesthesia for gynecologic procedures,[10] and counseling techniques for therapeutic abortions[11] also used pain scales to measure outcome. Efficacy of techniques is very difficult to evaluate because it is impossible to double-blind and almost impossible to randomize. In my study the conditions in phases 1 and 2 were very similar but not identical. There was no significant difference in the patients' maternal or gestational age. It is unlikely that the physicians improved other aspects of their techniques because they were all experienced physicians. There were no changes in the support staff's protocol or in the physical plant, but it is possible that unrecognized changes occurred other than the one measured. Phase 1 had 10 cm^3 2% lidocaine and phase 2 had 20 cm^3 1% lidocaine; it is possible that this dilution of the anesthetic, rather than just the position of the injection, produced some of the improvement. The magnitude of the difference in pain scales lends validity to the results; it was immediately obvious to the physicians and support staff that deep injection was a better technique. Further research should determine whether the benefit was from the depth of injection or the dilution of anesthetic.

We thank Dr. Lucy Lemieux, Dr. Erle Mitchell, and Christine Tang for assisting with the study, and Dr. Jonathan Berkowitz at the Department of Family Medicine of University of British Columbia for providing statistical evaluation.

Simultaneous ovarian and intrauterine pregnancy: Case report

Anna Bernabei, MD, Giuseppe Morgante, MD, Massimo Mazzini, MD, Elisabetta Guerrini, MD, Antonio Fava, MD, and Secondo Danero, MD

Siena, Italy

The simultaneous presence of an ovarian and a normal intrauterine pregnancy is a very rare condition. We report such a case seen as an ovarian cyst during gestation. It was immediately and successfully treated, thus allowing for the normal physiologic continuation of the gestation. (AM J OBSTET GYNECOL 1992;167:134-5.)

Key words: Ovarian pregnancy, twin pregnancy, ovarian cyst during gestation

We describe a case of simultaneous ovarian and intrauterine pregnancy.

Case report

A 25-year-old woman, para 0, gravida 1, was hospitalized in our department for an ovarian cyst diagnosed by ultrasonography. The patient was at 9 weeks of gestation, completely asymptomatic. She reported menarche at the age of 14, normal and regular cycles, no allergies, and an appendectomy at age 16.

The gynecologic examination revealed a gravid uterus corresponding to the period of amenorrhea and an orange-sized, mobile mass, localized in the pouch of Douglas. The transabdominal ultrasonographic examination confirmed the presence of a viable intrauterine pregnancy and a 101 × 73 mm ovoid mass with sharp borders in direct contact with the uterine fundus. The inner echo structure was finely granular, hypoechogenic, and characterized by a 10 mm well-defined, small, solid part at the bottom. The ultrasonographic image displayed no characteristics of a cystic gravid corpus luteum.

Other routine examinations were performed (i.e., blood and urine examinations, electrocardiogram, Papanicolaou test, colposcopy, and vaginal bacteriologic examination). All results were within normal limits. The patient was pretreated with one intramuscular injection per day of progesterone for 3 days before surgery.

The woman then underwent laparotomy, with a Pfannenstiel incision, under general anesthesia. At the opening of the abdomen a cystic mass was found in the left pelvis. It was tightly adherent and regular, with a smooth surface. Brownish cystic fluid was aspirated. The cyst was then removed, and a peritoneal washing was performed before suture of the abdominal wall.

The postsurgical period was normal, and the ultrasonographic examinations showed a physiologic progression of the intrauterine gestation. Histologic examination of the cyst showed an ovarian pregnancy.

The patient was discharged 7 days after the operation in good condition. She had a normal gestation until term. A healthy 3.2 kg male baby was delivered spontaneously after a normal labor.

Comment

The incidence of extrauterine pregnancy is one in 200 gestations. The incidence of ovarian pregnancy is one in 34 extrauterine gestations and one in 7000 normal gestations.

The causes of an ovarian implantation are obscure. Numerous hypotheses have been formulated: a delay in the release of the ovum, a thickening of the tunica

albuginea, a tubal malfunction, or an intrauterine contraceptive device. Pelvic inflammatory disease, which is often involved in the genesis of a tubal pregnancy, does not seem to be important in the ovarian implantation of the ovum.[1] Ovarian gestation is a rare condition per se, which becomes even less frequent when an intrauterine pregnancy develops.

However, if this unlikely event occurs, we can probably think of a double ovulation with a double fertilization (biovular or bizygotic pregnancy). One embryo can regularly implant in the endometrium, and the other one can abnormally implant in ectopic tissue outside the uterus. The differential diagnosis includes a dermoid cyst, a serous or pseudomucinous cystoma, sometimes a pedunculated myoma or a uterine cornua, and less frequently a malignant tumor.[2] Although ultrasonography can be of some help in the diagnosis, the surgery and the following histologic examination constitute the decisive diagnostic tools.

Surgery is important not only for diagnostic purposes but also as a therapeutic tool. An adnexal mass during gestation must be removed because it can easily rupture or twist or be seen as an intracystic hemorrhage. This, in turn, may cause the obstetrician to suspect an "acute abdomen," thereby jeopardizing the intrauterine pregnancy.

Antibodies to *Chlamydia trachomatis* in sera of women with recurrent spontaneous abortions

Steven S. Witkin, PhD, and William J. Ledger, MD
New York, New York

OBJECTIVE: The relationship between high-titer immunoglobulin G antibodies to *Chlamydia trachomatis* and recurrent spontaneous abortions was evaluated.
STUDY DESIGN: Sera from the female partners of 258 couples with unexplained infertility, no history of chlamydial infection, and negative cervical cultures were diluted 1:128 and tested for immunoglobulin G antibodies to *Chlamydia trachomatis*. A subset of patients was also tested for antibodies to cytomegalovirus, cardiolipin, nuclear antigens, lactoferrin, and spermatozoa.
RESULTS: Seven (41%) of 17 women with three abortions and 6 (60%) of 10 women with four abortions had chlamydial antibodies as opposed to 20 (13.5%) of 148 with no abortions, 6 (12.8%) of 47 with one abortion, and 4 (12.1%) of 33 with two abortions ($p < 0.01$). The incidence of ≥3 spontaneous abortions was 31.8% among women with high-titer chlamydial antibodies and 7.5% among women who had seronegative results ($p < 0.001$). There was no relation between any of the other antibodies and ≥3 abortions or antibodies to *Chlamydia trachomatis*.
CONCLUSION: High-titer immunoglobulin G antibody to *Chlamydia trachomatis* was associated with recurrent spontaneous abortions. The mechanism may involve reactivation of a latent chlamydial infection, endometrial damage from a past chlamydial infection, or an immune response to an epitope shared by a chlamydial and a fetal antigen. (Am J Obstet Gynecol 1992;167:135-9.)

Chlamydia trachomatis infections of the female urethra and cervix are often asymptomatic and therefore undetected. The organism can evade host immune defense mechanisms, persist for long periods of time,[1] and ascend to the uterus and fallopian tubes in the absence of clinical symptoms. The sequelae of chronic

silent chlamydial infections, an increased incidence of tubal infertility, and ectopic pregnancy have been well documented.[2]

The possible influences of a *C. trachomatis* infection on pregnancy outcome are less clear and have recently been reviewed.[3] An association between a cervical chlamydial infection and preterm labor, premature rupture of membranes, or low birth weight have been observed in many, but not in all, investigations.

Most of those studies dealt with women whose chlamydial infections were diagnosed during the second or third trimester of pregnancy. Effects of *C. trachomatis* on the early stages of pregnancy, that is, on the occurrence of first-trimester spontaneous abortions, have been infrequently investigated. Quinn et al.[4] reported an increased prevalence of immunoglobulin (Ig) G antibodies to *C. trachomatis* in women with recurrent spontaneous abortions as compared with fertile controls. The inability of Quinn et al. to detect *C. trachomatis* from the male and female partners by culture prompted their conclusion that a current chlamydial infection was probably not the direct cause of the abortions. A similar possibility was advanced by Rowland et al.[5] in their study of women undergoing in vitro fertilization (IVF). They observed that women with IgG antibodies to *C. trachomatis* who lacked IgM antibodies or positive *Chlamydia* cultures had poorer outcomes after embryo transfer than women who had seronegative results. A subsequent analysis of IVF patients refuted these findings[6]; however, more recent studies have confirmed and extended the original observations.[7,8] Only in those IVF patients whose IgG *Chlamydia* antibody titer was ≥1:128 was there a significantly increased prevalence of spontaneous abortion after embryo transfer.

To further examine the possible relationship between an undetected asymptomatic chlamydial infection and early-stage pregnancy loss, we tested for IgG antibodies to *C. trachomatis* in the female partners of 258 infertile couples and 92 women of proven fertility, all with no history or clinical evidence of chlamydial infection. Our results confirm an association between prior undetected exposure to *C. trachomatis* and increased incidence of recurrent spontaneous abortions.

Material and methods

Subjects. Sera were obtained from the female partners of 258 infertile couples whose cervical cultures were negative for *C. trachomatis*, had no self-reported history of chlamydial infection or pelvic inflammatory disease, and whose tubes appeared to be patent by hysterosalpingography. Sera from 92 women of proven fertility who met these exclusion criteria were also analyzed. A history of infections and pregnancy outcomes was obtained from a questionnaire and an interview.

Antibodies to *C. trachomatis*. Sera were diluted 1:128 in phosphate-buffered saline solution and tested for IgG antibodies to *C. trachomatis* by a commercial assay (ICN Biomedicals, Inc., Costa Mesa, Calif.). In brief, the diluted sera were incubated on slides containing fixed McCoy's cells that had been infected with *C. trachomatis* strain L2. After 45 minutes at 37° C the slides were washed, dried, and incubated with horseradish peroxidase–conjugated rabbit antibody to human IgG. After a second 45-minute incubation the slides were washed, dried, and incubated with a chromogen-substrate solution. After 15 minutes the slides were again washed, dried, covered with a coverslip, and examined microscopically under 10 × 20 magnification. For each sample the entire slide was examined, the presence of IgG antibody to *C. trachomatis* was indicated by the observation of dark blue cytoplasmic inclusions. At least 5% of the cells were positive in the presence of a specific antibody, and a clear distinction between positive and negative sera was easily made. In addition, positive and negative control sera were tested on each slide.

Analysis for other antibodies. Sera were tested for IgG, IgA, and IgM antibodies to spermatozoa by indirect Immunobead binding assay.[9] IgG antibodies to cytomegalovirus were detected by a commerical enzyme-linked immunoassay (Sigma, St. Louis). IgG antinuclear antibody was detected by a commercial indirect immunofluorescence assay with the HEp-2 human cell line fixed to slides (Sigma). IgG and IgM antibodies to cardiolipin and to lactoferrin were detected by enzyme-linked immunoassay, following the procedure of Cowchock et al.[10] with isotype-specific alkaline phosphatase–conjugated goat antibodies to human IgG and IgM (Kirkegaard and Perry, Gaithersburg, Md.). Positive and negative controls were always assayed in parallel to the test samples.

Statistics. Differences in the occurrence of chlamydial antibodies between women with various pregnancy

Table II. Relation between IgG antibodies to *C. trachomatis* and other antibodies in sera of female partners of infertile couples

Antibody	No. positive	
	Chlamydia-antibody positive	*Chlamydia-antibody negative*
Cardiolipin (IgG)	1	3
Cardiolipin (IgM)	5	6

Nuclear (IgG)	15	8
Lactoferrin (IgG)	2	0
Lactoferrin (IgM)	4	3
Spermatozoa (IgG)	6	5
Spermatozoa (IgA)	2	2
Spermatozoa (IgM)	7	10

Sera from 44 women who had seropositive and 44 women who had seronegative test results for chlamydial IgG were tested for other antibodies by enzyme-linked immunosorbent assay (cardiolipin, cytomegalovirus, lactoferrin), immunofluorescence (nuclear) and immunobead binding (spermatozoa).

histories were evaluated for significance by the χ^2 test with the Yates' correction factor.

Results

Antibodies to *C. trachomatis* in relation to history of spontaneous abortions. Sera were tested for antibodies to *C. trachomatis*–infected cells at a dilution of 1:128. This high titer was chosen to enhance the specificity of the analysis and to focus our attention on those women with vigorous immune responses to *C. trachomatis*. Previous findings indicated that a *C. trachomatis* antibody titer ≥1:128 successfully identified women with an increased incidence of spontaneous abortion.[7] We realize that some women with low-titer IgG antibodies would have remained undetected. Our results, therefore, probably underestimate the incidence of chlamydial antibodies in the populations studied. The use of *Chlamydia*-infected cells allows the detection of antibodies to a wider range of antigens than would be possible in an analysis with only purified elementary bodies. With the present assay immune responses to antigens present on reticulate bodies and elementary bodies and antigens produced by mammalian cells in response to a chlamydial infection can all be evaluated. The assay in its present form does not discriminate between chlamydial antigens and infection-induced host antigens. This may be an important consideration because a stress-induced mammalian protein can cross react with a chlamydial antibody (see Comment).

In our fertile controls 9 (9.8%) of 92 women had IgG antichlamydial antibodies in their sera. Among the 258 patients, 44 (17.1%) had seropositive results. This difference between the two groups was significant ($p < 0.05$). Further analysis revealed, however, that the prevalence of chlamydial antibodies in patients with no history of spontaneous abortions (20 13.5% of 148) or with one (6 12.8% of 47) or two (4 12.1% of 33) prior abortions did not differ from the controls (Table I). Significant increases over the control group in the occurrence of chlamydial IgG antibodies were only observed in women with histories of three ($p = 0.01$) or four ($p = 0.006$) spontaneous abortions. Seven (41.1%) of 17 women with 3 abortions and 6 (60%) of 10 women with four abortions had seropositive results.

Table III. Relation between frequency of spontaneous abortion and maternal age

No. of abortions	*No. of patients*	*Mean age ± SD*
0	148	35.0 ± 4.6
1	47	36.7 ± 5.0
2	32	37.0 ± 5.2
3	17	36.5 ± 4.2
4	10	36.6 ± 5.4

There was a greater than fourfold increase ($p < 0.001$) in the incidence of >3 spontaneous abortions in the 44 (31.8%) women with high-titer chlamydial antibody as opposed to the 214 (7.5%) seronegative women.

Relation between antibodies to *C. trachomatis* and other antibodies. The increased prevalence of IgG antibodies to *C. trachomatis* could have been a consequence of a nonspecific polyclonal activation of B lymphocytes caused by a viral infection[11] or an autoimmune process. Autoantibodies to cardiolipin have been associated with recurrent abortions.[10, 12] The relation between IgG antibodies to *C. trachomatis* and antibodies to cytomegalovirus, cardiolipin, and nuclear antigens and to lactoferrin and spermatozoa was examined in a subset of patients (Table II). The prevalence of any of these antibodies was similar in sera from 44 women who had seropositive and 44 women who had seronegative test results for chlamydial antibodies. In addition, with the exception of chlamydial antibodies there was no relationship between any of the antibodies tested and ≥3 spontaneous abortions.

Relation between maternal age and spontaneous abortions. The incidence of spontaneous abortion may also be related to maternal age; however, in our study no relation between these two variables was noted (Table III).

Comment

Among the female partners of 258 infertile couples and the 92 fertile women with no history or clinical indications of exposure to *C. trachomatis*, IgG antibody reactive with *C. trachomatis*–infected cells was detected in 17.1% and 9.8% of patients and controls, respectively. These findings again highlight the high preva-

lence of asymptomatic chlamydial infections in females. In addition, in confirmation of previous studies those women with histories of three or four spontaneous abortions had the highest prevalence of IgG antibodies to *C. trachomatis*. These observations lead to the conclusion that a chronic silent chlamydial infection may increase susceptibility to first-trimester pregnancy loss, at least in those women with evidence of a vigorous immune response to this organism.

The mechanism whereby a chlamydial infection adversely affects early-stage pregnancy remains to be determined. The continued absence of positive chlamydial cervical cultures in any of our subjects or in their male partners, coupled with similar negative culture findings in the subjects of previous studies,[4,5,8] suggests that it is highly unlikely that viable *C. trachomatis* is present in the majority of subjects whose test results for IgG are seropositive. Our inability to detect IgM antibody to *C. trachomatis* in the subjects whose test results for IgG are positive (unpublished observations) further suggests the absence of an ongoing active chlamydial infection. We cannot exclude the possibility, however, that a nonproductive chlamydial infection, such as has been observed in patients with trachoma,[13] can still be present and can induce a deleterious inflammatory response in the endometrium. Immune system activation and cytokine production in response to chlamydial antigens may interfere with embryo implantation or regulatory mechanisms that protect the fetus from attack by the maternal immune system.

Alternatively, a past chlamydial infection that has subsequently been cleared may have damaged the endometrium sufficiently that successful embryo implantation becomes less likely. There is little evidence to support or refute this possibility.

Another attractive but as yet unproven mechanism involves the induction of an autoimmune response as a result of long-term exposure to *C. trachomatis* antigens. Morrison et al.[14] have demonstrated that a single chlamydial antigen, a 57 kd protein, was responsible for the induction of a hypersensitive immune response in guinea pigs who were previously sensitized to *C. trachomatis*.[14] Furthermore, this protein was shown to be a member of the 60 kd family of heat-shock proteins.[15] Analogous heat-shock proteins are also present in mammalian cells; their production is markedly increased under conditions of stress such as elevated temperature or immune system activation.[16] A member of this protein family exists in man and shares considerable sequence homology with the chlamydial 57 kd protein.[17] The 60 kd heat-shock protein is also one of the first proteins produced by the developing embryo.[18] Therefore sensitization of T lymphocytes to the chlamydial heat-shock protein may result in the generation of lymphocytes that can also react with the analogous human heat-shock protein that can be expressed by the embryo or maternal cells in the pregnant uterus. The resultant immune system activation might directly destroy the embryo or interfere with immune regulatory mechanisms. The detection of cytotoxic T cells specific for epitopes of a mycobacterial heat-shock protein that were also present in the human heat-shock protein and which could lyse human cells expressing the human heat-shock protein has been reported.[19] The presence of antibodies to the chlamydial 57 kd heat-shock protein in patients' sera and expression of the heat-shock protein in infected McCoy's cells is currently under investigation. IgG antibodies reactive with the chlamydial 57 kd heat-shock protein have been detected in some women with *Chlamydia*-associated salpingitis and ectopic pregnancy.[20]

Alternatively, a fetal component that shares an epitope with *C. trachomatis* might have been the eliciting antigen. If true, these women might never have had chlamydial infections, and chlamydial antibodies could merely be a surrogate marker for the presence of an antifetal antibody.

Continued testing for high-titer *Chlamydia* IgG antibody will lead to improved identification and characterization of this subgroup of women whose recurrent abortions or infertility is currently unexplained. We hope that further analysis of these women will clarify the mechanism for their inability to maintain a pregnancy and lead to the development of methods to overcome this problem.

Randomized, double-blind study of cefotetan and cefoxitin in post–cesarean section endometritis

Rob Roy MacGregor, MD,[a] Amy L. Graziani, PharmD,[b] and Philip Samuels, MD[c]
Philadelphia, Pennsylvania

OBJECTIVE: The hypothesis of the study is that cefotetan and cefoxitin will be equally efficacious and safe in the treatment of post–cesarean section endometritis.
STUDY DESIGN: In a double-blind, randomized manner 140 patients with post–cesarean section endometritis were treated with cefotetan, 2 gm intravenously every 12 hours, or cefoxitin, 2 gm intravenously every 6 hours. They were followed prospectively for clinical response and side effects. Cure rates between the two groups were compared with the χ^2 test.
RESULTS: The cure rates were 83% for cefotetan and 79% for cefoxitin ($p = 0.56$). No patient required a change in therapy due to adverse effects, and no abnormal bleeding occurred.
CONCLUSION: In this study cefotetan and cefoxitin appeared equally effective in treating endometritis with no difference in side effects or complications. (Am J Obstet Gynecol 1992;167:139-43.)

Key words: Endometritis, cefotetan, cefoxitin

Postpartum endometritis is generally treated with broad-spectrum antibiotics possessing activity against aerobic and anaerobic gram-positive and gram-negative organisms. Cefotetan and cefoxitin are two such antibiotics. Cefoxitin is administered every 6 hours and has activity against *Bacteroides fragilis subspecies fragilis* and the other *B. fragilis* subspecies. Cefotetan is administered every 12 hours and, compared with cefoxitin, has increased activity against gram-negative aerobic bacteria but less activity against the nonfragilis *B. fragilis* subspecies (i.e., *B. ovatus, B. distasonis,* and *B. thetaiotaomicron*).[1] The cefotetan molecule, unlike cefoxitin, contains the methylthiotetrazole group, which has been associated with hypoprothrombinemia during therapy with cefoperazone, cefamandole, cefmetazole, and moxalactam.[2]

*Includes two minor wound infections.

†Includes one wound infection requiring a change in therapy.

Because of its favorable in vitro activity, prolonged half-life, and lower cost, cefotetan has replaced cefoxitin in some hospitals for the treatment of pelvic infections. However, no blinded, randomized study comparing the efficacy of the two drugs has yet been reported.[3-6] Therefore we conducted such a study in 140 consecutive women with post–cesarean section endometritis.

Methods

One hundred forty women who had recently undergone cesarean section were enrolled in this randomized, double-blinded study. The protocol and consent form were reviewed and approved by the Committee Involving Research on Human Beings at the University of Pennsylvania. The standard regimen prescribed for surgical prophylaxis was cefazolin, 1 gm intravenously at cord clamping and then every 8 hours for two more doses, or cefonicid, 1 gm intravenously at cord clamping. Patients with a history of mitral valve prolapse received 2 gm ampicillin plus 80 mg gentamicin at cord clamping and for two more doses postoperatively. Patients were included in the study if the following conditions were present ≥12 hours postoperatively: (1) uterine tenderness, and (2) either a single temperature elevation ≥38.3° C or two temperatures ≥38° C ≥6 hours apart. Patients were not eligible for enrollment if they had another obvious site of infection. Other exclusion criteria were age <18 years, history of an immediate hypersensitivity reaction to a penicillin or cephalosporin, and evidence of antepartum infection (e.g., chorioamnionitis).

Drug regimen. Patients were assigned by a computer-generated randomization schedule to receive either cefotetan, 2 gm intravenously every 12 hours alternating with placebo every 12 hours, or cefoxitin, 2 gm intravenously every 6 hours. All doses were identical in appearance and were dispensed from the pharmacy in 150 ml of 5% dextrose in water. Patients were treated intravenously until deemed cured and were sent home without any oral antibiotics.

Study procedures. The following laboratory tests were performed before the study, every 5 days during therapy, and after the study: complete blood cell count with differential and platelet count, prothrombin time, partial thromboplastin time, liver function tests, serum creatinine, and blood urea nitrogen. Blood and urine cultures were performed in all patients at the time of enrollment. Because of the well-described character of the organisms associated with post–cesarean section endometritis, endometrial cultures were obtained only in patients who failed therapy.[3, 7-10] Patients who did not respond to the study drugs in at least 48 hours were given ampicillin, gentamicin, and either metronidazole or clindamycin. Patients found to have enterococcal bacteremia had therapy changed to ampicillin and gentamicin. Follow-up was obtained 4 to 6 weeks after discharge either at a clinic visit, office visit, or by telephone.

Definitions for evaluating response. Cure was defined as a decrease in temperature and uterine tenderness within the first 48 hours of therapy, with complete resolution of both by the end of therapy. Failure was defined as either a persistently elevated temperature without a trend towards improvement or uterine tenderness without improvement after 48 hours of therapy. All patients with enterococcal bacteremia were considered failures regardless of their clinical responses. Relapses were those patients who met the criteria for cure who subsequently developed signs and symptoms of wound infection, abscess, or recurrent endometritis during the 4 to 6 week follow-up period. All clinical decisions, including those regarding termination of study treatment because of an unsatisfactory response, were made by the primary physicians, not by the study team.

Statistical analysis. Proportions were compared with a χ^2 test or a two-tailed Fisher's exact test. Means were compared with a pooled t test or the Welch's t test in the case of groups with unequal variances.

Results

One hundred forty patients were enrolled in the study; 66 were evaluable in the cefotetan group and 63 in the cefoxitin group. Patients were nonevaluable for the following reasons: chorioamnionitis (four), age <18 years (three), termination of treatment at 24 hours due to rapid clinical response (two), pneumonia (one), and drug administration error (one).

The mean age was 26 years in both groups. Only 13% to 16% of patients had prolonged rupture of mem-

branes (>24 hours) or were in labor for >24 hours, with similar percents in both groups. Most patients were primarily cared for by our resident physicians, 86% and 83% in the cefotetan and cefoxitin groups, respectively. Twelve percent and 11%, respectively, had undergone previous cesarean sections.

Complete cure was achieved in 83% (55) of cefotetan patients and 79% (50) of cefoxitin patients ($p = 0.56$) (Table I). The duration of therapy, time to defervescence (<38.5° C), and length of hospital stay were similar in both groups (Table I).

Wound infections developed in one patient treated with cefotetan and in two treated with cefoxitin. The patient treated with cefotetan had persistent fever, and ampicillin, gentamicin, and metronidazole were prescribed afer a bedside debridement to remove a large amount of necrotic tissue. This was considered a cefotetan failure. The cefoxitin patients had minor wound infections and, after bedside debridement, only local care was required. Therefore they were considered cefoxitin cures. All wounds ultimately healed well.

Follow-up was obtained in 85% of patients. One patient in each group had what was considered a relapse during the 4 to 6 week follow-up period. One patient in the cefotetan group, receiving warfarin because of a history of pulmonary embolus, 1 week after discharge fell from a moving car and developed a left lower quadrant hematoma with fever. She declined needle aspiration for culture of the hematoma, and her temperature resolved during a 10 day course of empiric ampicillin, gentamicin, and metronidazole therapy. The cefoxitin patient with relapse was seen in the emergency room with abdominal pain, fundal tenderness, and a temperature of 99.9° F 4 days after discharge from the hospital. She refused readmission and was treated with oral ampicillin and doxycycline; her symptoms resolved.

Table III. Organisms isolated from endometrial cultures (from clinical failures only)

Organism	Total isolates	Cefotetan patients*	Cefoxitin patients

NA, Not available.
*Total number of isolates with number resistant to study drug in parentheses.

Seven patients were bacteremic before initiation of cefotetan therapy, compared with three in the cefoxitin group. Gram-positive, gram-negative, and anaerobic organisms were isolated (Table II). Most organisms were susceptible to both study drugs except for enterococcus, which was cephalosporin-resistant, and *B. oris,* which was cefoxitin resistant. Endometrial cultures from the patients who failed therapy showed mixed aerobic and anaerobic flora. As with the blood isolates, most organisms were susceptible to both cefotetan and cefoxitin. Nine of the 22 treatment failures had enterococci resistant to both drugs isolated from their endometrial cultures (Table III).

Therapy with both drugs was well tolerated. The adverse effects that occurred were generally mild and

Table IV. Adverse effects*

§>350,000 per microliter.

self-limited and did not require discontinuation of the study drugs. Clinical adverse effects included diarrhea, nausea and vomiting, pruritus, vaginal candidiasis, and headache (Table IV). Three of the six patients in the cefotetan group who developed diarrhea and one of the four in the cefoxitin group did so 2 to 3 days after changing antibiotic therapy to ampicillin, gentamicin, and metronidazole because of treatment failure. Therefore the relative contribution of the various drugs is uncertain. One patient in each group had *C. difficile* toxin–positive diarrhea. The following laboratory abnormalities occurred in approximately equal numbers in each group: aspartate aminotransferase or alanine aminotransferase levels twice normal, thrombocytosis, anemia, and prolongation of prothrombin time (Table IV).

Comment

Post–cesarean section endometritis was encountered in 40% to 70% of patients before prophylactic antibiotic use became accepted practice.[11] Currently, in spite of routine prophylaxis, endometritis still develops in up to one third of patients in reported series.[11] Risk factors for postoperative infection include young age, low socioeconomic status, extended duration of labor and ruptured membranes, multiple vaginal examinations, and prolonged operation time and delivery because of cephalopelvic disproportion.[11] High rates of cure have been achieved with a number of different antibiotic regimens, all chosen for their efficacy against the mixed aerobic-anaerobic polymicrobial etiology of the infection. Cure rates of 75% to 95% are reported for most with no regimen clearly and consistently superior to the others.[11-16] Therefore issues of cost and ease of administration were important and led us to compare cefoxitin with cefotetan because of the latter's lower cost and less frequent dosing requirement.

The cure rates of 79% and 83% in the present study are similar to our previously reported results comparing cefoxitin with clindamycin plus gentamicin, in which 80% of patients were cured.[17] Some groups have reported higher success rates in treating endometritis. This may be the result of our protocol, which only allowed 48 hours for a clinical response to occur. This cut-off is significantly shorter than what has been used in some studies.[3-5, 9, 18, 19] A second reason for our relatively low response rates may be that we classified patients with enterococcal bacteremia as failures. If we had defined these patients as nonevaluable, the clinical cure rates would have been increased slightly to 87% for the cefotetan group and 81% for the cefoxitin group ($p = 0.31$). In addition, we exercised no influence on the obstetricians' decision to change treatment, and some "failures" may merely represent the care team's impatience with the speed of clinical response. Nonetheless, the double-blinded, randomized nature of our study allows the conclusion that no difference in efficacy could be distinguished between the two drugs.

Our study design elected not to do endometrial cultures unless clinical failure occurred because of the wealth of data previously developed concerning the organisms typically found in post–cesarean section endometritis.[3, 7-10] Therefore it is possible that our two study groups may not have been similar microbiologically. We think this unlikely, owing to the randomized nature of the study and the large number calculated to avoid such statistical aberrations. Moreover, the similarity between the two groups concerning age, incidence and duration of ruptured membranes, duration of labor, incidence of repeat cesarean sections, and socioeconomic status offers further evidence that they were well matched.

Because β-lactam antibiotics containing the methylthiotetrazole side chain have been reported to cause bleeding problems, we monitored patients in both arms of the study for clinical or laboratory evidence of clotting disorders.[1, 2, 20] No abnormal bleeding tendency was detected in this well-nourished population who received only a few days of antibiotic treatment. The mild reduction in hemoglobin and elevation in platelet counts seen in some patients were more likely a result of surgery than of antibiotic treatment. Nonetheless, it seems prudent to be alert for bleeding problems in sicker patients receiving a longer duration of therapy. Other adverse experiences, such as nausea, diarrhea, and abnormal liver enzyme levels, were uncommon and of similar frequency in the two treatment groups.

Cost analysis showed that cefotetan saved an average

of $75 per treatment course. Also, because of the twice daily dosing, nursing time can be used more effectively. Given the equal responses and toxicities, we believe it responsible to use the less costly treatment. Furthermore, we predict that future studies will demonstrate that additional savings can be effected by giving 24 to 48 hours of intravenous treatment followed by a similar period of suitable oral medication.

In conclusion, we found no difference in the clinical cure rate or toxicity of cefotetan and cefoxitin in the treatment of post–cesarean section endometritis in spite of some differences in the chemical configurations and in vitro activities of the two drugs.

We thank the Obstetrics and Gynecology House Staff who assisted in enrolling the patients in this study and the women who volunteered to participate.

Interactions between intrauterine contraceptive device use and breast-feeding status at time of intrauterine contraceptive device insertion: Analysis of TCu-380A acceptors in developing countries

Gaston Farr, MA, and Roberto Rivera, MD
Research Triangle Park, North Carolina

OBJECTIVE: This paper is a reassessment of earlier findings from a preliminary analysis of data from a multicenter international trial regimen on breast-feeding and non–breast-feeding women in which events related to insertion, expulsion, and removal of the TCu-380A intrauterine contraceptive device (ParaGard 380) were investigated.
STUDY DESIGN: Performance of the TCu-380A through 12 months after insertion was compared with life-table rate analysis, χ^2, Fisher exact test, or Student's *t* test. Variables were events reported during intrauterine contraceptive device insertion and events throughout the 12 months of study participation by breast-feeding status.
RESULTS: Breast-feeding among intrauterine contraceptive device users was associated with fewer insertion-related complaints and lower removal rates for bleeding and pain. No uterine perforations were reported throughout the study.
CONCLUSION: Differences in the performance of the TCu-380A intrauterine contraceptive device suggest physiologic effects associated with lactational amenorrhea. The TCu-380A intrauterine contraceptive device is a viable option for women breast-feeding at the time of intrauterine contraceptive device insertion. (Am J Obstet Gynecol 1992;167:144-51.)

Key words: Breast-feeding, intrauterine contraceptive device, TCu-380A IUD and breast-feeding, TCu-380A insertion and adverse reactions

The benefits of breast-feeding for both mothers and infants are widely accepted. For the mother it is a natural, convenient, and cost-effective option that offers some protection against pregnancy.[1-6] For the infant prolonged breast-feeding is one of the most important factors for improving chances for survival, growth, and development. In many developing countries breast-feeding also plays a very important role in spacing births.[1, 4] However, current family planning programs in these countries emphasize the use of modern contraceptive methods, most often intrauterine contraceptive devices (IUDs) and hormonal methods (oral pill, implants, and injectables). In some instances lactating women are excluded from using IUDs because of a risk of uterine perforation.[7] On the other hand, IUDs are often recommended for contraceptive use among breast-feeding women because of the lack of adverse effects on lactation.[8]

Family Health International is an international nonprofit organization that conducts research and provides technical assistance in health, family planning, sexually transmitted diseases, and acquired immunodeficiency syndrome. In an earlier analysis of data from Family Health International's multicenter comparative trial regimens of the TCu-380A, breast-feeding women were more likely to experience pain-free insertion, few problems with postinsertion bleeding and pain, no uterine perforations, and a high continuation rate after 6 months of use.[2] Also, breast-feeding women were no more likely to experience accidental pregnancy or intrauterine contraceptive device expulsion than non–breast-feeding women. However, that study represented a preliminary analysis of data from five sites participating in Family Health International's multinational comparative clinical trial regimens of the TCu-380A. More than 20 sites in 11 countries participated in these trial regimens.

Recently Family Health International completed data processing for these sites and is now compiling these data into a worldwide database. The earlier study fo-

cused on 3- and 6-month rates because follow-up at each of the five sites had not been completed through 12 months. Our article represents a reassessment of these earlier findings with 12-month data from the expanded Family Health International TCu-380A database.

Material and methods

The copper-T-380A (TCu-380A) is a plastic, T-shaped IUD with copper wire wound around the stem and copper collars on each side of the cross arm of the T. This IUD has a total exposed copper surface area of 380 mm^2. It is 36 mm long, 32 mm wide, and has two monofilament marker strings attached to a ball at the bottom of the vertical stem. The TCu-380A has been shown to be an effective contraceptive option, with life-table failure rates of <1 per 100 women after 12 months of use.[10] It has been approved for use in the United States for ≤8 years.

Family Health International's international clinical trial regimens of the TCu-380A IUD were designed to compare this device with the IUD most widely used in each of the participating countries, including the TCu 200, the TCu 220, the Lippes Loop, and the Multiload 250. All sites used identical study protocols and case record forms. IUDs were randomly assigned to participants according to sealed random-allocation envelopes, preprinted before study initiation, and opened at the time of IUD insertion. All study subjects were healthy women who had no contraindications for IUD contraceptive use and who gave informed consent to participate in the study.

The clinical protocol specified that women were to be sexually active and between 18 and 40 years of age. Insertions were performed in the interval period (last pregnancy ended at least 42 days before insertion). Patients were to return for follow-up at 1, 3, 6, and 12 months after insertion and at any time complications occurred. Medical examinations were performed during each contact with the patient. A woman was discontinued from the study if she became pregnant or if her IUD was expelled, displaced, or removed for any reason.

Information on selected sociodemographic characteristics, reproductive and contraceptive histories, and preexisting medical conditions was obtained at the time of admission into the study. The woman's breast-feeding status was determined at admission. Insertion-related events were recorded on the admission form; subsequent pertinent events such as accidental pregnancy, expulsion, removal, complications, and complaints were recorded at each follow-up visit. A total of 2533 women had TCu-380A IUDs inserted at 25 research sites in Nigeria, the Philippines, Mexico, Peru, Cameroon, Pakistan, Sri Lanka, Thailand, Malaysia, El Salvador, and Chile. Insertions were performed between May 1985 and September 1988.

A woman was included in the analysis if her last pregnancy resulted in a vaginally delivered, live, term birth. The study population consisted of 2275 women. At the time of insertion, 1243 of the women indicated they were not breast-feeding and 1032 indicated they were. (Breast-feeding status includes both full lactation and partial lactation, which is defined as providing supplementary food in addition to breast-feeding.)

Performance of the TCu-380A through 12 months after insertion was compared between women who were not breast-feeding and those who were breast-feeding at the time of insertion by life-table rate analysis. Rare but medically serious insertion-related events were compared between the two groups by the χ^2 test of association or the Fisher exact test if the numbers were small. Student's t test was used to compare differences between continuous variables. Gross cumulative life-table event rates were calculated by Potter's method[11] and compared by the log-rank method.[12] Herson's method was used to produce rates adjusted for any differences in baseline characteristics.[13] A p value of <0.05 (two-tailed) was considered statistically significant.

Results

Table I presents data on selected baseline characteristics of the two groups of women. On the average breast-feeding and non–breast-feeding women were similar in their number of live births and in their number desiring additional children sometime in the future. However, non–breast-feeding women were almost 2.5 years older and had completed at least 1 more year of schooling. Non–breast-feeding women were more likely to be using some form of contraception in the month before this TCu-380A IUD insertion, to have had a completed menstrual cycle before insertion, and to have had a shorter time interval (<6 months) between the date the study IUD was inserted and the date their last pregnancy ended (all differences significant at $p < 0.001$).

Events experienced during IUD insertion are presented in Table II. Two failed insertions were reported in this population, with one in each group; these women appear only in Tables I and II. No reports of uterine perforation at the time of insertion were recorded. Other insertion events were rare; when they occurred the number was usually higher among non–breast-feeding women. More non–breast-feeding women than breast-feeding women experienced some degree of pelvic pain during insertion ($p < 0.001$, χ^2 test), and more required cervical dilatation to ease insertion ($p < 0.03$, Fisher exact test). No statistically significant difference were noted between the two groups in the

incidence of cervical laceration at insertion or insertion-related complications such as syncope or diaphoresis. Most of the women were diagnosed with retroverted uteri.

A total of 2207 women (1203 (97%) in the non–breast-feeding group and 1004 (97%) in the breast-feeding group) returned for at least one follow-up visit during the study. Table III presents gross cumulative life-table event rates for 3, 6, and 12 months after insertion. Event rates were found to be comparable for the two groups of women at each follow-up period, with the exception of removals for bleeding or pain. At each time interval studied breast-feeding women experienced fewer removals for this reason than did non–breast-feeding clients.

There were not statistically significant differences in pregnancy and expulsion rates between breast-feeding and non–breast-feeding women. Although breast-feeding women tended to have lower pregnancy rates, pregnancy was very unusual in either group (0.6 per 100 women in the non–breast-feeding group, compared with 0.3 per 100 women in the breast-feeding group). Expulsion tended to be more frequent in breast-feeding women, although expulsion rates were low in both groups as well (2.8 per 100 women among non–breast-feeding women compared with 3.9 in breast-feeding women).

Because the two IUD study groups differed as to (1) age, (2) use of contraception before IUD insertion, (3) menstrual status, (4) length of time between last pregnancy outcome and IUD insertion, and (5) incidence of pain during insertion, life-table termination rates were standardized to calculate adjusted cumulative rates.[13]

Table IV presents 12-month cumulative life-table rates when adjusted for differences in age (<20, 20 to 24, 25 to 29, 30 to 34, 35+ years old); use of contraception before study admission (no, yes); menstrual status at insertion (still amenorrheic, resumed menses); pain at insertion (no, yes); and the length of the open interval between the outcome date of the woman's last pregnancy and the date of IUD insertion (<6 months, 6 to 12 months, 12 to 24 months, 24+ months).

The lack of difference between the two groups for pregnancy, expulsion, or removal for other medical reasons was maintained after the life-table rates were adjusted for differences in each of these baseline characteristics. However, there was a difference in magnitude between the two groups regarding removals resulting from bleeding or pain when life-table rates were adjusted for age.

Breast-feeding women continued to have statistically significantly lower removal rates for bleeding and pain than non–breast-feeding women (5.1 vs 2.9 per 100 women, respectively, $p = 0.015$).

The relationship between the degree of breast-feeding at insertion and the impact on pertinent life-table rates at 3, 6, and 12 months is shown in Table V. Breast-feeding status was separated to differentiate between women breast-feeding and giving supplementary foods (partial) and those breast-feeding without supplementation (full). Women partially and fully breast-feeding experienced similar rates of removal for bleeding or pain, and non–breast-feeding women had a much higher rate of removal for bleeding at 3 months after insertion ($p < 0.001$) and at 6 months after insertion ($p < 0.05$).

Differences among the three groups in bleeding and pain removal rates were no longer statistically significant by 12 months after insertion. Women in the fully breast-feeding group had slightly higher removal rates for bleeding or pain (3.7 per 100 women) than women in the partial breast-feeding group (2.7 per 100 women), but this difference was not statistically significant.

because of bleeding and pain for non–breast-feeding women and breast-feeding women who were either amenorrheic or nonamenorrheic at IUD insertion are presented in Table VI. No significant differences in removal rates were detected when comparing rates for non–breast-feeding women and breast-feeding women who had resumed menses, nor were there significant differences when comparing rates for breast-feeding women who had resumed menses with those of women who still had amenorrhea at the time of IUD insertion.

However, significant differences were detected when comparing removal rates at each time period for non–breast-feeding women and breast-feeding women who still had amenorrhea. Overall, breast-feeding women who still had amenorrhea at the time of IUD insertion had the lowest removal rates for bleeding and pain at 3, 6, and 12 months after insertion.

Time since last pregnancy outcome (open interval) was not significantly associated with the incidence of removal of the TCu 380A for bleeding or pain (Table VII). Although women whose last pregnancy ended <6 months before IUD insertion were less likely to have their IUDs removed for bleeding complications than women ≥7 months post partum, differences in the 3-, 6-, and 12-month removal rates were not statistically significant at $p < 0.05$. When bleeding and pain removal rates were adjusted for breast-feeding or menstrual status at the time of IUD insertion, these differences virtually disappeared. Removal of an IUD for bleeding or pain may not be a reflection of postpartum status as much as of whether these women were actively breast-feeding or had amenorrhea (or both) at the time the IUD was inserted.

Comment

The TCu-380A has been shown to provide very effective and safe protection against pregnancy when compared with other IUDs and is becoming the IUD of choice in many family planning programs throughout the developing world.[14] A number of studies have focused on the safety and efficacy of this device, including the effect of IUD use on lactation.[3-6, 9] A limited number of studies have been conducted to assess the impact of breast-feeding status at insertion on the performance of this IUD.

Some studies have found an increased risk of uterine perforation and other complications during IUD insertion in breast-feeding women.[7] However, recent studies have reported few if any uterine perforations among breast-feeding or non–breast-feeding women.[2, 3]

In our study the incidence of accidental pregnancy was found to be low for both study groups. This incidence confirms the results of earlier studies that found the incidence of accidental pregnancy was not affected by breast-feeding status at the time of IUD insertion.[8]

The earlier Family Health International study also did not find an increased risk for expulsion among breast-feeding women.[2] Although expulsion rates were

higher among breast-feeding women at each follow-up interval, the difference in rates were not statistically significant. Breast-feeding women may be at a slightly higher risk of IUD expulsion, but this risk may be more the result of their recent postpartum status than of breast-feeding alone. This risk also held true when these rates were adjusted for differences in the length of time between IUD insertion and the women's last pregnancy outcome.

Removals for bleeding or pain comprise most IUD discontinuations. Breast-feeding women in our study experienced fewer removals for bleeding or pain complications than non–breast-feeding women at each follow-up interval studied. This difference was greatest during the first 3 months after insertion, when the risk of increased bleeding associated with IUD use is highest. Rates were beginning to converge by the end of the study (12 months after insertion), but this difference was still statistically significant.

Breast-feeding status may not be the sole reason for differences in the rates of IUD removal resulting from bleeding and pain complications; breast-feeding women were not similar to non–breast-feeding women across many baseline characteristics. Almost all non–breast-feeding women were menstruating at the time of IUD insertion compared with less than half of the breast-feeding women.

The finding that bleeding and pain removal rates for breast-feeding women with amenorrhea were significantly lower than those removal rates for non–breast-feeding women is not unexpected. Breast-feeding has been found to prolong postpartum amenorrhea (lactational amenorrhea) and to inhibit ovulation and reduce the likelihood that pregnancy may occur.[16, 17] Thus, as long as a woman continues to breast-feed, she is more likely to have amenorrhea and thereby continue to have a lower risk of IUD-related bleeding than menstruating women.

Some of the differences in the baseline characteristics between breast-feeding and non–breast-feeding women, such as use of contraception in the month before IUD insertion, the completion of a menstrual cycle before insertion, and the length of the interval between delivery and IUD insertion are clearly related to breast-feeding status. Therefore it is not a surprise that the differences in bleeding-and-pain removals and in pain at insertion disappear when the two groups (breast-feeding and non–breast-feeding) are adjusted by the above-mentioned differences.

It is important to note that no uterine perforations were reported among these women. It has previously been thought that women who were breast-feeding at

the time of IUD insertion were at higher risk of uterine perforation than non–breast-feeding women,[7, 17] although other researchers have not always found this to be the case.[9, 18] The absence of reports of uterine perforation in this study cannot be construed to mean that IUD perforation should no longer be considered a risk factor among women using IUDs.

However, these results are reassuring and may suggest that inserters trained under a similar insertion procedure can have low perforation rates. It is also reassuring that no increased risk of perforation in breast-feeding women was observed in a multicenter study involving a large number of women with different individuals performing the IUD insertions.

Of special importance is the lower incidence of pain reported at the time of IUD insertion and fewer removals for bleeding and pain among breast-feeding women, particularly among those women who still had lactational amenorrhea at the time of insertion. The lower incidence of both pain at insertion and pain being a reason for IUD removal is likely to be the result of the same factors that are associated with lactational amenorrhea.

Researchers now accept the fact that an increased secretion of β-endorphin is responsible for the maintenance of lactational amenorrhea. The suckling stimuli produce an increased hypothalamic secretion of β-endorphin, which in turn inhibits the activity of the hypothalamic luteinizing hormone pulse generator.[19] β-endorphin is a potent analgesic, several times more potent than morphine.[20] It has been reported that endorphins increase the threshold of pain in the rat[21]; an

Table VII. Comparisons* of cumulative life-table rates per 100 women for removals because of bleeding and pain by open interval since last pregnancy outcome; gross rates and rates adjusted by breast-feeding and menstrual status at the time of insertion of the TCu-380A device, 1985-1988

§Defined as amenorrheic and resumed menses.

increased tolerance to pain at the end of pregnancy, attributed to an increase in β-endorphin, has been reported in normal women.[22]

Another hormonal factor associated with lactational amenorrhea is absent or very low estrogen secretion. It has been shown that the sensitivity of the uterus varies according to the phases of the menstrual cycle in the rat.[23] In general, estrogens increase the sensitivity of afferent uterine neural fibers.[25] When rats are in vaginal estrus or proestrus, the hypogastric uterine fibers are more sensitive to stimulation such as pressure or stretching.[24] It is possible that the lower incidence of pain during IUD use among breast-feeding women observed in this study may be because of increased levels of β-endorphin and low levels of estrogens.

These two situations are more likely to be present when breast-feeding women are still in amenorrhea, which is also consistent with the findings of the study. Lower rates of removals for bleeding and pain at 3 and 6 months of IUD use among breast-feeding women who were still in amenorrhea or who were fully breast-feeding at the time of IUD insertion are also consistent with a β-endorphin and estrogen-mediated effect. β-endorphin levels decrease and estrogen levels increase with a reduction in the breast-feeding stimuli, a situation that is likely to occur because the postpartum period is extended.

In summary, these data suggest that removals for bleeding and pain occur within the first few months postinsertion and that women with amenorrhea who are breast-feeding at the time of IUD insertion may be less likely to experience a removal because of bleeding and pain complications during this time than women who are not. An increased risk of adverse effects, including uterine perforation, was not apparent among women using the TCu-380A IUDs who were breast-feeding at the time of insertion. Breast-feeding women experienced easier and less painful insertion procedures and were less likely to prematurely stop IUD use because of bleeding complications associated with IUD use.

Differences in the rate of removal continued to persist over time, suggesting that breast-feeding at the time of IUD insertion may have more impact on long-term continuation of use than was previously expected.[23] What may cause this lower risk is uncertain; most likely it is the result of the amenorrhea of many of the breast-feeding women at the time of IUD insertion and that the women probably continued to have amenorrhea during the early postinsertion months and not specifically to their postpartum status. This effect can only be maintained if women continue to breast-feed and have amenorrhea for a period of time.

Differences detected in the performance of the TCu-380A IUD may be caused by factors associated with lactational amenorrhea and other dissimilarities between breast-feeding and non–breast-feeding women. These findings suggest that use of the TCu-380A is a viable option for women who are breast-feeding at the time of IUD insertion. The potential of a lower incidence of pain at the time of IUD insertion and of lower rates of removals for bleeding and pain can actually be an advantage for the use of IUDs in breast-feeding women, particularly during the period of lactational amenorrhea.

We thank all collaborating investigators involved in this study for their valuable contribution to this trial regimen, thank I-Cheng Chi, Caroline Raby,

John Stanback, and Kathy Kennedy for reviewing the draft, and thank Inder Sharma for suggestions concerning the life-table analysis.

Survival and disease progression in human immunodeficiency virus–infected women after an index delivery

D. Jay Gloeb, DO, Shenghan Lai, PhD, JoNell Efantis, RN, ARNP, and Mary Jo O'Sullivan, MD
Miami, Florida

OBJECTIVE: Our objective was to provide information on survival and disease progression in human immunodeficiency virus antibody–positive pregnant women undergoing prospective evaluation.
STUDY DESIGN: After an index delivery, 103 human immunodeficiency virus antibody–positive pregnant women were identified and underwent follow-up for 3 years. The patients were assessed medically and/or gynecologically when hospitalized for a human immunodeficiency virus–related illness or at each follow-up visit. The life-table method was used to estimate the cumulative probabilities of survival and remaining free of acquired immunodeficiency syndrome. Cox's proportional-hazards analyses were used to identify prognostic factors for survival and progression to acquired immunodeficiency syndrome.
RESULTS: The majority of human immunodeficiency virus–infected pregnant women were alive 3 years later. Lymphadenopathy syndrome or herpes genitalis was significantly associated with a subsequent diagnosis of acquired immunodeficiency syndrome. Of the 103 original patients, six had acquired immunodeficiency syndrome at the index delivery and acquired immunodeficiency syndrome developed in 24. Approximately 94% of evaluable patients with development of acquired immunodeficiency syndrome had CD4-lymphocyte counts <200/mm³. The most common opportunistic infection was *Pneumocystis carinii* pneumonia. Acquired immunodeficiency syndrome and postpartum zidovudine therapy were independent prognostic factors affecting survival.
CONCLUSION: Survival was affected by Centers for Disease Control group status of human immunodeficiency virus infection at the index delivery. (Am J Obstet Gynecol 1992;167:152-7.)

Key words: Acquired immunodeficiency syndrome (AIDS) in pregnancy, survival of human immunodeficiency virus (HIV)–infected women, Cox's model, time-dependent covariates

The acquired immunodeficiency syndrome (AIDS) had been reported in nearly 19,000 women in the United States as of July 1991.[1] AIDS was the eighth leading cause of death in women 15 to 44 years old in 1987,[2] and in 1990, 11.3% of all new AIDS cases occurred in women.[1] On the basis of current trends, AIDS will be among the five leading causes of death in women of childbearing age in 1991.[2]

Several studies have suggested that women have a lower median survival than men.[3-7] It is unknown whether pregnancy or cofactors such as genitourinary tract infections, sexually transmitted diseases, age[8,9] simultaneous infection with the human T-lymphotropic virus type I (HTLV-I),[10,11] the mode of acquisition of human immunodeficiency virus (HIV) infection,[12] and the biologic properties of HIV variants[13] increase the rate of progression to AIDS. This observational study provides information on survival and disease progression in HIV antibody–positive pregnant women undergoing prospective evaluation after an index delivery.

Patients and methods

Population characteristics. Between Jan. 28, 1986, and Dec. 21, 1988, 103 HIV antibody–positive pregnant women were identified for clinical follow-up during a pregnancy that resulted in an index preterm or term delivery at Jackson Memorial Hospital. All patients were voluntarily tested for HIV before delivery because of admitted risk factors or medical indications and had either a repeatedly reactive enzyme-linked immunosorbent assay and a confirmatory Western blot or a repeatedly reactive enzyme-linked immunosorbent assay and ultimate development of clinical manifestations of HIV infection as defined by the Centers for Disease Control. Historically, there is a strong correlation between the clinical manifestations of HIV infection and the presence of HIV antibody.[14] The majority of patients were seen for follow-up in a special antepartum clinic. During this period, there were

38,305 deliveries in a predominantly socioeconomically disadvantaged obstetric population ethnically distributed as 45% African-American, 35% Hispanic, 10% Haitian, and 10% white.

In the study population, the majority (53.4%) were Haitian followed by 37 (35.9%) African-Americans, six (5.8%) Hispanics, and five (4.9%) white patients. The mean age at the index delivery was 29.0 years (range 16.5 to 43.5 years). The median length of follow-up after the index delivery was 837 days (range 1 to 2308 days). Most (60.2%) patients were followed up >2 years; 18.4% were monitored from 1 to 2 years, and 21.4% were evaluated for ≤1 year.

Assessments and end points. The defined entry point was an observed pregnancy resulting in a preterm or term delivery. After delivery, the patients were assessed medically and/or gynecologically when hospitalized for an HIV-related illness or at each follow-up clinic visit.

CD4-lymphocyte counts were used to determine the need to treat with zidovudine and to give prophylaxis for *Pneumocystis carinii* pneumonia. Historic and current data on HIV-related medical conditions were obtained by systematic abstracting of the subjects' medical records.

Patients were classified according to the Centers for Disease Control system for HIV infection (Table I) and were not reclassified if clinical findings resolved. AIDS was diagnosed with the revised 1987 Centers for Disease Control surveillance case definition.[15]

Statistical analyses. The outcomes of interest in the analyses were time from entry into the study (index delivery date) to date of: (1) AIDS diagnosis and (2) death (survival time). The cumulative probabilities of survival and remaining AIDS-free after a given number of years were estimated by both the life-table method[16] and Kaplan-Meier analysis,[16] and differences in survivor function among the Centers for Disease Control groups were tested with both the log-rank and generalized Wilcoxon tests. Cox's proportional-hazards analyses[16, 17] identified prognostic factors for survival and progression to AIDS. The outcome variables of primary interest were: the Centers for Disease Control group of HIV infection at the index delivery, a diagnosis of AIDS, and postpartum zidovudine therapy. The covariates included in the models to be controlled were for age, race-ethnicity, and gravidity. The diagnosis of AIDS and postpartum zidovudine therapy were functions of time; therefore they were treated as time-dependent covariates in the proportional-hazards model.[16, 17] Genitourinary tract infections and sexually transmitted diseases (including syphilis, gonorrhea, herpes genitalis, and condyloma) diagnosed during pregnancy, known HIV infection status of the index neonate on the basis of Centers for Disease Control criteria,[18] the occurrence of a subsequent pregnancy, and history of drug use were also tested in the models. The Pearson χ^2 statistic (two-tailed) was used to examine possible associations among the variables. All p values of <0.05 were considered statistically significant.

Table I. Summary of Centers for Disease Control classification system for human immunodeficiency virus infection[14, 15]

Group I	Acute infection
Group II	Asymptomatic infection*
Group III	Persistent generalized lymphadenopathy*
Group IV	Other disease†
Subgroup A	Constitutional disease
Subgroup B	Neurologic disease‡
Subgroup C	Secondary infectious diseases
Category C1	Specified secondary infectious diseases listed in Centers for Disease Control surveillance case definition for AIDS‡
Category C2	Other specified secondary infectious diseases
Subgroup D	Secondary cancers‡
Subgroup E	Other conditions

*Patients in groups II and III may be subclassified on the basis of a laboratory evaluation.

†There is no hierarchy of severity among group IV, subgroups A through E.

‡Includes those patients whose clinical presentation fulfills the definition of AIDS used by the Centers for Disease Control for national reporting.

Results

Impact of HIV infection on maternal outcome. When the Centers for Disease Control classification system (Table II) was applied to the 103 patients at the index delivery, 82 (79.6%) were asymptomatic (group II), 13 (12.6%) had lymphadenopathy syndrome (group III), six (5.8%) had AIDS (group IV, C1), and two (1.9%) had oral candidiasis fulfilling the criteria for other specified secondary infectious diseases (group IV, C2).

Over the long term, of the 82 asymptomatic patients, only 32 (31.1%) did not have progression of HIV during the study. In 22 (21.4%) patients, lymphadenopathy syndrome developed. Of the remaining 28 (26.2%) patients, one died of an unrelated HIV-AIDS cause, AIDS developed in 15, and 12 had progression to constitutional disease (n = 3), other specified secondary infectious diseases (n = 4), and simultaneous constitutional disease and other specified secondary infectious diseases (n = 5).

Regarding the 30 patients with AIDS, six (5.8%) had AIDS at the index delivery and AIDS developed in 24 (23.3%). The most common AIDS diagnosis was *Pneumocystis carinii* pneumonia (11, 36.7%) followed by *Candida* esophagitis and toxoplasmosis (four each) and HIV encephalopathy (three cases). Additional AIDS diag-

*Other includes six asymptomatic patients, five of whom had simultaneous development of constitutional disease and other specified secondary infectious diseases and one who died of an unrelated HIV-AIDS cause, and one patient who had progression from lymphadenopathy syndrome to AIDS with a mixed infection.

Table III. Cox's proportional-hazards analysis of time until progression to AIDS after index delivery*

Variable	*Hazard ratio*	*95% Confidence interval*	*p Value*
Centers for Disease Control group	4.73	1.79-12.54	0.002
Herpes genitalis	8.05	2.18-29.68	0.002
Age	0.90	0.32-2.51	0.837
Race-ethnicity	1.40	0.59-3.30	0.448
Gravidity	0.57	0.17-1.93	0.362

*All variables were dichotomized: Centers for Disease Control group of HIV infection (II vs III), age (≤30 vs >30 years), race-ethnicity (Haitian vs non-Haitian), and gravidity (0 vs ≥1).

Table IV. Cox's proportional-hazards analysis of survival after index delivery*

Variable	*Hazard ratio*	*95% Confidence interval*	*p Value*
Model I			
Group III	6.08	2.00-18.53	0.00
Group IV	9.68	2.50-38.07	0.00
Age	2.05	0.77-5.49	0.15
Race-ethnicity	1.06	0.40-2.77	0.91
Gravidity	0.40	0.11-1.42	0.16
Zidovudine	0.47	0.09-2.51	0.38
Model II			
AIDS	211.59	48.89-955.50	0.00
Age	2.03	0.71-5.86	0.19
Race-ethnicity	0.88	0.50-2.69	0.83
Gravidity	0.84	0.17-4.07	0.83
Zidovudine	0.14	0.02-1.09	0.06

*Centers for Disease Control groups were coded as three categories (group II was the reference); AIDS was coded as yes or no; age was coded as ≤30 or >30 years; race-ethnicity was coded as Haitian or non-Haitian; gravidity was coded as 0 or ≥1; and zidovudine was coded as used or not used.

noses included one case each of Kaposi's sarcoma, cryptococcosis, cryptosporidiosis, and a mixed infection (*Pneumocystis carinii* pneumonia and toxoplasmosis) and four cases of AIDS, not classified. Twenty-two patients have died, two shortly after the index delivery (i.e., 1 and 5 days), accounting for the wide range of follow-up.

There were no statistically significant differences between the Haitian and African-American subpopulations regarding age, gravidity, known HIV infection status of the index neonate, number of subsequent pregnancies, zidovudine therapy, Centers for Disease Control group status, a diagnosis of AIDS, and death.

Zidovudine therapy was evaluated relative to Centers for Disease Control group status, race-ethnicity (Haitian and non-Haitian), age, and the development of AIDS. No statistically significant differences were noted between recipients and nonrecipients of zidovudine. Patients in whom AIDS did and did not develop were equally likely to have been treated with zidovudine.

Among the 24 with development of AIDS, 17 of 18 (94.4%) evaluable patients had CD4-lymphocyte counts <200/mm³ at the time AIDS was diagnosed. Lymphocyte counts were not a significant predictor of survival.

Progression to AIDS. The Kaplan-Meier estimates of the cumulative probabilities of remaining AIDS-free for patients who were asymptomatic or had lymphadenopathy syndrome on entry into the study are shown in Fig. 1. The cumulative probability of remaining AIDS-free decreased over time in asymptomatic patients from 97.4% ± 1.8% (mean ± SE) at the end of 1 year to 78.8% ± 5.7% 3 years later. For those with lymphadenopathy syndrome, the cumulative probability of remaining AIDS-free was lower at the end of the first year (76.0% ± 12.1%), further declining to 26.6% ± 15.6% 3 years later. The cumulative probability of remaining AIDS-free for asymptomatic patients was statistically significantly greater than for patients with lymphadenopathy syndrome ($p < 0.001$).

The temporal relationship of Centers for Disease Control group status at the index delivery and progression to AIDS was examined with Cox's proportional-hazards model. Patients having lymphadenopa-

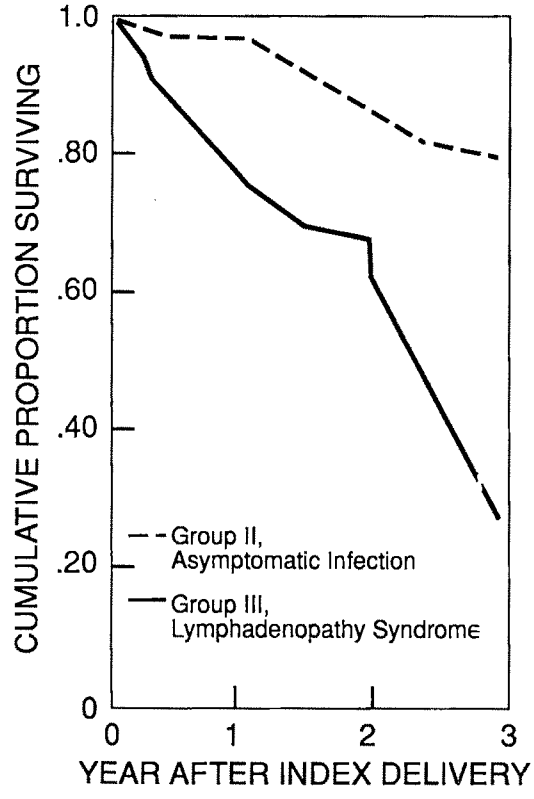

Fig. 1. Three-year cumulative probability of remaining AIDS-free in patients who were asymptomatic (group II) and who had lymphadenopathy syndrome (group III) at index delivery.

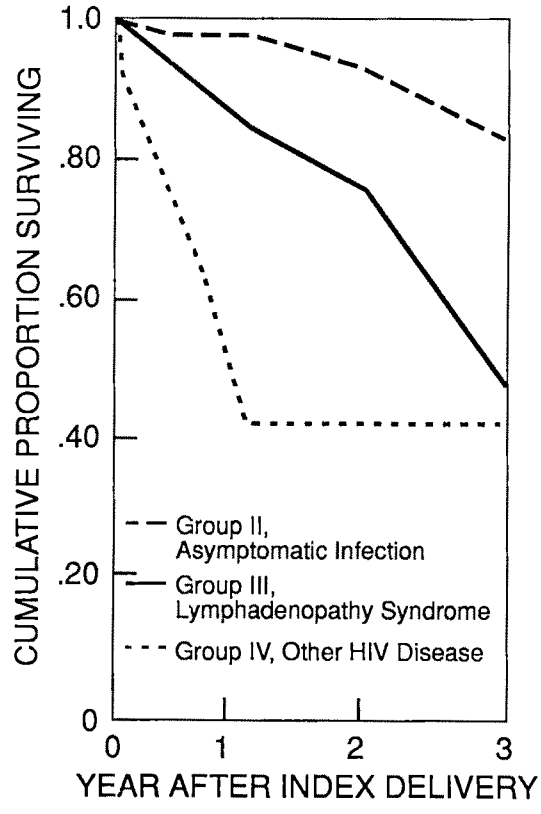

Fig. 2. Three-year cumulative probability of survival in patients who were asymptomatic (group II), had lymphadenopathy syndrome (group III), and had other HIV disease (group IV) at index delivery.

thy syndrome at the index delivery or herpes genitalis during pregnancy were about five and eight times, respectively, more likely to develop AIDS, controlling for age, race-ethnicity, and gravidity (Table III).

Survival of patients. Survival was also examined with Kaplan-Meier analysis. The cumulative probability of survival (mean ± SE) 1 year after the index delivery in asymptomatic patients was 97.4% ± 1.8%, decreasing over time to 83.6% ± 5.2% 3 years later (Fig. 2). For those with lymphadenopathy syndrome, survival was lower at the end of the first year (84.0% ± 10.4%), further declining to 47.5% ± 17.3% 3 years later. Survival in group IV patients was only 42.9% ± 18.7% 1 year after the index delivery. The cumulative probabilities of survival were statistically significantly different among all three groups ($p < 0.0001$). After seven patients who had incomplete follow-up were excluded, the median survival after an AIDS diagnosis was 189 days

The relationship of survival to Centers for Disease Control group status at the index delivery, as well as postpartum zidovudine therapy, was explored with Cox's proportional-hazards model (Table IV, model I). Zidovudine was given to patients at different times when deemed clinically appropriate; therefore this variable was treated as a time-dependent covariate in Cox's model. Group III and IV patients were approximately 6 and 10 times, respectively, more likely to die of AIDS as compared with group II patients, with age, race-ethnicity, gravidity, and postpartum zidovudine therapy controlled for.

The same model was used to explore the relationship of survival to the development of AIDS and postpartum zidovudine therapy with age, race-ethnicity, and gravidity controlled for (Table IV, model II). When these variables were treated as time-dependent covariates, development of AIDS was the most significant predictor of death. Postpartum zidovudine therapy was marginally significant, suggesting its effectiveness in prolonging survival.

Other covariates including genitourinary tract infections, sexually transmitted diseases (including herpes genitalis), known HIV infection status of the index neonate, the occurrence of a subsequent pregnancy, and history of drug use were not statistically significantly associated with survival.

Comment

The majority of HIV antibody–positive pregnant women who were either asymptomatic (group II) or

had lymphadenopathy syndrome (group III) at the index delivery were alive 3 years later. Lymphadenopathy syndrome was a significant prognostic factor for progression to AIDS in this study, in contrast to HIV-infected hemophiliacs[9] and homosexual men,[19] in whom no correlation was found between the presence of lymphadenopathy and progression to AIDS.

The most common AIDS diagnosis in these predominantly Haitian women was *Pneumocystis carinii* pneumonia (36.7%), in contrast to a predominantly non-Hispanic white female population, in whom *Candida* esophagitis was most common (38%).[20] In male HIV-infected patients, *Pneumocystis carinii* pneumonia is the most common AIDS-defining diagnosis.[21] It is possible these discrepant observations are the result of different sample sizes.

The most important laboratory marker for determining the risk of progression to AIDS is the CD4-lymphocyte count.[22, 23] Pregnancy may accelerate the HIV-induced depletion of CD4 lymphocytes and increase the risk of progression to AIDS.[24] Initially, counts were not regularly obtained on all study patients but were ordered on the basis of clinical suspicion that patients might require zidovudine and *Pneumocystis carinii* pneumonia prophylaxis. In 17 of 18 (94.4%) evaluable patients with AIDS, the counts were $<200/mm^3$. Insufficient serial counts were obtained to predict outcome or progression to AIDS, and therefore they were not a significant predictor of survival among the AIDS patients in our study.

There is a paucity of data regarding survival of women with AIDS. Several studies report a lower median survival of women (3.5 to 8.5 months) as compared with men (9.7 to 12.6 months), although the responsible factors are unknown.[3-5, 7] Carpenter et al.,[20] however, reported a longer median survival of 18.5 months in predominantly non-Hispanic white intravenous drug-abusing women, suggesting that ethnic background may be a surrogate marker for socioeconomic status and perhaps enhancing compliance with medical care and improving survival.

In our cohort the median survival after the index delivery was 6.7 months (201 days). As expected, the cumulative probabilities of survival over time decreased within and between all groups and were statistically significantly different. By use of time-dependent covariate methods, the development of AIDS and postpartum zidovudine therapy were predictors of survival.

This study has limitations. First, our cohort did not represent a random sample of all HIV-infected pregnant women. They were screened on the basis of criteria and were not selected from a voluntarily screened population of women. Second, the loss to follow-up was relatively high. It is possible that the patients experiencing progressively worsening HIV-related illnesses were more likely to have follow-up, whereas those remaining healthy were more likely to be lost to follow-up. Thus, we may have overestimated progression and underestimated survival. Consequently, our data should be interpreted with caution. Third, immunologic studies were not obtained from each participant at standardized intervals relative to the index delivery. CD4-lymphocyte counts were not obtained at entry point. Finally, within our clinic population the control group of nonpregnant HIV-infected women was not large enough for study of the impact of pregnancy on HIV infection. Nonpregnant gynecologic patients were not as likely to agree to HIV antibody testing in spite of admitted risk factors as were pregnant women. A prospective controlled cohort study to address this question is presently under way at this institution. In spite of these limitations, our preliminary data reflect current knowledge about survival and disease progression in HIV-infected women after an index pregnancy, including the identification of some prognostic factors. Knowing what these factors are is important, not only in the understanding of the natural history of HIV infection in women but also in the design and analysis of future studies.

In summary, both lymphadenopathy syndrome at the index delivery and herpes genitalis during pregnancy were significantly associated with a subsequent AIDS diagnosis. The most common opportunistic infection was *Pneumocystis carinii* pneumonia. Survival was affected by Centers for Disease Control group status of HIV infection at the index delivery. Our data support a lower median survival of women with AIDS as compared with men with AIDS. It is hoped that ongoing controlled cohort studies will confirm and refine these findings in other populations.

Enhanced follicle regulatory protein levels accompany reinitiation of ovulatory function after parturition

Barry D. Albertson, PhD,[a] Kathy E. Rodgers, PhD,[b] Thomas P. Tomai, MS,[a] Kathy Nolan-Watson, MD,[a] Michael J. Zinaman, MD,[a] and Gere S. DiZerega, MD[b]
Washington, D.C., and Los Angeles, California

OBJECTIVES: We examined the changes in follicle regulatory protein, estrone-3-glucuronide, pregnanediol-3-glucuronide, and luteinizing hormone levels in first-morning urine samples from postpartum, fully breast-feeding women to characterize the reemergence of these urinary hormones after pregnancy ovarian quiescence and early postpartum period and to determine whether follicle regulatory protein could be used prospectively to predict the return of fertility.
STUDY DESIGN: Twenty-five hundred urine samples collected from six postpartum women were evaluated. Daily urine samples collected from normally cycling women were used to establish normal urinary hormone and hormone metabolite cyclicity. Luteinizing hormone, estrone-3-glucuronide, and pregnanediol-3-glucuronide levels were measured by radioimmunoassay. Follicle regulatory protein level was assayed with a double-antibody enzyme-linked immunosorbent assay.
RESULTS: Although follicle regulatory protein levels were found to be very low or undetectable in early postpartum urine, they began to rise with episodes of estrone-3-glucuronide and pregnanediol-3-glucuronide secretion. A χ^2 analysis suggests that increasing urinary follicle regulatory protein levels are most closely associated with the luteal phase of the first menstrual cycles in postpartum women.
CONCLUSIONS: These results suggest that follicle regulatory protein is of little value in predicting either the onset of renewed ovarian activity or the fertile period. (Am J Obstet Gynecol 1992;167:158-62.)

Key words: Follicle regulatory protein, estrone-3-glucuronide, pregnanediol-3-glucuronide, ovulatory function, luteinizing hormone

Although increasing serum levels of estradiol and progesterone are hallmarks of the resumption of cyclic ovarian function after parturition, little is known about ovarian protein secretion during and after the human puerperium. Several ovarian proteins have recently been described and are suspected to be involved in a variety of intraovarian regulations, including follicle development, emergence of the dominant follicle, regulation of the corpus luteum, follicular and corpora luteal gonadotropin interactions, and steroidogenesis.[1] Among these are inhibin, activin, folliculostatin, oxytocin, gonadotropin-releasing hormone–like peptide, and substance P.

A new peptide now included in this group, follicle regulatory protein, has been identified in sheep, cow, swine, horse, and human follicular fluid with the inhibition of granulosa aromatase activity as the identifying bioassay.[2-5] The active components of these intraspecies follicular fluid follicle regulatory proteins have similar molecular weights (15,000 d) and isoelectric points (pH 7.4).[6] Follicle regulatory protein has been shown to demonstrate biochemical and biologic properties different from those of growth factors known to influence steroidogenesis, for example insulin-like growth factor-1, insulin-like growth factor-2, epidermal growth factor, transforming growth factor–α, and transforming growth factor–β.[7-9] Follicle regulatory protein is not toxic to granulosa cells in vitro, and its effect on granulosa steroidogenesis is reversible.[10, 11] Follicle regulatory protein has biologic properties different from inhibin or folliculostatin because it does not inhibit the release of follicle-stimulating hormone from rat pituicytes in vitro or in vivo.[12-14]

Levels of follicle regulatory protein were determined from the urine of regularly menstruating women. The nadir of follicle regulatory protein levels occurred during the early and midfollicular phase of the cycle, a time characterized by the largest number of nonatretic follicles. Levels of follicle regulatory protein were

found to rise beginning in the late follicular phase and reached their zenith by the midluteal phase.[15]

However, little is known about the emergence of follicle regulatory protein production by the ovary after the ovary has been quiescent. In our study immunoreactive urinary follicle regulatory protein, estrone-3-glucuronide (EG), pregnanediol-3-glucuronide (PDG), and luteinizing hormone (LH) were measured in consecutive daily urine samples collected from postpartum women throughout the puerperium and the first few ovulatory menstrual cycles to determine when follicle regulatory protein levels begin to rise after parturition. Specifically the investigations were designed to determine whether alterations in urinary follicle regulatory protein levels correspond with the return of follicular maturation and the emergence of the dominant follicle in breast-feeding women after parturition and whether changes in urinary follicle regulatory protein levels during the luteal phase correlated with the typical patterns of urinary steroid excretion.

Material and methods

Patient selection. Daily urine specimens were collected beginning at parturition and continuing for between 170 and 400 days from six women who had previously breast-fed. The women were between the ages of 25 and 30 years, and had been delivered of normal, healthy babies (Apgar scores at 5 minutes >8) at gestational ages between 39 and 42 weeks. First-morning urine samples were collected daily from the parturition through the months of full breast-feeding (i.e., feeding on demand with no other food supplement) until three or four ovulatory menstrual cycles were achieved as documented by regular menses, normal elevations in urinary EG, PDG, and midcycle urinary LH surges.

Hormone assays. Aliquots of 10 ml of the first-morning urine sample were collected and stored at −20° C until urinary creatinine or hormone assays were performed. EG and PDG levels were measured on all samples by direct radioimmunoassay (RIA) by previously published methods.[16-20] Urinary LH level was measured with a double-antibody RIA with reagents (Diagnostic Products Corporation, Los Angeles). Urinary hormones (EG and PDG) were normalized to urinary creatinine levels; creatinine was evaluated spectrophotometrically by the method of Taussky.[21] Follicle regulatory protein was measured by enzyme-linked immunosorbent assay[15] (ELISA) with a dual-epitope approach. Both polyclonal and monoclonal antibodies were raised against follicle regulatory protein with sufficient specificity to allow validation of the ELISA with the sensitivity necessary to quantitate levels of follicle regulatory protein in complex biologic fluids, including urine.[15] A competitive immunoassay was subsequently developed with a murine monoclonal antibody to measure immunoreactive follicle regulatory protein in human urine. Antibodies used in the follicle regulatory protein ELISA do not cross react with transforming growth factor-β, insulin-like growth factors, fibroblast growth factor, LH, follicle-stimulating hormone, prolactin, human chorionic gonadotropin, inhibin, insulin, or transferrin (Table I).[15]

Table I. Cross-reactivity of follicle regulatory protein ELISA with growth factors and reproductive hormones

Sample	*Optical density*
Buffer	0.032

Bovine inhibin	0.035

All proteins tested were used at a concentration of 100 ng/ml. Antibody pair used in this validation assay were $7H12F_3H_2$/(2 μg/ml) as the capture antibody, and biotinylated 9D1E1G11/(15 ng/ml) as the detector antibody. *FRP*, Follicle regulatory protein; *TGF*, transforming growth factor; *IGF*, insulin-like growth factor; *FGF*, fibroblast growth factor; *EGF*, epidermal growth factor; *FSH*, follicle stimulating hormone; *hCG*, human chorionic gonadotropin.

Urine from postmenopausal women and women during days 2 through 5 of the menstrual cycle had nondetectable levels of follicle regulatory protein (optical density <0.07). The immunoreactivity of follicle regulatory protein–spiked urine was 100% recoverable and diluted linearly.

Urinary hormone levels in normally cycling women. Urinary levels of EG, PDG, LH, and follicle regulatory protein in normally cycling women are shown in Fig. 1. Hormone levels used as cutoff points for the postpartum women were derived from these data, and were EG > 40 ng/ml urine/mg creatinine; PDG > 1 μg/ml urine per milligram of creatinine; and FRP > 0.07 optical density units. Urinary LH peaks were determined to be ovulatory if peak levels were fivefold the previous baseline measured during the early follicular phase. Moreover, PDG levels after the LH surge were required to be at least 1 μg/ml urine/mg creatinine during the luteal phase for 10 to 12 days to further qualify that cycle to be considered ovulatory.

Data analysis. Urinary steroid metabolites and LH

levels are expressed as the ratio of the hormones to follicle regulatory protein (EG/follicle regulatory protein, PDG/follicle regulatory protein, and LH/follicle regulatory protein), and analyzed statistically with a 2×2 χ^2 analysis.

Results

The initial distribution of hormone levels by (1) EG, (2) PDG, and (3) follicle regulatory protein levels are shown in Fig. 2. Five hundred thirty-six urine samples from 26 cycles were found to have EG levels >40 ng/ml/mg creatinine and 931 <40 ng/ml/mg creatinine. When individual urine EG levels were >40 ng/ml/mg creatinine, corresponding PDG levels were

FRP, Follicle regulatory protein.

equally distributed as <1 μg/ml/mg creatinine (n = 288) or >1 μg/ml/mg creatinine (n = 248). Follicle regulatory protein values are reported as negative or positive on the basis of previous menstrual cycle data[15] and were found to be negative in most of the urine samples measured regardless of the EG or PDG levels found in the urine. However, the ratio of positive to negative follicle regulatory protein in different groups (Table II) suggests that there is a statistically significant ($p < 0.01$) fourfold to fivefold increased chance of finding elevated follicle regulatory protein levels in urine samples that have elevated PDG (>1 μg/ml/mg creatinine) than for low PDG.

Individual subject distribution for this finding is shown in Table III in urine samples collected after the reinitiation of folliculogenesis, defined as EG levels being >40 ng/ml. Two of the six subjects had elevated follicle regulatory protein levels in the majority of urine samples with high PDG and high EG; four of the six did not. Positive follicle regulatory protein to negative

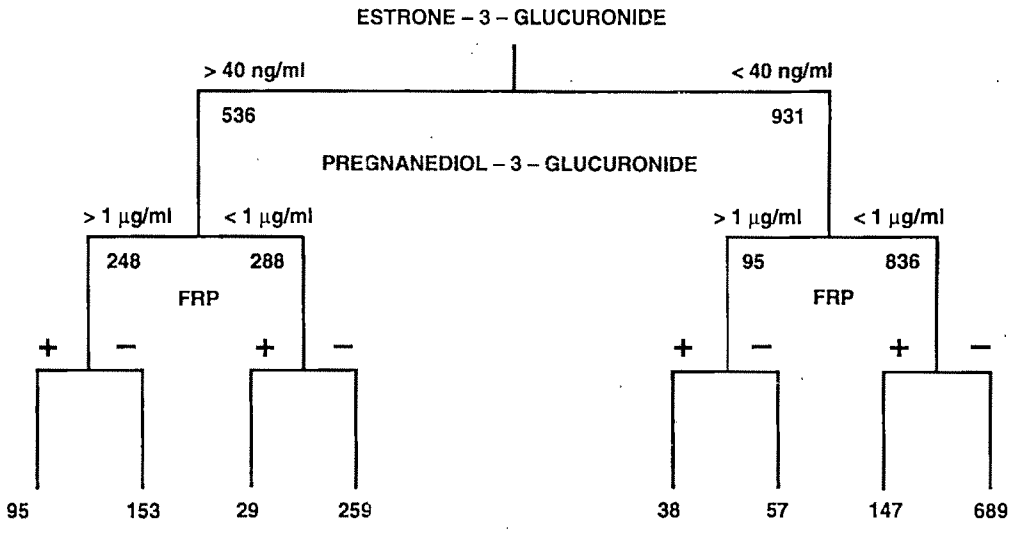

Fig. 2. Distribution of postpartum urine specimens by initial EG, PDG, and *FRP* levels (n = 1467). *FRP*, Follicle regulatory protein.

follicle regulatory protein values were approximately six times higher when PDG levels were elevated (95/153) than when PDG levels were low (29/259).

When the luteal phase was divided into segments comprising the first half (days 14 through 21), middle third (days 18 through 25), and last half (days 21 through 28) in those cycles that had clear LH surges, follicle regulatory protein levels mimicked or paralleled PDG levels in terms of rising and falling concentrations and seemed to be highest in the second half of the cycle in all six subjects (Table IV).

Comment

Although follicle regulatory protein has been shown to be a product of the granulosa cell, the physiologic role of this 15,000-molecular-weight peptide has yet to be elucidated. Investigators have speculated that follicle regulatory protein may be involved in the regulation of folliculogenesis, either in the selection of the dominant follicle or possibly retaining smaller follicles in the cohort ready for future ovulation. Because follicle regulatory protein possesses aromatase inhibiting activity, its role in regulating steroid hormone production or steroidogenesis during either the follicular or luteal phase of the menstrual cycle has been suggested.[1, 3-5, 9, 11]

From the data presented here it appears that urinary follicle regulatory protein levels do not predict either imminent fertile cycles or ovulation, per say, in postpartum women returning to full ovarian activity during breast feeding. It does appear that follicle regulatory protein is a marker of the luteal phase and may have a role in corpora luteal function. The close association of elevated follicle regulatory protein levels and high PDG concentrations in the urine may be related in a cause-effect manner, however, verification of this relationship will require further investigation.

The changing pattern of inhibin levels in the normal menstrual cycle have been shown to be quite similar to that of follicle regulatory protein,[12-14] suggesting that these intraovarian peptides may also be regulated in a similar fashion. Other ovarian peptides such as follistatin have been shown to fluctuate during the menstural cycle in ways not dissimilar to follicle regulatory protein and may themselves participate in the regulation of ovarian function. Whether these peptides affect any of the multitude of events that define endocrine physiologic characteristics in the follicular phase of the men-

strual cycle will be shown only by further investigations and improved quantitative assays for these hormones.

Postpartum women offered a unique biologic model for investigating ovarian physiologic characteristics and regulation in that ovarian function has essentially been turned off for a period of many months during gestation and breast-feeding. Ovarian function reemergence as an endocrine organ (either of primary or secondary function) after this quiescent period can provide important insight into the regulation of ovarian hormone production. Our studies suggest that the ovaries of postpartum women produce increasing amounts of follicle regulatory protein in a fashion not unlike other ovarian hormones, particularly steroids and most probably other ovarian peptides. These data further support the contention that follicle regulatory protein is a marker of the corpus luteum rather than of the emerging dominant follicle and may have a primary role in the regulation of corpus luteum formation and function. Whether urinary levels of follicle regulatory protein may be used to predict the return of reproductive function in postpartum, breast-feeding women remains to be shown, although from these studies these levels appear to have a very limited usefulness in this regard. Our data suggest that follicle regulatory protein appears to be temporally associated with the luteal phase of the menstrual cycle in postpartum, breast-feeding women and may be an important marker of luteal phase dysfunctions and pathologic conditions. However, urinary follicle regulatory protein levels often become measurable during the midfollicular phase in women; this measurability should stimulate investigators to look more closely at this intraovarian regulator and its role in folliculogenesis.

We thank Ms. Vicky Tyson for her customary excellence in performing the steroid metabolite RIAs.

Immunolocalization of the vasoconstrictor endothelin in human endometrium during the menstrual cycle and in umbilical cord at birth

Lois A. Salamonsen, PhD,[a] Anna R. Butt,[a] Anne M. Macpherson, BSc(Hons.),[b] Peter A.W. Rogers, PhD,[b] and Jock K. Findlay, PhD[a]

Clayton, and Victoria, Australia

OBJECTIVE: Our objective was to determine the localization of immunoreactive endothelin in human cyclic endometrium and in umbilical cord during normal delivery and after cesarean section.

STUDY DESIGN: Fixed dated endometrial tissue (n = 41) and umbilical cord (n = 6) were subjected to immunohistochemistry with an antiserum cross reacting with endothelin-1, -2 and -3.

RESULTS: Low levels of stromal endometrial staining were seen throughout the cycle. The strongest staining was in luminal epithelium throughout the secretory phase and in glandular epithelium in the late-secretory phase. In umbilical cord the most intense immunoreactivity was present on the amnion cells on the outer cord, with some staining in intermittent cells in the Wharton's jelly and in umbilical vein cells. No differences were detected between cord from normal delivery or cesarean section.

CONCLUSION: A paracrine role is suggested for endothelin in regulation of endometrial function and a role in vasoconstriction in the umbilical cord at birth. (Am J Obstet Gynecol 1992;167:163-7.)

Key words: Endothelin, endometrium, menstrual cycle, umbilical cord, cesarean section

It is well established that the endometrium is a target tissue for the actions of ovarian estradiol and progesterone, which are responsible for its growth and differentiation in preparation for implantation. More recent is the concept of paracrine and autocrine regulation of endometrial function, and a number of factors acting locally within the endometrium have now been described.[1, 2] It has been postulated that the recently discovered peptide endothelin may also be a paracrine factor in the endometrium.[3] Endothelin was originally identified as a product of endothelial cells, which had a paracrine action on vascular smooth muscle,[4] but it is now also known to be a product of certain types of epithelial cells. Immunoreactive endothelin has been described in epithelial cells of the kidney,[5] rat and mouse trachea,[6, 7] and human lung [8] and in rabbit endometrium.[9] In addition, avascular human amnion cells express endothelin messenger ribonucleic acid.[10]

In the endometrium of immature rabbits, endothelin immunoreactivity is present in the epithelial cells, but is limited to endometrial stromal cells after treatment with sex steroids.[9] Moreover, specific binding sites for endothelin have been demonstrated on both luminal and glandular epithelium of human endometrium.[11]

Umbilical cord is also a potential site of endothelin production. Concentrations of immunoreactive endothelin are increased in umbilical artery and vein and in amniotic fluid at term.[12, 13] The endothelial lining of umbilical veins stains positively with an antibody to endothelin,[14] and these cells release endothelin in culture.[15] Moreover, endothelin is a potent constrictor of umbilical vessels in vitro.[14] What has not been shown is whether the umbilical vein is the only source of endothelin in the cord and whether there are differences between cord at normal delivery and at cesarean section.

This study was therefore designed to determine by immunohistochemistry the localization of endothelin in human endometrium throughout the menstrual cycle of apparently normal women. In addition, the sites of immunoreactive endothelin in umbilical cord samples taken at normal delivery and at cesarean section were defined.

Material and methods

Endometrial tissue was obtained at curettage from 41 women (ages 22 to 43 years) undergoing examination for infertility and with no apparent endometrial dysfunction, who gave their informed consent for collection of the tissue. All tissue collections were approved by the Human Ethics Committee at the Epworth Hos-

From Prince Henry's Institute of Medical Research,[a] and the Department of Obstetrics and Gynaecology, Monash University.[b]
Supported by the National Health and Medical Research Council of Australia and by the World Health Organization Special Programme of Research, Development and Research Training in Human Reproduction.
Received for publication August 28, 1991; accepted December 30, 1991.

	Menstrual (n = 1)	*Proliferative (n = 9)*	*Early secretory (n = 9)*	*Midsecretory (n = 16)*	*Late secretory (n = 6)*
Glandular epithelium	1	0	1	1	2
Luminal epithelium	NA	0-1	2	2	2
Stroma	1	1	1	1	1

NA, Not available. Intensity of staining in each compartment was scored as negative *(0)*, low *(1)*, moderate *(2)*, or intense *(3)*, related to a positive control sample repeated in all runs. One section from each sample was scored after comparison with its own negative control. Within each group, mean intensity was quantitated by adding the scores and dividing by the number of sections.

pital. A small piece of tissue was taken for routine pathologic studies and endometrial dating, and the rest was immersed in phosphate-buffered formalin (pH 7.4) for 16 to 18 hours before washing in phosphate-buffered saline solution and embedding in wax. Tissues were allocated to four treatment groups: proliferative ($n = 9$), early secretory ($n = 9$), midsecretory ($n = 16$), and late secretory ($n = 6$). In addition, one menstrual stage sample was obtained. Some tissues were divided in two, one half being fixed immediately and the other incubated for 16 hours at 37° C in medium 199 (Flow Laboratories, North Ryde, Australia) containing 5 μmol/L monensin (Sigma Chemical Co., St Louis) before fixation.

Umbilical cord was obtained either at normal, term vaginal delivery ($n = 3$) or at cesarean section ($n = 3$) and fixed similarly.

A polyclonal antiserum against endothelin was obtained from Cambridge Research Biochemicals (Northwich, England) and used at a dilution of 1:2000. This antiserum was developed against endothelin-1 but cross reacts with both endothelin-2 and endothelin-3. Anti-

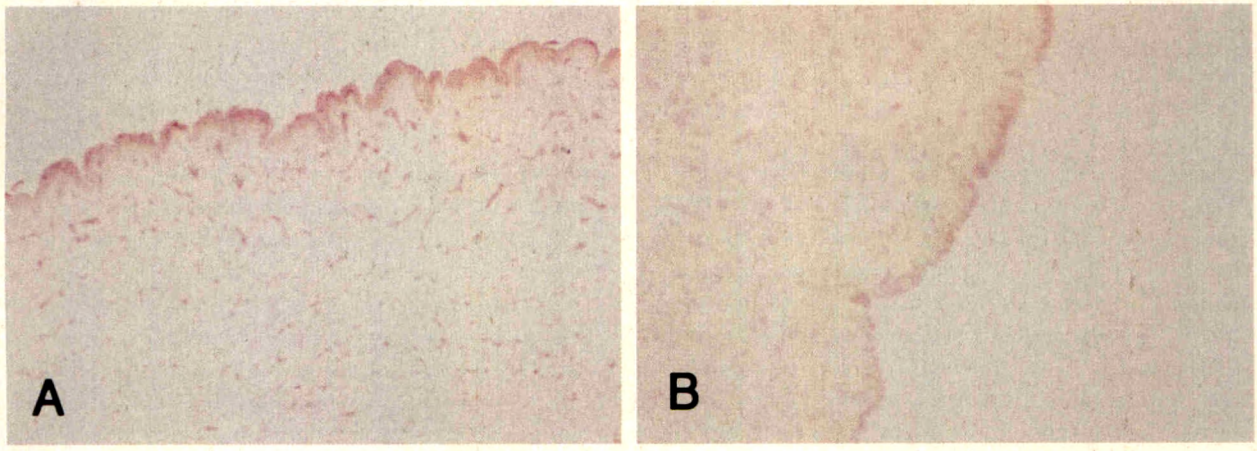

Fig. 2. Immunostaining of endothelin in umbilical cord. **A,** Outer surface of cord showing positive immunostaining for endothelin in amnion cells and in intermittent cells in Wharton's jelly. **B,** Positive staining for endothelin in endothelial cells in umbilical vein. (Original magnification × 10.)

serum against leukocyte common antigen was purchased from Dakopatts A/S, Glostrup, Denmark, and used at a final dilution of 1:100.

Samples were randomized for processing in batches with a section from a standard secretory phase endometrial sample being included with each batch as a positive control and for confirmation of reproducibility between batches. Three separate sections from each sample were processed, one with primary antiserum, one with normal rabbit serum (at the same dilution as the primary antiserum) and one separately stained with hematoxylin and eosin to establish morphologic features. Some additional samples were treated with antiserum that had been preincubated with an excess of endothelin-1 (Peninsula Laboratories, Belmont, Calif.). Immunohistochemical examination used the Strep-AviGen supersensitive kit (Bio Genex Laboratories, San Ramon, Calif.) with the supersensitive alkaline phosphatase system with fast red chromagen substrate and 0.65 mg/ml levamisole (Sigma). Reaction with primary antiserum or normal rabbit serum was for 30 minutes at 22° C. Stained sections were mounted in aqueous mountant and examined under an Olympus (Tokyo) BH2 microscope by two observers. Intensity of positive staining was given a score of 0 (negative), 1 (low), 2 (moderate), or 3 (strongly positive) for each cell type within each section. In a small number of sections (8%) luminal epithelium was not available for scoring. Mean scores within a treatment group were obtained by adding individual scores and dividing by the number of sections.

Results

Endometrial samples. Positive immunostaining for endothelin was observed in all endometrial tissues and is summarized in Table I. Low levels of immunoreactivity were observed in endometrial stroma in all tissues; this did not vary with the stage of the menstrual cycle, although there was considerable variation between individuals. The strongest staining was seen in luminal epithelium throughout the secretory phase but little staining was seen in this compartment during the proliferative phase. No immunoreactive endothelin was detected in glandular epithelium in the proliferative phase, but it was present throughout the secretory phase with the greatest intensity of staining occurring late in the cycle (Fig. 1, *A*). Staining was absent in sections treated with normal rabbit serum in place of antiserum or when antiserum was preadsorbed with endothelin-1. After treatment with monensin, there was a marked accumulation of immunoreactive endothelin in some of the cells, particularly in endothelial cells (Fig. 1, *B*) and in the glandular epithelium in secretory phase samples (Fig. 1, *C*). In the control secretory phase tissue processed in every batch, staining was very consistent throughout the period of the study. Regional differences within any individual tissues were small and less than differences between tissues within a group.

Umbilical cord. In sections from all subjects the most intense immunostaining for endothelin was apparent in the amnion cells on the outer surface of the cord (Fig. 2, *A*). This was consistent in all samples examined. In addition, there was staining of intermittent cells in the Wharton's jelly below the amnion (Fig. 2, *A*). These cells have not been positively identified, but it is unlikely that they are cells of hemopoietic origin, because they did not stain positively with antiserum to leukocyte common antigen. In addition, endothelial cells lining the umbilical vein stained positively for endothelin in five of six samples (Fig. 2, *B*), and in one sample some staining was apparent in cells lining the umbilical artery. No differences were observed between samples of cord obtained at normal delivery or at cesarean section.

Comment

The presence of immunoreactive endothelin has been demonstrated in both stromal and epithelial cells of the human endometrium. The cyclic nature of its localization in both luminal and glandular epithelium suggests differential regulation, possibly by ovarian steroids, in these cells but not in the stromal cells. These studies confirm and extend the preliminary findings of van Papendorp et al.,[16] who described immunoreactive endothelin localized to endometrial glands and most intense at the endometrial-myometrial junction. In their study all gland cells were said to be stained in secretory tissue, but there was a more heterogeneous picture in the proliferative phase. However, they did not describe staining in the endometrial stroma, this being a consistent finding in the large number of tissues in our study. Differences between the studies may be explained by the much longer delay between tissue collection and fixation for hysterectomy samples and those collected by curettage. In a detailed study with rabbit uterus, Maggi et al.[9] showed intense immunoreactivity for endothelin in the endometrial epithelium of immature rabbits. After treatment with 17β-estradiol, either with or without progesterone, endothelin was detected only in the uterine stroma. This contrasts with the situation described here in human endometrium, which suggests that progesterone administration after estrogen priming is necessary for the expression of endothelin in the epithelial cells.

To our knowledge the only other reported immunolocalization of endothelin in the umbilical cord is that of Haegerstraand et al.,[14] who demonstrated positive staining in the endothelial lining of umbilical veins. As in the current study staining was weak in umbilical arteries. However, they did not examine other parts of the cord, although they suggested that other origins of umbilical blood endothelin should be considered. Given the relative intensities of immunoreactive endothelin in amnion cells and in endothelial cells, we would suggest the former as a major source of endothelin in the cord. The nature of the other cells in the Wharton's jelly that contain immunoreactive endothelin remains unknown. We originally postulated that they may be macrophages because messenger ribonucleic acid for endothelin-1 has been demonstrated in macrophages.[17] However, these cells did not show positive immunostaining with the antibody to leukocyte common antigen. Wharton's jelly, a mucomyxoid tissue rich in mucopolysaccharides in which are embedded collagen fibers, mast cells, and large flat stellate cells, has as its known function mechanical protection of the umbilical vessels from trauma. However, the tissue is metabolically very active and may well have other important functions.

No differences in immunoreactive endothelin were demonstrated between cord obtained at normal delivery or at cesarean section; this is consistent with data that neonates delivered by elective cesarean section had similar endothelin levels in blood and amniotic fluid as that measured after normal delivery.[13] A possible function for endothelin at birth may be a contribution to the fetal hemodynamic changes. Indeed, human umbilical vein smooth muscle cells possess specific binding sites for endothelin,[18] and endothelin is a potent constrictor of umbilical vessels in vitro.[14]

The finding of endothelin-like immunoreactivity in cells does not necessarily imply synthesis of the peptide. Alternative explanations are uptake by the epithelial cells or cross-reactivity of antibodies with similar epitopes in other as yet undefined molecules. In cultured endothelial cells endothelin, like many other peptide hormones, is specifically localized in the rough endoplasmic reticulum, Golgi cisternae, and Golgi vesicles.[19] Therefore it was expected that if processing is by the same route in the endometrium, incubation of endometrial tissue with the ionophore monensin (which blocks intracellular transport of protein at the level of the Golgi apparatus[20]) would cause accumulation of endothelin in the cells in which it is synthesized. Demonstration of such accumulation in epithelial cells supports the supposition that endothelin is indeed synthesized in these cells. Production of endothelin by endometrial cells has recently been measured (Salamonsen LA. Unpublished observations) but the presence of specific messenger ribonucleic acid in endometrial tissue remains to be demonstrated.

Other questions of fundamental importance also remain to be answered. It has not yet been demonstrated whether there is any structural or functional difference between endothelin of epithelial compared with that of endothelial cell origin. If endothelin is produced by endometrial cells, does it act locally and on which cells? Biologically active receptors for endothelin are present on rabbit myometrium, these being increased by estrogen and decreased by progesterone,[9] but endometrial binding was not examined. In the human endothelin promotes contraction frequency in myometrium[21] and in the endometrium specific binding sites are present on glandular epithelium and on vascular endothelium at the endometrial-myometrial junction.[11] It has recently been reported[22] that endothelin increased prostaglandin release from explants of human endometrium, although this action requires confirmation. Thus the possibility exists for paracrine activity of endothelin in the uterus. A number of actions have now been described for endothelin in addition to its originally described function of vasoconstriction. These include mitogenic actions on smooth muscle,[23] bronchoconstriction,[24] and modulation of autonomic transmission.[25] Possible uterine functions include regulation of endometrial bleeding, vasoactivity associated with implan-

tation, mitogenesis, or regulation of secretion of other biologically active molecules.

In conclusion, immunoreactive endothelin has been localized in both human endometrium and umbilical cord. Accumulation of immunoreactivity after incubation of endometrial tissue with monensin suggests local synthesis of the peptide. An understanding of the means by which endothelin synthesis is regulated and of its local functions awaits further studies.

We thank Dr. Gabor Kovacs and the staff of the operating theater of the Infertility Service at Epworth Hospital for supplying the tissue and Dr. Andrew Ostor for dating the endometrial samples.

Reduced platelet tritium-labeled imipramine binding sites in women with premenstrual syndrome

John F. Steege, MD,[a] Anna L. Stout, PhD,[a, b, c] David L. Knight, BS,[c] and Charles B. Nemeroff, MD, PhD[c, d]

Durham, North Carolina

OBJECTIVE: We studied the possible role of serotonergic systems in the cause of premenstrual affective symptoms.

STUDY DESIGN: The binding of tritium-labeled imipramine to platelets is thought to parallel central nervous system binding and to indicate serotonergic activity. We measured platelet tritium-labeled imipramine binding sites in the follicular and luteal phases in 12 controls and in 9 women with well-documented late luteal phase dysphoric disorder. In statistical analyses we used repeated measures analysis of variance, with Student–Newman-Keuls and Duncan's one-tailed *t* tests, and Pearson's *r*.

RESULTS: The values of subjects with late luteal phase dysphoric disorder were lower than those of controls (F [1,39] = 5.13, $p = 0.03$). Both follicular and luteal phase levels were lower in subjects with late luteal phase dysphoric disorder but reached statistical significance only in the follicular phase.

CONCLUSION: Lower platelet tritium-labeled imipramine binding in women with late luteal phase dysphoric disorder supports the hypothesis that alteration of central serotonergic systems may contribute to premenstrual dysphoric symptoms. (Am J Obstet Gynecol 1992;167:168-72.)

Key words: Late luteal phase dysphoric disorder, premenstrual syndrome, depression, tritium-labeled imiprimine binding

The premenstrual occurrence of a variety of physical and emotional symptoms has been termed premenstrual syndrome (PMS) or, when affective symptoms are emphasized, late luteal phase dysphoric disorder.[1] Although epidemiologic and clinical evidence demonstrate significant psychiatric comorbidity in PMS and late luteal phase dysphoric disorder,[2] studies of putative biochemical markers of depression such as the dexamethasone suppression test[3] and the thyrotropin-releasing hormone stimulation test[4] have not revealed consistent deviations from normal values in women with PMS.

Platelet tritium-labeled imiprimine binding sites, which are believed to represent receptor sites that label the presynaptic serotonin transporter on the presynaptic nerve terminal, are lower in number in drug-free depressed patients during acute depressive episodes than they are in controls.[5] There is some evidence that the number of these sites returns to normal several months after clinical remission of depression, response to psychotropic medication,[6] or electroconvulsive therapy.[7] This platelet binding site has, therefore, been described as a state marker.[8] Because the affective state changes in a predictable fashion in late luteal phase dysphoric disorder, this disorder provides a model for the investigation of platelet [^{3}H]imipramine binding sites and their association with depression.

This study investigated the number and affinity of platelet [^{3}H]imipramine binding sites across the menstrual cycle in women without clinical affective disorder who fulfilled criteria for late luteal phase dysphoric disorder.

Material and methods

Twenty-three women aged 24 to 42 (mean 32.2 ± 6.0 SD) were recruited by advertisement and word of mouth to participate in a study of cardiovascular and neuroendocrine reactivity across the menstrual cycle. Subjects with late luteal phase dysphoric disorder and controls were of equivalent parity (mean ± SD 0.63 ± 0.98 for all subjects, range 0 to 2), and all were within ± 15% of ideal body weight. Women with late luteal phase dysphoric disorder reported symptoms for 3 to 11 years (mean ± SD 5.7 ± 2.8) and participated in the study primarily to obtain free evaluation for their premenstrual symptoms. Subjects gave informed consent under a protocol approved by the

institutional review board and were paid for their participation.

All subjects completed the Premenstrual Assessment Form[9] as a screening instrument and then completed prospective symptom charting over two consecutive menstrual cycles. Twelve women were designated asymptomatic controls, and nine met the DSM-IIIR criteria[1] for late luteal phase dysphoric disorder. A symptom was scored as present and cyclic if it was rated at ≤2 on a six-point ordinal scale throughout the postmenstrual follicular phase of the menstrual cycle and was present at moderate or severe levels (a score of ≥4) during at least 4 days of the premenstrual week. During baseline cycles, ovulation was detected by basal body temperature recordings. During cycles in which laboratory sessions took place, ovulation was documented by the Q-test (Becton Dickinson, Franklin Lakes, N.J.).

A total of 142 subjects were screened. All subjects met the following additional inclusion criteria: a normal Minnesota Multiphasic Personality Inventory profile, which was completed during the follicular phase; absence of Axis I diagnosis on the Structured Clinical Interview for the DSM-III-R[10]; a normal follicular phase Beck Depression Inventory score[11]; the absence of serious medical illness such as thyroid dysfunction; ingestion of no psychotropic, hormonal, or other medications; and a menstrual cycle length of 24 to 32 days. All subjects had normal complete physical and gynecologic examinations and normal laboratory studies, including complete blood counts, urinalysis, and thyroid-stimulating hormone and free thyroxine evaluations.

Subjects completed two laboratory sessions in the follicular and luteal phases of the menstrual cycle in counterbalanced order. Relative to the day of ovulation, cycle days of the laboratory studies were similar for control subjects and those with late luteal phase dysphoric disorder (follicular: control -5.1 ± 1.8 vs late luteal phase dysphoric disorder -6.2 ± 2.2, NS; Luteal: control 9.6 ± 2.4 vs late luteal phase dysphoric disorder 8.7 ± 1.5, NS). All sessions began between 1:30 and 3 PM. Each session lasted approximately 75 minutes, during which subjects were exposed to various stressors. At the beginning and end of each session, 35 ml of blood was drawn into evacuated glass tubes containing 2 ml of acid citrate-dextrose solution, which served as an anticoagulant. Platelet-rich plasma was obtained by centrifugation at 100*g* for 2 minutes; centrifugation was repeated three times. The platelet-rich plasma was then centrifuged (16,000*g* for 10 minutes at 4° C), and the resulting platelet-rich pellet was suspended in 50 mmol of Tris buffer (pH 7.5 at 4° C) containing 150 mmol of sodium chloride and 20 mmol of ethylenediaminetetraacetic acid by means of a Polytron homogenization medium probe (Polytron, Brinkmann Instruments, Westbury, N.Y.) at setting of 4 for 10 to 15 seconds. After centrifugation at 39,000*g* for 10 minutes, membranes were prepared by hypotonic lysis in 5 mmol Tris (pH 7.5), containing 5 mmol ethylenediaminetetraacetic acid and were then homogenized and centrifuged at 39,000*g* for 10 minutes. The supernatant was discarded, and the pellet was washed by resuspension in 70 mmol Tris (pH 7.5) and was centrifuged again at 39,000*g* for 10 minutes. The washed pellet was finally resuspended in the assay buffer, which consisted of 50 mmol Tris (pH 7.5 at 4° C) containing 120 mmol of sodium chloride and 5 mmol of potassium chloride. Aliquots were taken for protein determination. Platelets were then frozen at 70° C until they were used for the binding assay.

Platelet [3H]imipramine binding was conducted with a modification of the procedure of Nemeroff et al.[12] In each sample, total binding was assayed at seven different concentrations (0.25 nmol to 8 nmol) of [3H]imipramine (specific activity 45.4 Ci/mmol); the dissociation constant (K_d) is approximately 1 nmol. Each assay tube (all concentrations were measured in triplicate) contained approximately 100 μg of platelet protein, and the final assay volume was 250 mm^3. Tubes were incubated with the radiolabel for 60 minutes on ice. The reaction was terminated by addition of 5 ml of ice-cold assay buffer, and bound radioactivity was collected by filtration under vacuum over glass fiber filters presoaked for 3 hours in buffer. The filters were then washed three times with 5 ml of ice-cold assay buffer, and bound radioactivity was collected by filtration under vacuum over glass fiber filters presoaked for 3 hours in buffer. The filters were then washed three times with 5 ml of ice-cold assay buffer. Nonspecific binding was defined as binding persisting in the presence of 100 μmol of desipramine. Specific binding represented 80% of total binding, which was less than 5% of the total counts added. Scatchard analysis was used to obtain the maximum binding and K_d for [3H]imipramine. Linear regression of Scatchard plots was used to determine the correlation coefficient *r*. Assays with $r < 0.90$ were excluded. The interassay coefficients of variation were 10% for maximum binding and 5% for K_d.

Comparison of the first and second assays of imipramine binding sites in each laboratory session was performed by paired Student *t* test. The Student–Newman-Keuls test was used to compare pooled [3H]imipramine level results from controls with those from subjects with late luteal phase dysphoric disorder. Repeated measures analysis of variance was used to measure group (control vs late luteal phase dysphoric disorder) × time (follicular vs luteal) interactions. Analyses of variance with Duncan's one-tailed *t* tests were used to compare results from both groups within one

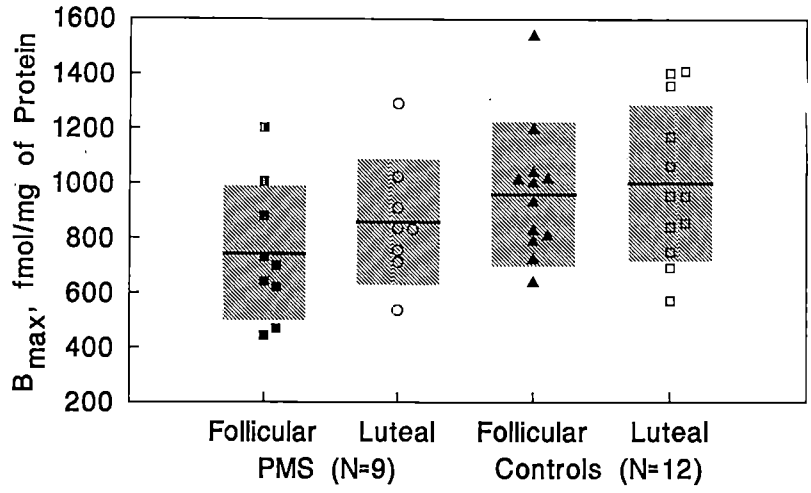

Fig. 1. [^{3}H]Imipramine binding sites in controls and women with premenstrual syndrome by menstrual cycle phase. *Bars,* means; *shaded areas,* ± 1 SEM. Only paired data points were used for statistical analysis.

cycle phase. Pearson's r was used to measure the correlation between luteal platelet binding site density and Beck Depression Inventory scores from baseline cycles. The $p < 0.05$ level of significance was used.

Results

Control subjects had, as expected, normal Beck Depression Inventory scores in the follicular (1.0 ± 1.2, mean ± SD) and luteal (2.4 ± 3.2, mean ± SD) phases of a baseline charting cycle. PMS subjects were normal in the follicular phase but were significantly depressed in the luteal phase; this was demonstrated by increased Beck Depression Inventory scores (2.1 ± 2.90 vs 17.1 ± 10.0, $p < 0.001$). Four of the nine PMS subjects had luteal phase Beck scores in the clinically depressed range (>16).

The number of [^{3}H]imipramine binding sites in samples obtained before and after the laboratory sessions did not differ significantly. This attests to the stability of platelet binding site characteristics over short time intervals, i.e., test-retest reliability. The mean value for each day was therefore used for subsequent analyses. For the analyses of variance, one subject was dropped from each group as a result of our inability to obtain samples in both menstrual cycle phases.

When follicular and luteal phase values within each subject group were combined, platelet [^{3}H]imipramine binding site density for PMS women was significantly lower than that of controls (800.2 ± 237.8 vs 981.4 ± 258.5 fmol/gm protein [$F(1,39) = 5.13$, $p = 0.03$]). Repeated measures analysis of variance revealed a time effect at the trend level ($F[1,17] = 2.57$, $p = 0.12$), but no time × group effect.

When platelet binding site number by cycle phase across subject groups was considered, (Fig. 1) women with PMS had lower maximum binding values than did controls in the follicular phase (744.8 ± 247.6 vs 963.0 ± 240.9 fmol/gm protein) by analysis of variance ($F[1,20] = 4.12$, $p = 0.057$) and Duncan's one-tailed t test ($p < 0.05$), but the two groups were not different in the luteal phase (862.4 ± 225.4 vs 1006.3 ± 284.2 fmol/gm protein; $F[1,18]$, $p = 0.27$, and $p > 0.05$, respectively). The increase in the number of [^{3}H]imipramine binding sites in platelets in PMS women from the follicular to the luteal phase was statistically significant (750.5 ± 264.1 vs 862.4 ± 225.4 fmol/gm protein, $p < 0.05$).

Luteal phase Beck Depression Inventory scores were not correlated with either follicular or luteal platelet [^{3}H]imipramine binding site density in PMS subjects.

Comment

This study documents lower numbers of platelet [^{3}H]imipramine binding sites in women with well-documented PMS who, in the follicular phase of the menstrual cycle, were clearly free of depression by stringent clinical and psychometric criteria. In results consistent with those of previous reports,[13, 14] asymptomatic women showed no influence of menstrual cycle phase on platelet [^{3}H]imipramine binding. Subjects in the present study with late luteal phase dysphoric disorder had lower values in the follicular as opposed to the luteal phase. Rojansky et al.[15] also noted differences in [^{3}H]imipramine binding in controls as opposed to women with "premenstrual changes," but they noted lower maximum binding values in early versus late luteal phase samples from symptomatic women. However, they observed a significant cycle phase effect on maximum binding in controls, a change that was not observed in this study or in previous reports.[13, 14] Their

subject population included some women with a lifetime diagnosis of depression, but this study excluded those women. The large degree of variability in the assay results and the limited number of times of sampling may further account for these apparent discrepancies.

The density of [3H]imipramine binding sites has been reported to be reduced in depressed patients in the majority of studies[8] and in scattered reports of a few possibly related conditions such as anorexia,[16] agoraphobia,[17] and obsessive-compulsive disorder.[16] The latter two disorders are among those overrepresented in an epidemiologic study of psychiatric disease and premenstrual symptoms (Duke Epidemiologic Catchment Area Study. Unpublished data). The number of platelet [3H]imipramine binding sites was about 18% lower in women with PMS than in controls; this was a smaller difference than the average 35% reduction seen in studies of depressed patients, which suggests that PMS may be a variant of depression modulated by the menstrual cycle.

The observation of a strong trend toward reduced binding sites to the serotonin transporter in women with PMS during their asymptomatic times is of interest. Platelets have a mean life-span of 21 days. Because [3H]imipramine binding sites are cell membrane characteristics of the anucleate platelet, they may be seen as evidence of synthetic events that occurred weeks earlier in the megakaryocyte. Low-follicular-phase density of the binding sites and the emotional state of the preceding luteal phase may both be the results of luteal phase biosynthetic events. Although previous studies have shown that platelet [3H]imipramine binding sites return to normal after the clinical resolution of depression, most researchers have measured this change 1 to 2 months after clinical improvement has occurred.[7, 18, 19] PMS may indeed provide a viable model for the study of affective state change that may resemble an acute depressive episode.

Sex hormones are well known to affect serotonergic systems. Pharmacologic doses of estrogen in rats[20] and physiologic replacement doses (10 mg of estradiol valerate monthly) in surgically menopausal women[21] increase the number of these binding sites approximately 20%. The time course of these changes is uncertain. In the latter study,[21] women given estrogen showed improved mood compared with that of their preoperative state, but controls failed to show any decline in mood while deprived of estrogen replacement. The precise relationship of estrogen levels to mood thus remains enigmatic with respect to both premenstrual and postmenopausal states.

Previous studies of serotonergic mechanisms in PMS have yielded contradictory findings. Whole blood serotonin levels[22, 23] and 5-hydroxytryptamine[24] uptake are reported to be lower in premenstrual women with premenstrual syndrome, and the maximum volume of platelet serotonin uptake is reportedly decreased premenstrually as well.[22] Malmgren et al.,[25] in a study limited by the absence of daily symptom ratings, compared women who had PMS with control subjects and found no effect of subject group or cycle phase on platelet serotonin uptake.

The lack of correlation of a state measure of depression (Beck Depression Inventory score) with the density of binding sites is consistent with reports of depressed patients in which psychometric measures of mood failed to correlate with this measure of presynaptic serotonergic function.[12] The high level of variance in binding site data in general makes it difficult to show such associations without studying large numbers of subjects and diminishes the potential clinical diagnostic value of this laboratory measure.

This study provides impetus for the further investigation of the dynamics of this presynaptic serotonergic binding site as a marker of affective state across the menstrual cycle and the relationship between premenstrual emotional changes and more continuous depressive disorders.

The development of ultradian rhythms in the human fetus

Mary Pillai, MB, David K. James, MD, and Michael Parker, MB
Bristol, Canada

OBJECTIVE: Our objective was to determine the normal sequence of neurobehavioral development in the human fetus between 14 weeks' gestation and delivery.
STUDY DESIGN: The study was performed by longitudinal ultrasonographic observation of 45 low-risk singleton fetuses.
RESULTS: During the first half of the midtrimester there was a high rate of spontaneous movement that appeared randomly distributed. By the end of that trimester an increase in the duration of intervals of quiescence resulted in activity appearing cyclically distributed, with the duration of quiet cycles progressively increasing to term. Fetal mouthing and breathing were linked with cyclic behavior from the time of their emergence. Fetal heart rate pattern A could be recognized from around 32 weeks, due to a reduction in baseline variability in quiet cycles after 30 weeks, whereas pattern B could be recognized several weeks earlier. From the time cyclic behavior and heart rate patterns could be recognized, intervals of coincidence of the fetal behavioral state variables increased progressively with advancing gestation. (Am J Obstet Gynecol 1992;167:172-7.)

Key words: Fetal behavior, ultradian rhythms

The first half of pregnancy is characterized by rapid emergence of a wide variety of fetal movements of relatively high frequency but little neurologic organization.[1, 2] During the second half of pregnancy these movements become organized. Diurnal rhythms are not demonstrable at 13 weeks but have been reported

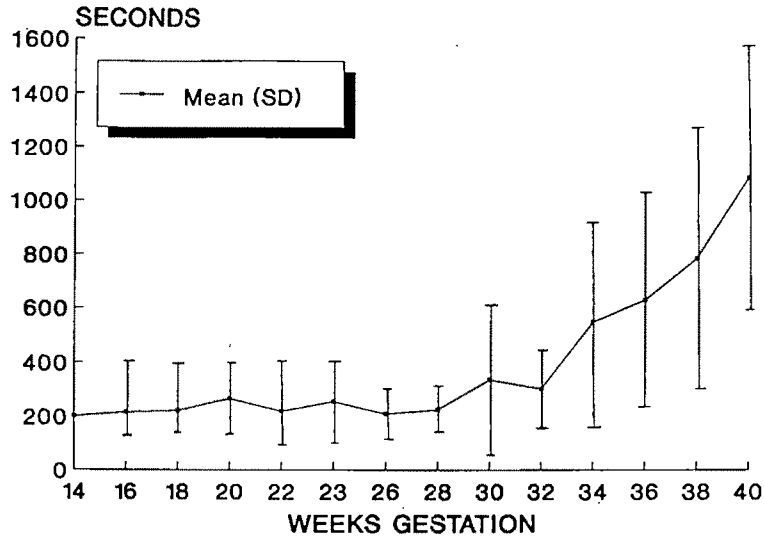

Fig. 1. Duration (mean and SD) of longest interval of complete quiescence during 100-minute longitudinal recordings between 14 weeks' gestation and term.

at 20 to 22 weeks,[3] 24 to 28 weeks,[4] and during the last 10 weeks of pregnancy.[5] All of these studies found peaks of fetal activity occurring in the late evening, in keeping with the commonly reported pattern of maternally perceived movements. These diurnal fluctuations are generally thought to be under maternal control, being related to diurnal fluctuations in maternal cortisol production[6] and inhibited by suppression of these fluctuations with exogenous steroids.[7]

More short-term, or ultradian, fluctuations in fetal activity also occur. In late pregnancy these are manifested as different behavioral states[8] that are very comparable to behavioral states of the newborn infant.[9] The stability, close linkage, and simultaneous change of the conditions of the different behavioral state variables is present in healthy fetuses from around 36 weeks' gestation. Before this, linkage of the variables is less consistent, but fluctuations in activity or rest-activity cycles are evident throughout the last trimester and sometimes even earlier.

The aims of the current study were to describe the development of these ultradian rhythms in the human fetus.

Patients and methods

A total of 21 primigravid and 24 multigravid women with no risk factors for fetal growth retardation, preterm delivery, gestational diabetes, or hypertension was recruited for longitudinal study of multiple fetal variables. Recordings began between 14 and 18 weeks' gestation and were repeated monthly until delivery.

Fetal diaphragmatic movements, limb, body, mouthing, and eye movements, were detected with real-time ultrasonography and recorded polygraphically at a paper speed of 3 cm/min (Hewlett Packard 7754A). The fetal heart rate (FHR) was also recorded ultrasonically with a standard FHR monitor (Hewlett Packard 8040A) with an output to the polygraph to allow synchronizing of all variables. During most of the second trimester recordings were made with a single scanner (Siemens Sonoline SL1 with 3.5 MHz transducer). However, in the last trimester two scanners were used, one giving a parasagittal view of the fetal face (Siemens Sonoline SL1 with 3.5 MHz transducer) and the other a transverse view of the fetal abdomen (Toshiba SAL 20A with 2.4 MHZ transducer). Fetal eye, somatic, and mouthing movements; breathing; and hiccups were recorded on separate channels of the polygraph with multiple hand-held push buttons.

Recordings were made with the patient in a comfortable, semirecumbant position for which we found a Parker Knoll chair most suitable. Recordings began between 9 AM and 6 PM and continued for 90 to 100 minutes. Within individuals, recordings were repeated at the same time of day and at the same interval after meals, and the small minority of mothers who smoked did not do so during the recording or for 2 hours before the recording.

All participants were outpatients with no risk factors known to affect fetal behavior or breathing. The following definitions were used:

Rest-activity cycles: A relatively high base rate of fetal movements interrupted by periods of quiescence lasting ≥6 minutes but which may be interrupted by a single startle.

Behavioral states: Stable association of heart rate pattern

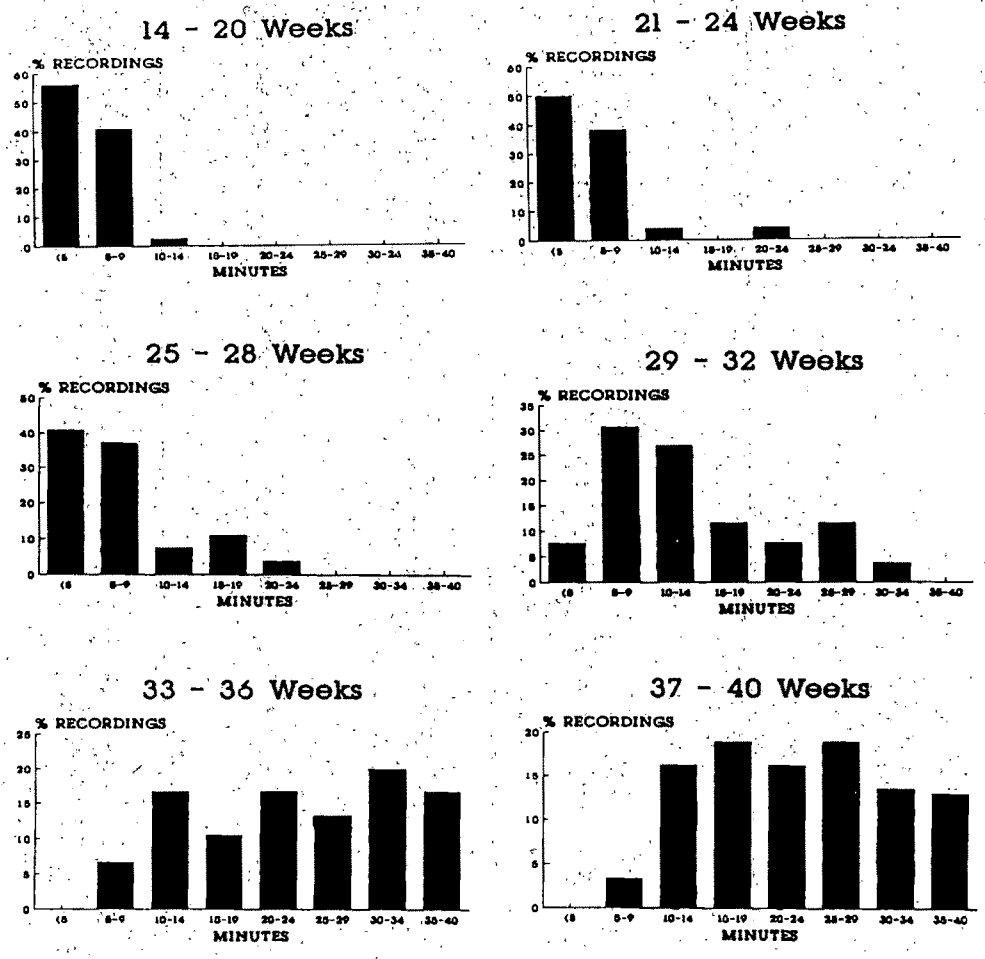

Fig. 2. Distribution of longest intervals of quiescence by gestational age grouping.

and condition of eye and somatic movements for intervals of ≥3 minutes with simultaneous transition (usually within 3 minutes) of all three variables at times of state transition.[8]

Fetal breathing: Contraction of the diaphragm resulting in downward and outward displacement of the abdominal contents and inward displacement of the thorax. All episodes of fetal breathing were counted provided they contained a minimum of four consecutive breaths sustained for ≥5 seconds. All episodes where the breath-to-breath interval was ≥6 seconds were excluded.[10] Isolated diaphragmatic movements were not counted.

Statistical analysis of the data was performed with analysis of variance and the paired *t* test.

Approval for the study was obtained from the hospital's research and ethical committee.

Results

The total number of recordings was 268 (mean 6.0, range 4 to 7 per fetus), and the total recording time was 402.4 hours.

Quiescence. Before 28 weeks the longest intervals of quiescence were around 200 seconds (mean 191 to 271 seconds), so that activity appeared randomly distributed with a high base rate of activity and very little quiescence. The longest interval of complete quiescence increased significantly ($p < 0.001$) with advancing gestational age after 28 weeks (Fig. 1).

The longest observed intervals of quiescence were allocated to 5-minute intervals between 0 to 5 and 35 to 40 minutes (only one quiescent interval lasted >40 minutes). Within six different gestational age groups the number of individuals with a particular interval of quiescence was plotted (Fig. 2). Before 24 weeks the majority of longest identifiable quiet intervals were <5 minutes, whereas after 32 weeks most quiet intervals were between 10 and 35 minutes. Although this clearly shows that fetal inactivity is gestional age dependent, evaluating only complete inactivity may not be an appropriate way to discriminate intervals of rest and activity. In the newborn, quiet (non–rapid eye movement) sleep may be interrupted by startles without a change of state occurring; we have therefore included

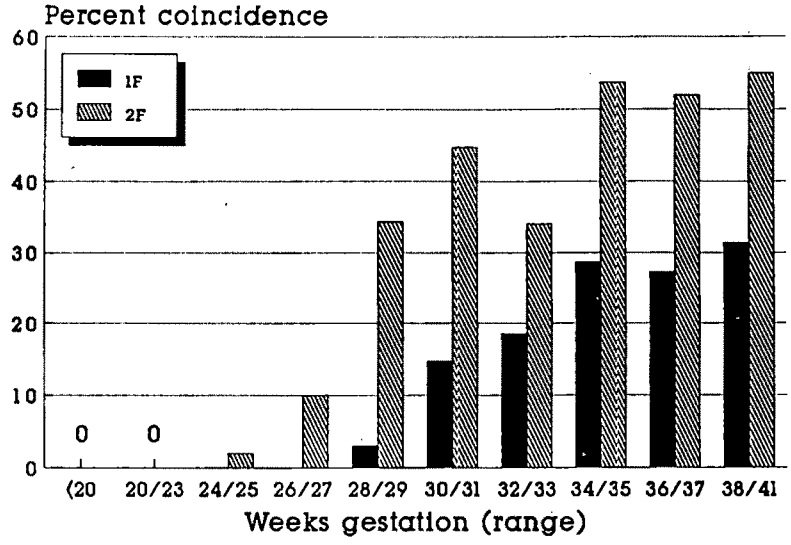

Fig. 3. Mean percentage coincidence 1F and 2F between 20 weeks' gestation and term.

quiet intervals interrupted by a single burst of movement in the fetus.

Rest-activity cycles. With the arbitrary definition of 6 minutes' total quiescence or interrupted by a single burst of movement for the minimum duration of a rest cycle, rest-activity cycles were rarely observed before 24 weeks, but by 29 weeks they were present in >80% of recordings.

Behavioral states. Fixed and recurring associations of body movements, eye movements, and the FHR pattern into well-defined fetal behavioral states were first observed in one fetus at 33 weeks and were present in >80% of recordings after 36 weeks. We have previously drawn attention to the fact that fetuses demonstrating state behavior may not consistently complete state transitions in a 3-minute interval.[11] We have therefore included recordings in this group, provided there was coincidence of the state variables for >90% of the recording and completion of at least one transition within 3 minutes.

Before the development of behavioral states there were intervals during which the behavioral variables would coincide in the conditions required for state behavior, although the heart rate patterns were never as distinct as they were after the development of states. Brief intervals of coincidence 2F and 1F were first observed in one fetus at 25 and 29 weeks, respectively. The percentage coincidence 1F and 2F is plotted in Fig. 3.

Eye movements. For determination of presence or absence of eye movements those intervals during which the eye was clearly visible were divided into 30-second epochs. Eye movements were considered intermittent if one to four occurred per epoch and continuous if there were more than five per epoch.

At all gestations eye movements tended to be absent during prolonged intervals of inactivity. During the first half of the middle trimester eye movements were often absent during episodes of activity and when present were intermittent. Towards the last trimester eye movements became more consistently associated with episodes of movement, and throughout the last trimester the percentage of active epochs with continuous eye movements progressively increased.

FHR patterns. FHR patterns were considered present once the baseline variability in quiet cycles was visibly narrow compared with that in active cycles (in practice a mean difference in variability ≥3 beats/min). By definition it follows that they could not be recognized in recordings without cycles; however, they were usually present several weeks before behavioral states.

State transitions. Consideration of the order of change of variables at the time of state change revealed that, at the gestational age at which states are present, FHR accelerations and fetal movements were so closely linked that the baseline variability was obscured by the presence of an acceleration at the onset of fetal movement. Thus it was impossible to determine if the FHR pattern and fetal movements changed simultaneously.

Fetal breathing. Throughout the gestational range studied fetal breathing movements were significantly more common in the active cycles ($p < 0.001$); however, within individuals this finding was not consistent with six recordings containing more breathing in quiescence than during the active cycles.

Fetal mouthing. Mouth opening, yawning, and tongue protrusion were observed throughout the gestational range studied. When rest and activity cycles were apparent in recordings these types of mouthing movements were almost confined to active cycles of

behavior. A very different type of mouthing, characterized by recurrent bursts of rhythmic movements of the tongue and mandible at a frequency of 1 to 3 Hz was observed once these were established. Rhythmic mouthing was observed during 67% of quiet cycles and 75% of intervals of state 1F, when the mouth was visible. Late in the second and early in the third trimester the duration of each burst was short, typically 1 to 2 seconds three or four times per minute. However, from around 34 weeks the burst duration was more variable, 2 to 15 seconds two to four times per minute.

Fetal outcome. All participants were delivered at term. All 1-minute Apgar scores were >5 and 5-minute scores were >7. The mean birth weight was 3532 gm (SD 435 gm, range 2700 to 4650 gm). One infant was admitted to the neonatal unit for investigation of pyrexia, which resolved without treatment, and in one other infant sudden, unexplained death occurred at 8 weeks. Careful retrospective examination of the recordings from this fetus did not reveal any differences from the other fetuses studied. With this one exception all infants are currently between 2 and 3 years of age and are developing normally.

Comment

We have previously shown that if biophysical evaluation of fetal well-being happens to coincide with state 1F, an abnormal or suboptimal result is obtained in a high percentage of normal fetuses.[12] The results of these observations reveal the converse at earlier gestations. Rest cycles, if present at all, are of short duration, and consequently observation of as few as three movements in a 30 minute interval (as recommended in the biophysical profile[13]) can hardly be considered a reassuring sign of well-being.

In the middle trimester there is an increase in baseline variability in both active and quiet cycles, whereas in the last trimester there is a significant reduction in baseline variability in quiet or 1F cycles with advancing gestational age beyond 30 weeks.[14] It is this which accounts for the appearance of the different heart rate patterns (A and B) previously described by Nijhuis et al.[8] It also accounts for the failure to identify intervals of 1F before 30 weeks, whereas brief intervals of 2F could often be identified several weeks earlier.

Although there is evidence that diurnal fluctuations are under maternal control,[6, 7] as yet it is unknown whether ultradian rhythms are under anything other than fetal control. We have previously reported absence of cyclic behavior in an abnormal fetus at 36 weeks, in whom FHR monitoring and the biophysical profile satisfied normal criteria.[15] Rhythmic mouthing movements have previously been reported as a concomitant of state 1F,[16, 17] and as with the state variables its presence during appropriate (quiet) epochs increased with advancing gestation. We have previously suggested that, because this is the fetal activity most frequently observed during quiet behavior, it would be useful to investigate its potential to discriminate between the quiet healthy fetus and one that is sick.[18]

Although clear trends were observed in human fetal behavioral maturation, the most consistent difficulty encountered was the inability to assign normal criteria for behavior for any particular gestational age. For example, although as a rule fetuses did not exhibit cyclic behavior before 24 weeks, six recordings did fulfill the criteria for a rest cycle, and two of these recordings were earlier than 17 weeks. Observations on a fetus not included in this study, but in whom fetal movement was absent during a routine scan lasting 20 minutes at 18 weeks, revealed only two sluggish movements during 45 minutes of recording at 19 weeks. The mother was well, did not smoke, drink, or take any drugs, and serial recordings throughout the remainder of pregnancy were completely normal, as was the baby at birth and at the age of 8 months.

Indeed, one of the most striking features of normal fetal behavior is its diversity. In terms of quantitative evaluation almost anything is acceptable, and gross deviation is necessary before it is recognizably abnormal. The lack of organization of behavior in early pregnancy makes identification of abnormality particularly difficult, although excessively forceful and monotonous movements have been noted in anencephalic fetuses.[19] In later pregnancy qualitative evaluation of coincidence of behavioral variables has revealed differences between groups of normal fetuses and fetuses subject to high maternal alcohol intake,[20] hydrocephalic fetuses,[21] fetuses of diabetic mothers.[22] and growth-retarded fetuses.[23] However, the wide range of coincidence found in normal fetuses at any particular age may render such observations valueless as a screening test for anything other than very severe neurologic impairment.

Effect of calcitonin gene-related peptide on the uterine vasculature of the nonpregnant ewe

Daseng Yang, MD, George A. Van Buren, MD, and Kenneth E. Clark, PhD
Cincinnati, Ohio

OBJECTIVES: The current study was designed to evaluate the uterine vascular effects of calcitonin gene-related peptide on the uterine vasculature of nonpregnant sheep and compare them with the effects of prostacyclin.
STUDY DESIGN: Five nonpregnant oophorectomized ewes were instrumented with uterine and pulmonary artery flow probes and catheters. Dose-response curves were constructed according to increasing doses of calcitonin gene-related peptide (0.01, 0.03, 0.1, 0.3, 1, and 3, μg/min) and prostacyclin (0.03, 0.1, 0.3, 1, 3, and 10 μg/min) via 10-minute uterine artery infusions.
RESULTS: Both calcitonin gene-related peptide and prostacyclin produced a significant increase in uterine blood flow and a decrease in uterine vascular resistance. Calcitonin gene-related peptide was found to be approximately 17 times more potent than prostacyclin as a vasodilator. Local uterine artery infusions of calcitonin gene-related peptide led to significant increases in heart rate but did not alter blood pressure, cardiac output, or total peripheral resistance at the doses tested. In contrast, at doses of prostacyclin that produced similar uterine vasodilatation, prostacyclin led to significant decreases in systemic arterial blood pressure and total peripheral resistance and increases in heart rate and cardiac output.
CONCLUSION: These data strongly suggest that calcitonin gene-related peptide, an endogenously occurring vasoactive peptide, could play an important role in regulating uterine and systemic hemodynamics. (Am J Obstet Gynecol 1992;167:178-84.)

Key words: Sheep, prostacyclin, calcitonin gene-related peptide, uterine blood flow, vasodilatation

Calcitonin gene-related peptide is a newly discovered 37-amino-acid peptide translated from the calcitonin gene.[1] Immunohistochemical studies showed that calcitonin gene-related peptide–containing fibers are found in various perivascular nerves. The major role of circulating calcitonin gene-related peptide released from these peripheral nerves is thought to be control of organ blood flow. There is mounting evidence implicating calcitonin gene-related peptide as a potent vasodilator in the cardiovascular system.[2-6] Calcitonin gene-related peptide–containing nerve fibers have been localized in the nonpregnant guinea pig uterus and uterine artery.[7, 8] In addition, circulating levels of calcitonin gene-related peptide have been reported to be significantly elevated in pregnancy with the highest concentration occurring close to term.[9] However, our knowledge of the vasoactivity of calcitonin gene-related peptide in the uterine vasculature is currently limited to in vitro experiments.[10, 11] Thus these experiments were designed to determine the effects of calcitonin gene-related peptide on the uterine vasculature using a chronically catheterized nonpregnant sheep preparation.

Material and methods

Surgical procedures. Five parous, nonpregnant sheep of mixed breed weighing 47 to 55 kg were used in this investigation. All animals underwent two operations, which are described below.

Thoracotomy. Before operation the sheep were fasted for 48 hours and water was withheld for 24 hours. Animals were initially anesthesized with pentobarbital (12 mg/kg), intubated, and placed on a ventilator with 3% to 4% isoflurane and oxygen to maintain anesthesia. The pulmonary artery was exposed via a left lateral thoracotomy and fitted with a 24 mm Doppler ultrasonographic flow probe (Transonic Systems, Inc., Ithaca, N.Y.) for determination of cardiac output. The thorax was closed in layers and drained by catheter to continuous vacuum suction for 3 days. The probe

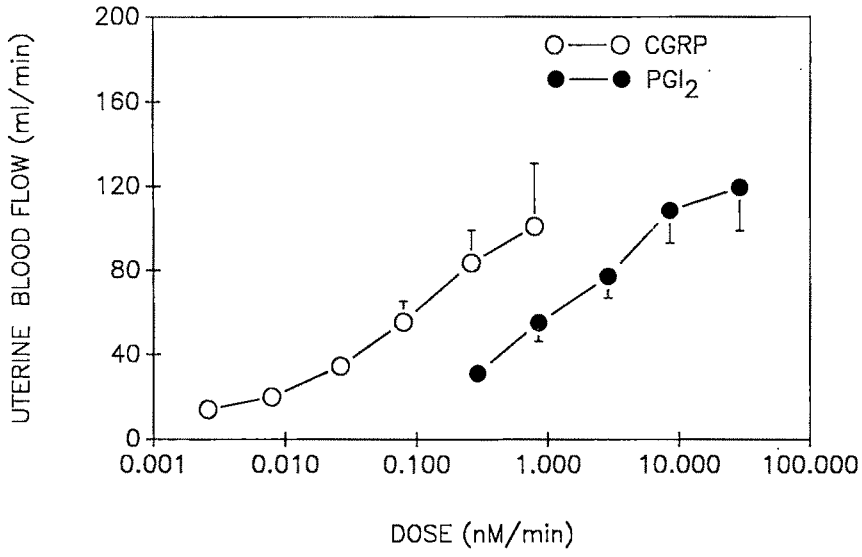

Fig. 1. Dose of calcitonin gene-related peptide *(open circles)* and prostacyclin *(solid circles)* versus increases in uterine blood flow (milliliters per minute) in nonpregnant ovine preparation ($n = 5$ for both compounds at all doses except for calcitonin gene-related peptide at highest dose where $n = 3$). Values are means ± SEM. Calcitonin gene-related peptide and prostacyclin induced significant increases in uterine blood flow ($p = 0.0001$).

cable was tunneled subcutaneously to exit the left flank and stored in a canvas pouch. After the operation the ewes were housed in individual portable cages and provided with commercial feed and water ad libitum.

Abdominal preparation. Subsequent to a 5- to 7-day recovery period from thoracotomy, sheep were fasted and anesthetized as described previously. Through a left groin incision, polyvinyl catheters were inserted into the ewe's femoral artery and vein to the level of the distal aorta and vena cava respectively. These catheters were used to monitor arterial blood pressure or for systemic administration of drugs. The uterus was exposed by a midline incision, and electromagnetic flow probes were placed on both uterine arteries. To allow direct intraarterial administration of compounds, the lateral branch of each uterine artery was catheterized distal to the flow probe. All animals underwent ovariectomy to prevent cyclic fluctuation. The incision was closed, and catheters and cables were passed through a subcutaneous tunnel, exteriorized through a small incision on the ewe's flank, and stored in a canvas pouch attached to the ewe's side. All catheters were flushed every other day with heparin (1000 U/ml) to maintain patency. Each ewe received an intravenous injection of 17β-estradiol (1 μg/kg) each day to prevent uterine atrophy.

Experimental procedure. Experiments were not performed before the fifth postoperative day after the second operation to assure full recovery from surgical stress. After a 30-minute baseline recording period of arterial pressure, heart rate, cardiac output, and uterine blood flow, calcitonin gene-related peptide or prostacyclin was administered as a continuous 10-minute infusion through either the left or right uterine artery catheter. Compounds were infused at the rate of 0.1 or 0.3 ml/min. Cumulative dose-response curves were obtained for calcitonin gene-related peptide (0.01 to 3 μg/min) and prostacyclin (0.03 to 10 μg/min) on separate days. At the end of each experiment animals were given 1 μg/kg of 17β-estradiol via the femoral vein to evoke a maximum uterine blood flow response, which allowed us to normalize our data and evaluate the uterine potency of calcitonin gene-related peptide and prostacyclin.

Physiologic measurements. Uterine blood flow was measured by a square-wave electromagnetic flowmeter (RF 2100, Dienco, Los Angeles) in all five sheep, and cardiac output was measured in three of the five sheep with a Doppler ultrasonographic flowmeter (Transonic T 101, Transonic Instruments, Ithaca, N.Y.). Arterial blood pressures were monitored by Micron MP 15 pressure transducers (Micro Instruments, Simi Valley, Calif.), and heart rate was determined by cardiotachometer couplers (Sensor Medics, Anaheim, Calif.) triggered by arterial pressure pulses. All parameters were continuously recorded with Sensor Medics R612 physiologic recorders. Total peripheral and uterine vascular resistance was computed from mean arterial pressure and cardiac output or uterine blood flow, respectively, with no correction being made for central venous pressure.

Drug preparations. Calcitonin gene-related peptide

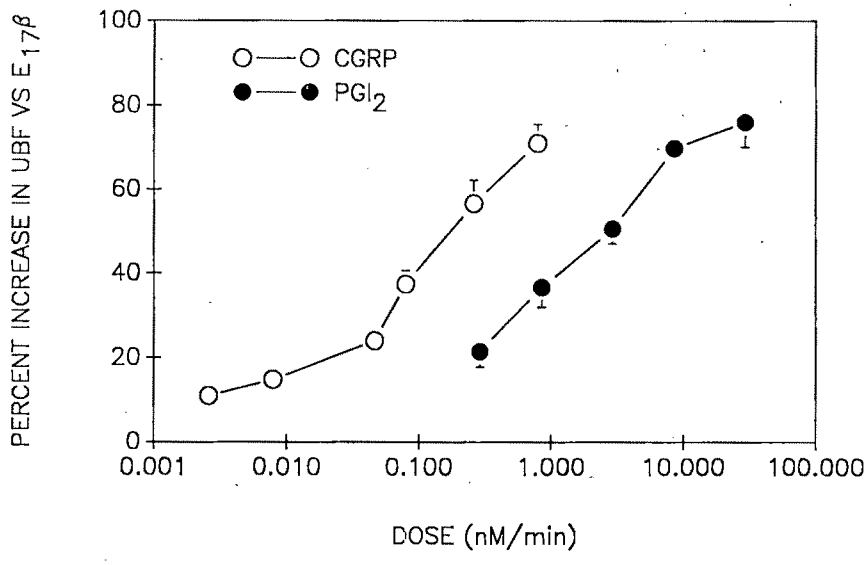

Fig. 2. Dose of calcitonin gene-related peptide *(open circles)* and prostacyclin *(solid circles)* versus percent of uterine blood flow response to 17β-estradiol in nonpregnant ovine preparation ($n = 5$ for both compounds at all doses except for calcitonin gene-related peptide at highest dose where $n = 3$). Values are means of individual percent changes ± SEM. At highest doses of calcitonin gene-related peptide and prostacyclin tested uterine blood flow was increased to 71% ± 5% and 76% ± 6% of maximum uterine response to estrogen.

(Peptides International, Louisville, Ky.) was prepared as a stock solution of 0.1 mg/ml in distilled water and stored at −20° C until use, at which time it was serially diluted with normal saline solution to the desired concentrations and kept on ice until used. Prostacyclin sodium salt (The Upjohn Company, Kalamazoo, Mich.) was prepared fresh immediately before use by dissolving it in 0.01 mol/L Tris buffer, pH 9.4, to prevent degradation.

Data analysis. The uterine vasodilator effects of calcitonin gene-related peptide and prostacyclin were expressed as both the absolute uterine blood flow changes (milliliters per minute) and as a percent of the maximum dilatation produced by 17β-estradiol and reported as mean ± SEM. In five sheep arterial pressure and heart rates were recorded, and in three of the five sheep cardiac output was recorded and total peripheral resistance was computed. All the parameters were measured during the last 2 minutes of each 10-minute infusion. Data were analyzed by one-factor analysis of variance, and the Newman-Keuls procedure was used to determine which mean was significantly different from baseline ($p < 0.05$).

Results

Effect of local intraarterial infusion of calcitonin gene-related peptide on uterine blood flow. Local intraarterial infusion of calcitonin gene-related peptide and prostacyclin produced significant dose-related increases in uterine blood flow in the nonpregnant ewes as illustrated in Fig. 1. Uterine blood flow increased from a baseline of 9 ± 1 ml/min to a maximum of 101 ± 30 ml/min during the infusion of 3 μg/min of calcitonin gene-related peptide. Responses reached a steady state by the end of each 10-minute infusion. Prostacyclin increased uterine blood flow from a baseline of 13 ± 1 ml/min to a maximum of 120 ± 21 ml/min at the 10 μg/min dose. On a nanomoles per liter per minute basis, calcitonin gene-related peptide was about 17 times as potent as prostacyclin in dilating the uterine circulation (Figs. 1 and 2). At the doses tested, calcitonin gene-related peptide (0.79 nmol/L/min = 3 μg/min) and prostacyclin (29 nmol/L/min = 10 μg/min) were able to increase uterine blood flow to 71% ± 5% and 76% ± 6% of the maximal estrogen response, respectively (Fig. 2). The vehicles, saline solution for calcitonin gene-related peptide or 0.01 mol/L Tris buffer for prostacyclin, did not significantly alter uterine blood flow at the infusion rates used. In animals receiving calcitonin gene-related peptide the calculated uterine vascular resistance decreased significantly from a baseline of 8.72 ± 1.18 to 0.84 ± 1.89 mm Hg/ml/min at the highest dose, whereas in animals receiving prostacyclin the uterine vascular resistance decreased from 6.23 ± 1.17 to 0.56 ± 0.10 mm Hg/ml/min at the highest dose infused (Fig. 3). The amount of time required for the highest dose of each vasodilator to decrease the half of

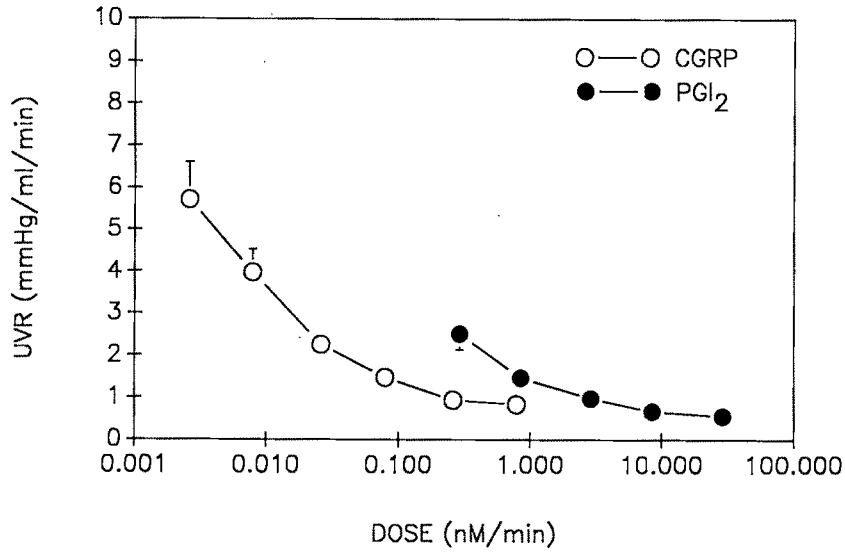

Fig. 3. Dose of calcitonin gene-related peptide *(open circles)* and prostacyclin *(solid circles)* versus decreases in uterine vascular resistance *(UVR)* in nonpregnant ovine preparation ($n = 5$ for both compounds at all doses, except for calcitonin gene-related peptide at highest dose where $n = 3$). Values are means ± SEM. Calculated uterine vascular resistance decreased significantly from a baseline of 8.72 ± 1.18 to 0.84 ± 0.18 mm Hg/ml/min at highest dose of calcitonin gene-related peptide infused and from 6.23 ± 1.17 to 0.56 ± 0.10 mm Hg/ml/min at highest dose of prostacyclin.

baseline after the completion of the 10-minute infusion was significantly longer for calcitonin gene-related peptide than prostacyclin (12 ± 1 vs 7 ± 2 minutes, $p = 0.02$).

Effect of intraarterially administered calcitonin gene-related peptide and prostacyclin on systemic hemodynamics. The local intraarterial infusion of calcitonin gene-related peptide led to significant increases in heart rate (94 ± 9 beats/min to 120 ± 6 beats/min) but did not significantly alter systemic arterial pressure, cardiac output, or calculated total peripheral resistance at the doses tested (Figs. 4 and 5). Because of the expense of purified calcitonin gene-related peptide higher doses were not investigated. Local infusion of prostacyclin led to a significant decrease in systemic arterial pressure (73 ± 4 to 59 ± 4 mm Hg) and total peripheral resistance (12.38 ± 0.65 to 8.39 ± 0.61 mm Hg/ml/min) with a significant increase in heart rate (92 ± 2 to 125 ± 5 beats/min) and cardiac output (5.8 ± 0.4 to 7.3 ± 0.4 L/min). Results are depicted graphically in Figs. 4 and 5.

Comment

The current work confirms and extends our knowledge about the effects of calcitonin gene-related peptide on the uterine vasculature. We have used a chronically instrumented unanesthetized nonpregnant sheep model in which we have administered calcitonin gene-related peptide directly into the uterine artery via an intraarterial infusion to determine its uterine vascular response. Our data showed that calcitonin gene-related peptide is a very potent vasodilator in the nonpregnant sheep uterus and is able to produce uterine vasodilatation, which is equivalent to that observed with 17β-estradiol. On a molar basis calcitonin gene-related peptide was about 17 times more potent than prostacyclin as a uterine vasodilator. On stopping the infusion of calcitonin gene-related peptide the duration of the vasodilatation produced was about 50% longer than that seen with prostacyclin. These data support the concept that calcitonin gene-related peptide is a potent uterine vasodilator and could possibly play an important role in the regulation of uterine blood flow in the nonpregnant and pregnant states.

Calcitonin gene-related peptide–containing fibers have been identified in nonpregnant guinea pig uterus and uterine artery by immunocytochemical examination.[7, 8] In addition, circulating plasma levels of calcitonin gene-related peptide have been reported to be significantly increased throughout pregnancy with the highest concentration close to term.[9] However, our knowledge of the physiologic significance of calcitonin gene-related peptide on the regulation of uterine blood flow in the nonpregnant or pregnant state is currently limited. Recently calcitonin gene-related peptide has been shown to be a potent vasodilator of in vitro preparations of preconstricted human and guinea pig uterine arteries.[10, 11] Nelson[10] showed that uterine arteries

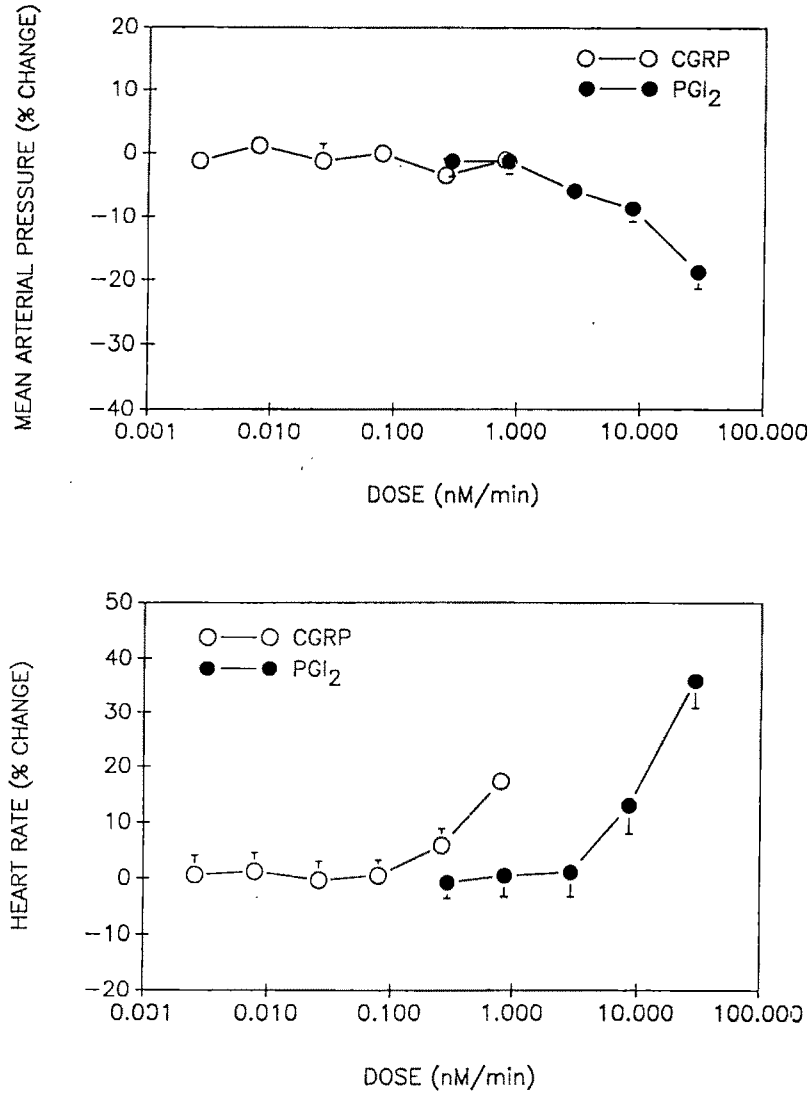

Fig. 4. Effect of local uterine artery infusion of calcitonin gene-related peptide and prostacyclin on mean arterial blood pressure *(upper panel)* and heart rate *(lower panel)*. Values are percent change from baseline ($n = 5$ for both compounds at all doses except for calcitonin gene-related peptide at highest dose where $n = 3$). Calcitonin gene-related peptide produced significant increases in heart rate ($p < 0.05$) at highest dose, whereas prostacyclin decreased blood pressure ($p = 0.0002$) and increased heart rate ($p = 0.0002$) in a dose-related fashion.

from pregnant women were more sensitive to the vasodilator effects of calcitonin gene-related peptide than were those from nonpregnant women, suggesting that calcitonin gene-related peptide might play an important role in regulating urine blood flow in pregnancy. Further investigations will be needed to assess the effects of calcitonin gene-related peptide on uterine blood flow in pregnancy.

Although calcitonin gene-related peptide is approximately 17 times more potent than prostacyclin as a vasodilator in the uterine circulation, systemic hemodynamic responses to the local uterine infusion suggest that the systemic vasculature may be less sensitive. While calcitonin gene-related peptide at the doses evaluated did not significantly change arterial blood pressure, prostacyclin significantly decreased systemic arterial pressure at the two highest doses. Both calcitonin gene-related peptide and prostacyclin significantly increased heart rate. This increased heart rate is most likely a compensatory response to peripheral vasodilatation produced by both compounds. Under the current protocol only prostacyclin produced significant increases in cardiac output and decreases in total peripheral resistance. The lack of systemic responses to calcitonin gene-related peptide at doses that are equally potent as vasodilators in the uterus can be interpreted

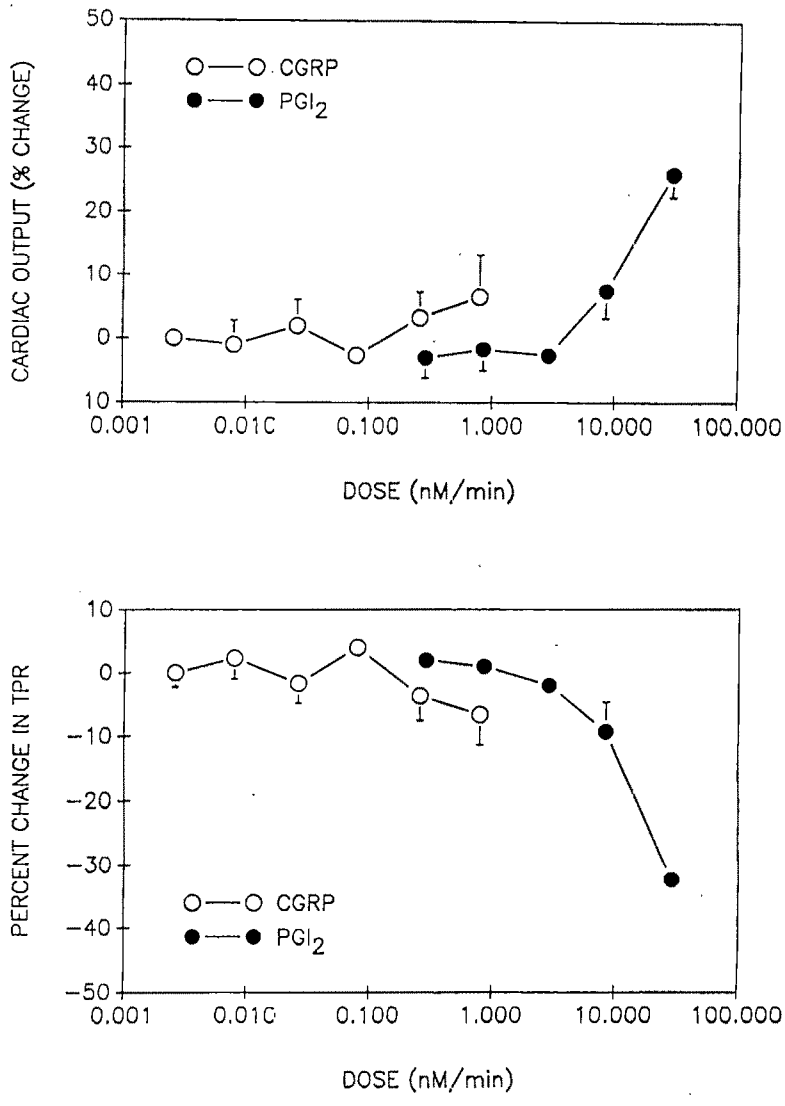

Fig. 5. Effect of uterine artery infusions of calcitonin gene-related peptide and prostacyclin on cardiac output *(upper panel)* and calculated total peripheral resistance *(lower panel)*. Values are percent change from baseline (n = 3 for both compounds at all doses). Prostacyclin produced a dose-related increase in cardiac output (p = 0.04), whereas calcitonin gene-related peptide had no significant effect on cardiac output at doses tested. Prostacyclin also produced a significant decrease in calculated total peripheral resistance (p = 0.003).

in two different ways. First, calcitonin gene-related peptide may be broken down or be metabolized before reaching the peripheral circulation, a possibility that does not seem likely because at least in humans it has a circulating half-life of 10 minutes[4] and in our study the uterine vascular response had a half-life of 12 minutes. A second possibility is that the systemic vasculature is less sensitive to calcitonin gene-related peptide than is the uterine vasculature. It appears (Figs. 4 and 5) that increasing doses of calcitonin gene-related peptide would have led to significant decreases in arterial blood pressure and total peripheral resistance, as well as increases in cardiac output. Thus, although the uterus appears to be more sensitive to calcitonin gene-related peptide than to prostacyclin, the systemic vasculature may not share this sensitivity. To determine this, higher doses of calcitonin gene-related peptide would have to be used.

In summary, in the current study we have investigated the vasoactive properties of calcitonin gene-related peptide on uterine vasculature. Calcitonin gene-related peptide appears to be a potent vasodilator agent in the ovine uterine vasculature. On a molar basis, it appears to be approximately 17 times more potent than prostacyclin, the most potent uterine vasodilator prostaglandin.[12] These properties suggest that this com-

pound could potentially play an important role in regulating uterine blood flow.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

An ultrastructural study of the developing urogenital tract in early human fetuses

W. Dwayne Lawrence, MD,[a] Diana Whitaker, MS,[b] Hoshiki Sugimura, MD,[c] Gerald R. Cunha, PhD,[d] G. Richard Dickersin, MD,[e] and Stanley J. Robboy, MD[f]

Detroit, Michigan, Philadelphia, Pennsylvania, San Francisco, California, Boston, Massachusetts, Newark, New Jersey, and Mie-Kan, Japan

OBJECTIVES: This study examines the gonoducts during the ambisexual stage of human fetal development to define their ultrastructural characteristics, including the origin and anatomic relationship of the mesonephric and paramesonephric ducts during gonoductal development.

STUDY DESIGN: The reproductive tracts from five fetuses ranging in gestational age from 35 to 45 days were processed for ultrastructural examination. The developing mesonephric ducts, paramesonephric ducts, and their surrounding mesenchyme were studied with a Phillips 300 transmission electron microscope.

RESULTS: The mesonephric ducts and paramesonephric ducts have distinctive cytoplasmic and cell surface ultrastructural characteristics, as well as different morphologic patterns of epithelial-mesenchymal interaction. Cephalad portions of mesonephric ducts and paramesonephric ducts are separated by mesenchyme, but more caudal aspects move progressively closer until they are juxtaposed but separate.

CONCLUSIONS: Early mesonephric ducts and paramesonephric ducts may be distinguished because of their distinctive ultrastructural features; epithelial-mesenchymal interaction may be important in their differentiation and maintenance; both gonoducts retain their morphologic identity throughout, supporting their separate origins. (Am J Obstet Gynecol 1992;167:185-93.)

Key words: Ultrastructure, fetus, urogenital, paramesonephric, müllerian, mesonephric, wolffian

The early reproductive tract in humans consists of two paired gonoducts. The mesonephric (wolffian) ducts develop first, arising around gestational day 24 from the paravertebral mesenchyme as a solid cord of cells. The ducts grow caudad, and around the 26th postovulatory day a lumen develops. By day 27 the mesonephric ducts have reached and opened into the cloaca, where they serve as the main excretory ducts of the embryo.

The paramesonephric (müllerian) ducts do not begin their development until postovulatory day 37, when they appear as funnel-shaped openings of the coelomic epithelium. The paramesonephric ducts appear to follow the mesonephric ducts like a "guidewire"; on day 48 the paramesonephric ducts are approximately halfway to the urogenital sinus and pass ventral to the mesonephric duct. The paramesonephric ducts continue to approach each medially and then grow to and contact the urogenital sinus at a ventral projection of its dorsal wall called the müllerian tubercle, which is situated between the openings of the mesonephric ducts. Around day 56, the paramesonephric ducts fuse to become the uterovaginal canal, the primordia destined to become the uterine corpus, cervix, and vagina. The upper unfused paramesonephric ducts become the fallopian tubes.

Although ultrastructural studies of the developing genital tract in experimental animals have been reported,[1, 2] to our knowledge no such studies of human material exist in the literature. This report, which is part of an ongoing study of the normal and abnormal development of the human genital tract,[3-5] presents our findings in five fetuses from approximately 35 to 45 postovulatory days of age. This period occurs during the ambisexual stage of gonadal development, during which the gonad is indifferent and not distinguishable morphologically as ovary or testis by traditional light

microscopy. In this communication, emphasis is placed on the ultrastructure of the developing mesonephric and paramesonephric ducts and their surrounding mesenchyme.

Material and methods

Human fetal material was obtained as described in detail elsewhere.[3] The ages of the fetal specimens, ascertained by heel-toe measurements,[6, 7] were 35 to 45 days of age (postovulatory). For such early specimens, determination of sex on morphologic grounds was impossible.

The reproductive tracts, which rarely exceeded 4 mm in length, were randomly placed in neutral buffered formalin for light microscopic analysis or were placed in Karnovsky's fixative for 2 hours at room temperature.

The specimens prepared for light microscopy were fixed in Bouin's solution, embedded in paraffin, sectioned at 6 μm, and stained with hematoxylin and eosin. In total, each genital tract yielded an average of 100 to 150 sections. The specimens prepared for transmission electron microscopy were divided after fixation into six to eight blocks. Sections of 1 μm stained with toluidine blue were prepared from each block, and where appropriate, ultrastructural analysis was performed using a Phillips 300 transmission electron microscope.

Results

Transmission electron microscopy of the gonoducts. The cells lining the early human paramesonephric duct are pseudostratified columnar in type, extending from the basal lamina to the lumen; cells are closely packed and nuclei are found at varying levels in the epithelium (Figs. 1 and 2). Apices of the cells exhibit numerous microvilli, many of which are elongate with rare terminal branching. Occasional cilia, although present, are poorly formed and lack the usual nine-plus-two internal arrangement. Apices of some cells bulge into the lumen in a manner reminiscent of the merocrine type of secretion observed in mature endometrial cells. Tight junctions are a prominent feature of the apical cell membranes. Desmosomes (macula adherentes) are present along the lateral borders of the cells, and are small and buttonlike. Nuclei of the paramesonephric duct epithelium show variability in size and shape and often contain one to three large nucleoli. The cytoplasm of the paramesonephric duct cells contains numerous polyribosomes and most cells contain from one to three Golgi complexes. Mitochondria are abundant. Lipid droplets are scattered throughout the cytoplasm and large lysosomes may be found in both supranuclear and subnuclear locations. A few cells contain subnuclear or supranuclear aggregates of glycogen. The basal aspect of the cells is relatively flat and cytoplasmic filaments may be present in a linear array adjacent and parallel to the basal lamina.

The stroma in the region of the developing paramesonephric duct is cellular and numerous mitotic figures are present. The stromal cells are large and epithelioid with abundant cytoplasm (Fig. 3). Nuclei are large with prominent nucleoli. The cell membrane is drawn out into fingerlike microvillus processes, which, over much of their length, lie in direct apposition to those of neighboring stromal cells. The cytoplasm contains long and short profiles of granular endoplasmic reticulum, polyribosomes, mitochondria, and scattered lipid droplets. The Golgi apparatus is well developed and is sometimes multiple. Small membrane-bound electron-lucent vesicles may be seen at the secretory end of the Golgi apparatus.

In contrast to the stroma around the mesonephric duct, the subepithelial stromal cells and their fine processes around the paramesonephric duct closely approach the base of the ductal epithelial cells and extend relatively short processes to make contact with the basal cell membranes. The basal lamina in these areas of close epithelial-stromal apposition appears incomplete or is absent (Fig. 3). The previously mentioned secretory vesicles appearing to arise from the Golgi apparatus may be numerous and sometimes fill the cytoplasm on the epithelial side of the stromal cell. Focally, the vesicles appear to merge with the stromal cell plasmalemma and others appear within the stroma as isolated membrane-bound vesicles. In paramesonephric duct epithelial cells, pinocytotic vesicles similar in size to those within underlying stromal cells appear at the basal plasmalemma, as well as in the basal portion of the cytoplasm. Some of the stromal cells contain cytoplasmic filaments, and poorly formed junctionlike attachments rarely are seen between stromal cells.

Mesonephric duct cells are tall, columnar and generally show less pseudostratification as compared with their paramesonephric counterparts (Fig. 4). The luminal border has short, stubby microvilli and the cilia are rudimentary, as in the paramesonephric ducts. The lumen focally contains degenerated and necrotic cell debris.

The most prominent feature of mesonephric duct cytoplasm is the presence of glycogen lakes, usually localized in a subnuclear position, although similar aggregations may be supranuclear (Fig. 4). Lipid droplets are less numerous than in the paramesonephric ducts. The cytoplasm of the epithelial cells contains prominent Golgi complexes, which are often concentrated in the apical portion. Polyribosomes are abundant and scattered diffusely throughout the cytoplasm.

When compared to the paramesonephric duct, the nuclear membrane of the mesonephric duct cells shows less irregularity and nucleoli are prominent. The basal aspect of the cell is generally flat. A delicate basal lamina underlies the base.

Large epithelioid stromal cells are present in the periductal stroma. Nuclei appear large, with prominent nucleoli. The cytoplasm contains numerous Golgi complexes, which, as in the stroma about the paramesonephric ducts, are more often polarized to the epithelial side of the cell. Polyribosomes are numerous and profiles of dilated rough endoplasmic reticulum contain a granular precipitate. Inclusions suggestive of primary lysosomes are found in scattered stromal cells, some of which show nuclear pyknosis and cytoplasmic degeneration.

Most of the stromal cells associated with the mesonephric ducts have long attenuated cell processes that

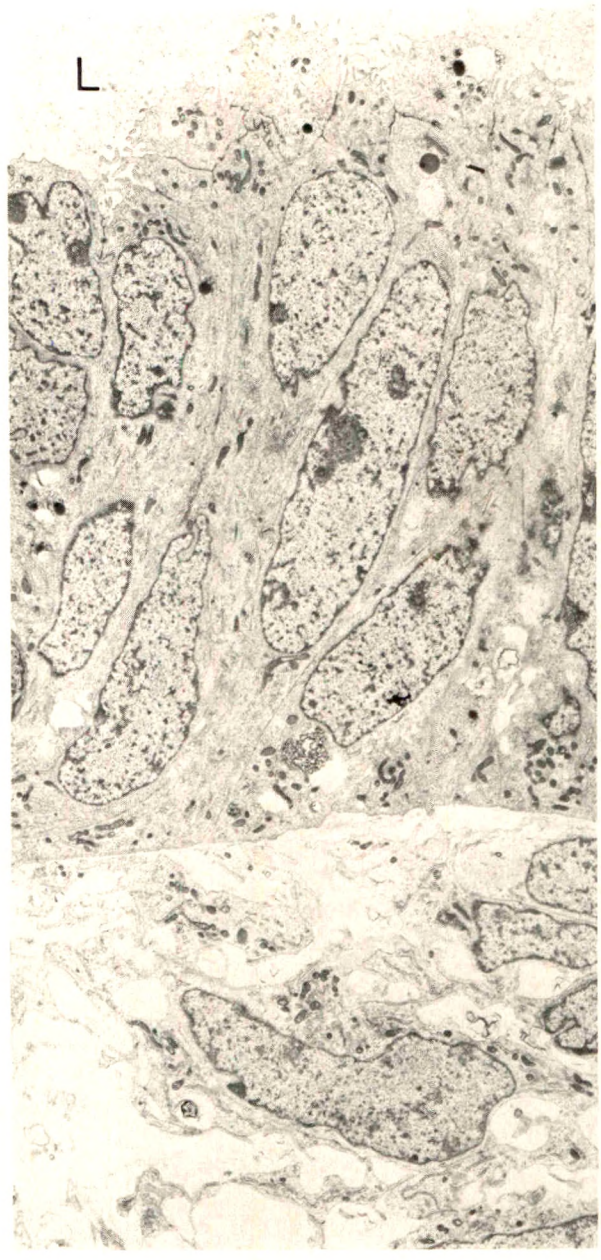

Fig. 2. Paramesonephric duct. Cells show pseudostratification; nuclei are large and contain prominent nucleoli. Microvilli extend from cell apices into lumen *(L)*. (×2548.)

interdigitate with those of neighboring cells, imparting the appearance of a network of subepithelial mesenchymal cells connected by delicate cell processes (Fig. 5). Often the cell body, which includes the nucleus, does not appear in a subepithelial zone of varying width. Consequently, this zone appears pale on light microscopy since it contains few nuclei and is composed primarily of delicate cell processes (Figs. 6 and 7).

Those stromal cells near the basal lamina of the mesonephric ducts have elongate fingerlike processes that

Note absence of basal lamina where epithelial stromal cell *(S)* closely approaches basal plasmalemma *(arrowheads)* of paramesonephric duct *(PMD)*. Delicate basal lamina *(large arrow)* is present at periphery. Stromal cell contains a large Golgi complex *(G)*. (× 10,200.)

Fig. 4. Mesonephric duct. Cells are columnar and appear less pseudostratified than paramesonephric duct. Lumen *(L)* contains granular precipitate. Subnuclear glycogen vacuoles *(V)* are prominent. Stromal cell processes closely abut basal lamina. (×3600.)

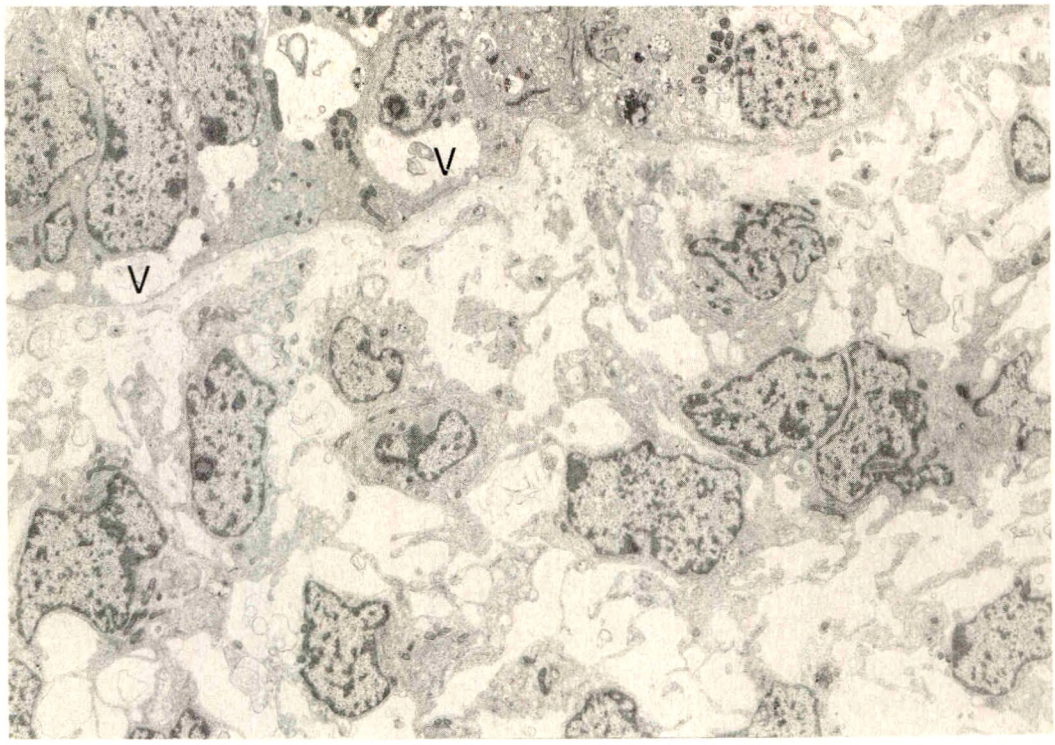

Fig. 5. Mesonephric duct. Stromal cells underlie mesonephric duct epithelium with subnuclear vacuoles *(V)*. Epithelioid stromal cells exhibit elongated cytoplasmic processes that interdigitate with neighboring cells. Nuclei are large, irregularly shaped, and contain prominent nucleoli. (×3913.)

extend to and make contact with the basal lamina (Fig. 6). In spite of the delicate nature of the cytoplasmic processes, they contact the basal lamina in such numbers that its surface is virtually covered, imparting a fine structural appearance reminiscent of podocytes in the renal glomerulus. This situation contrasts with the paramesonephric ducts, in which subepithelial stromal cells lie immediately subjacent to the basal lamina, accompanied by its focal dissolution. The basal lamina of the mesonephric duct appears continuous. There are, however, pinocytotic vesicles like those observed in the paramesonephric ducts present along the basal plasmalemma of the mesonephric duct; likewise, membrane-bound vesicles similar to those in stromal cells in the immediate vicinity of the paramesonephric ducts are observed in the stromal cells of the mesonephric duct.

In its most caudal portion, which represents the advancing edge, the paramesonephric duct is in direct apposition to the mesonephric duct (Fig. 8). In addition to their anatomic location, the gonoducts in this region are easily differentiated by the presence of abundant intracytoplasmic glycogen in the mesonephric ducts and its near absence in the paramesonephric ducts. In the advancing paramesonephric duct, cell membranes are tightly apposed, with complex interdigitations and sparse, poorly formed intercellular attachments. Numerous mitotic figures are present. Abundant microtubules are present throughout the cytoplasm.

At the point where the two gonoducts are immediately adjacent, mesonephric duct and paramesonephric duct cells are in intimate contact; cell membranes are directly apposed and no basal lamina is present between them (Fig. 9); basal lamina is present, however, in patches along the coelomic aspect of the advancing edge of the paramesonephric duct. Cytoplasmic filaments parallel to the long axis of the duct are present near the cell membrane in apposing ductal cells. Although focal thickening of the cell membrane is observed, the few intercellular attachments that are present lack the structure of a complete desmosome.

Comment

No differences in the light and ultrastructural features of the gonoducts could be discerned between sexes in genital tracts obtained during the ambisexual stage of development; during this time period, the developing testis has not yet produced müllerian-inhibiting substance, which induces regression of the paramesonephric duct.

The finding of comparable morphologic features between the early paramesonephric and mesonephric ducts of both sexes is similar to that observed in mice of 12 days' gestation,[1] in which the critical period of

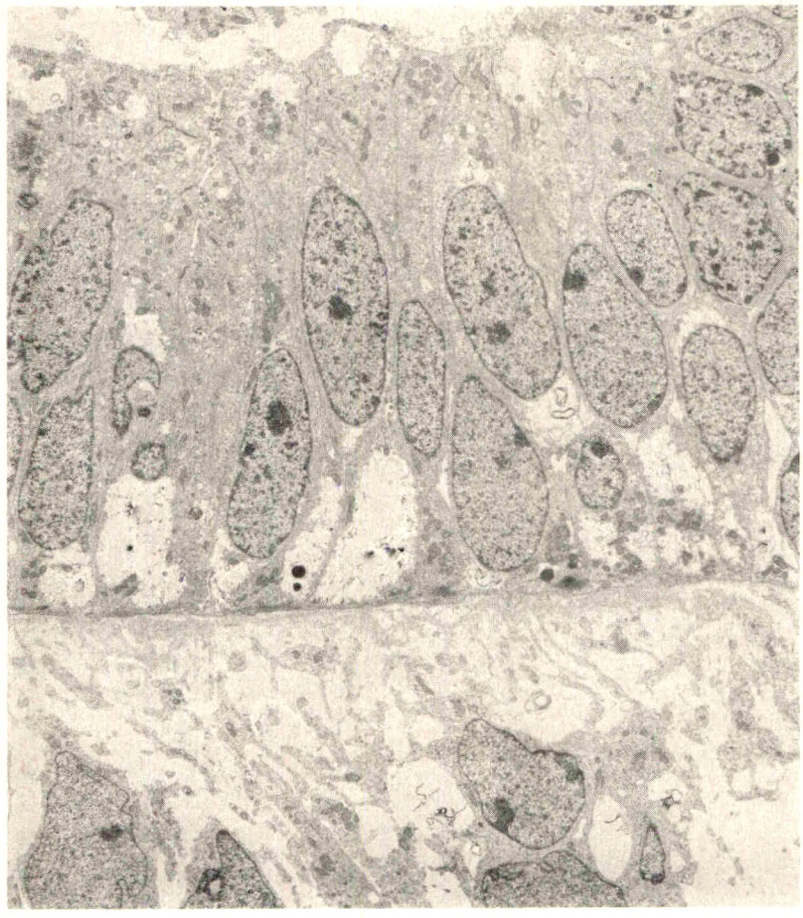

Fig. 6. Mesonephric duct. Subepithelial zone of stroma is composed predominantly of delicate stromal cell processes. (×2548.)

mesonephric duct and paramesonephric duct regression occurs between 13 and 14 days.

The paramesonephric and mesonephric ducts could be readily differentiated by their position in the mesonephros; the paramesonephric duct is situated most laterally, between the overlying coelomic epithelium and the mesonephric duct. Besides positional differences in the mesonephros, the early developing gonoducts have certain light microscopic and ultrastructural characteristics that permit their identification. By light microscopy, cells of the paramesonephric ducts generally appear more pseudostratified than the mesonephric duct, an impression that is supported by the closely packed and crowded columnar cells with their nuclei at varying levels within the epithelium. As in the mouse,[1] mesonephric duct cells, in contrast, have relatively straight cell borders and less variation in nuclear position than their paramesonephric duct counterparts.

Both gonoducts show apical microvilli bordering the lumen; however, those of the paramesonephric ducts are generally more numerous and elongate, sometimes with terminal branching; the latter's appearance resembles that seen in the adult endometrium, fallopian tube, and endocervix, all of which are derived from the paramesonephric duct. Microvilli of the mesonephric duct cells are sparse, short, and stubby, a picture similar to that seen in the paratubal mesonephric ducts of the female adult.[7] Although both mesonephric ducts and paramesonephric ducts of the early embryo may produce cilia-like structures, they are rudimentary and the ciliary shafts lack the characteristic nine sets of peripheral double tubules surrounding a central pair of tubules. No well-formed ciliary bodies or cross-striated rootlets were identified. Ciliated cells found in paramesonephric-derived epithelia probably function in the movement of surface materials such as endometrial secretions. The absence of well-formed cilia in the developing gonoducts may reflect the lack of need for such locomotor ability at that particular stage of differentiation. Abundant cilia have been described in the tubules of the paratubal mesonephric remnants, but not in the mesonephric ducts of the female adult.[7]

The most striking light microscopic and ultrastruc-

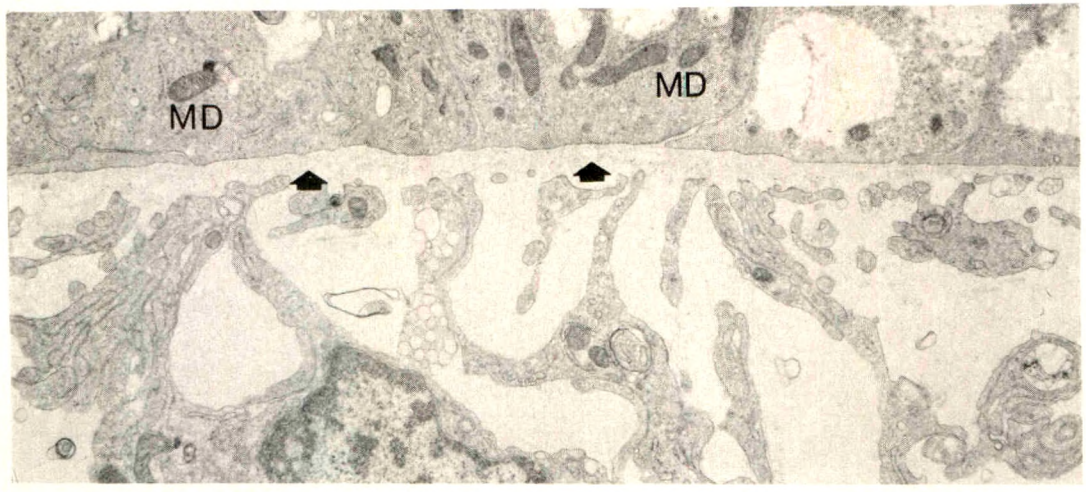

Fig. 7. Mesonephric duct. High magnification of epithelial-stromal interface shows elongated stromal cytoplasmic processes that make contact with basal lamina *(arrowheads)* of mesonephric duct *(MD)* cells. (× 10,200.)

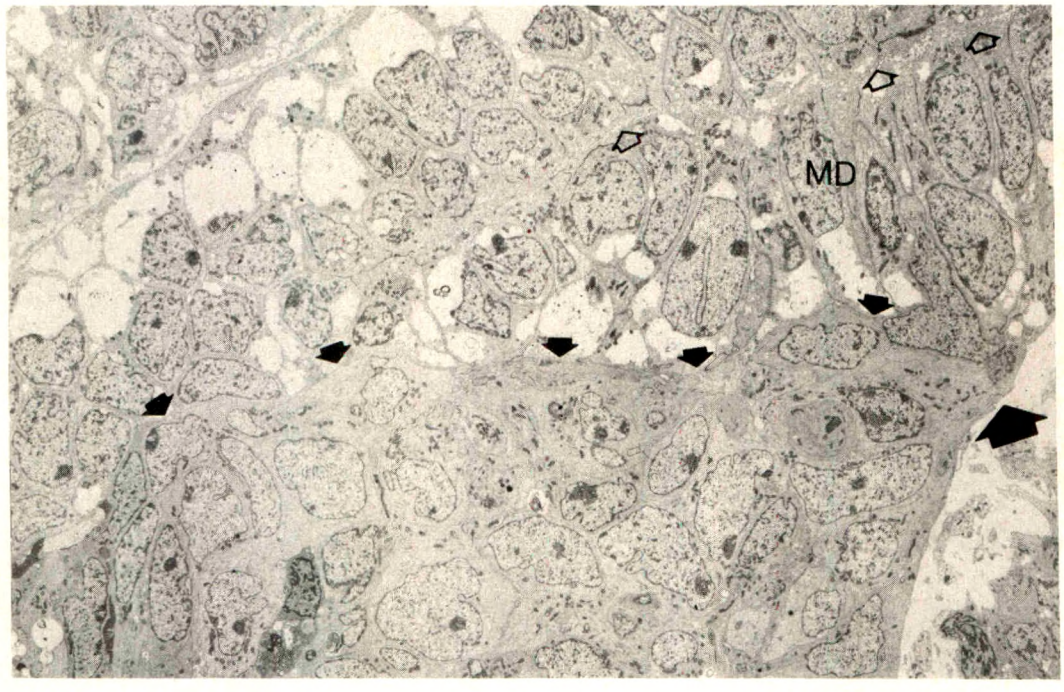

Fig. 8. Paramesonephric and mesonephric ducts. Advancing edge of paramesonephric duct *(large arrowhead)* composed of solid mass of cells without lumen formation growing adjacent to mesonephric duct cells *(MD)*. tural difference between the early gonoducts is the presence of abundant intracytoplasmic glycogen within the mesonephric duct cells. Glycogen most commonly forms a single, large subnuclear vacuole reminiscent of that seen in secretory endometrial glands of day 16 or 17. Similar aggregates of glycogen are rarely seen in cells of the paramesonephric duct. This is in contrast to the frequent and often prominent role of glycogen in the paramesonephric-derived tissues, especially the endometrial glands, of the mature female. In the adult endometrium, glycogen moves from a subnuclear to a supranuclear position and eventually is discharged into the lumen, presumably for nutritive purposes for the implanted conceptus. In the mesonephric ducts, conversely, glycogen infrequently assumes an apical position in the cytoplasm and has not been identified within

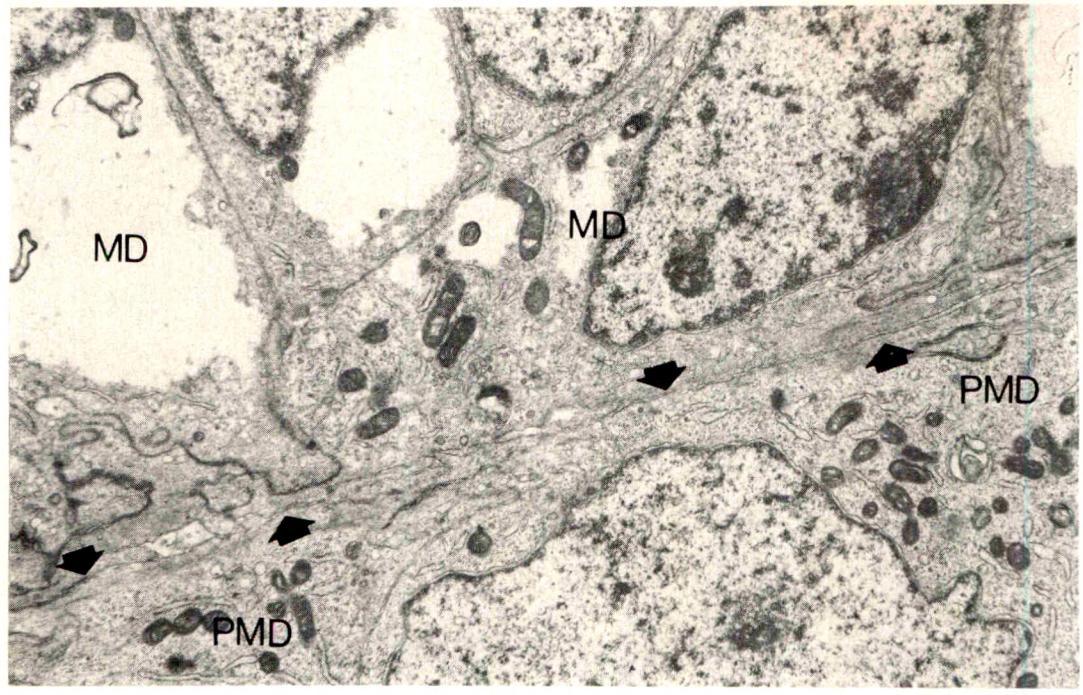

Fig. 9. Higher magnification of paramesonephric-mesonephric duct junction *(arrowheads)*. Neither basal lamina nor desmosomes are present between paramesonephric *(PMD)* and mesonephric *(MD)* duct cells. (×12,375.)

the lumen. Ultrastructural studies of the paratubal remnants in adult women[7] have demonstrated that the mesonephric ducts and tubules retain the ability to synthesize glycogen, as evidenced by the accumulation of glycogen particles in their cytoplasm. In the developing mesonephric ducts large aggregates of glycogen may be used for energy purposes rather than as a secretory product.

In cephalad sections, abundant mesenchyme clearly separates the gonaducts. More caudally, the ducts appear progressively closer until they are adjacent, without identifiable stroma or basal lamina between them. The latter finding, plus the clinical observation that paramesonephric, or müllerian, development is ablated if the mesonephric duct is missing, is responsible for the widely held belief that the paramesonephric duct uses the mesonephric duct as a "guidewire" in its descent to the urogenital sinus.

Few studies have dealt with the close anatomic relationship of the mesonephric and paramesonephric ducts. Gruenwald's early study of human and chick embryos[6] emphasized the influence of the mesonephric duct on the developing paramesonephric duct. Interruption of the mesonephric duct inhibited growth of the paramesonephric duct distal to that point. Developmental anomalies in man also support the hypothesis that a similar relationship exists between the paramesonephric and mesonephric ducts in human embryos.

The current ultrastructural study supports many of Gruenwald's light microscopic findings[6]; the caudal tip of the elongating paramesonephric duct is a solid wedge of cells forming a bulge on the lateral wall of the mesonephric duct, where it is closest to the coelomic epithelium. That this is the proliferating end of the paramesonephric duct is suggested by the numerous mitotic figures and the lack of a lumen at this stage of gonoductal development. Gruenwald interpreted the advancing wedge of paramesonephric duct cells to be within the basement membrane of the mesonephric duct. In our experience the basal lamina of the medial, or anticoelomic, aspect of the mesonephric duct is intact and continuous; however, the basal lamina appears to be interrupted at the most caudal point where the advancing paramesonephric duct cells contact the basal aspect of the mesonephric duct cells. No basal lamina was identified around the solid cord of paramesonephric duct cells, nor was basal lamina found between the two types of ductal cells in the region of the contiguous mesonephric and paramesonephric ducts.

Some early workers stressed, on the basis of light microscopic evidence, that the paramesonephric (müllerian) wedge splits off from the mesonephric duct. However, our findings show both to retain their histologic and ultrastructural identity throughout their length, including the area of apposition, which supports the separate origin of the two gonoducts.

Cunha and Lung[8, 9] have shown that normal development of the uterus and vagina depends on interactions between the epithelium and stroma of those tissues that are ultimately derived from the paramesonephric duct. The unusual relationship between the mesonephric and paramesonephric ducts and their periductal stroma suggests that epithelial-stromal interaction is important in the morphogenesis, and possibly maintenance, of both. Our ultrastructural findings suggest that the gonaducts have different morphologic patterns of epithelial-stromal contact. Intimate contacts between the stromal cell processes and the basal lamina of the mesonephric duct may provide an avenue for transfer of inductive substances to the basal lamina. The stromal cell processes are numerous so that the basal lamina of the mesonephric duct is virtually covered by them, resulting in a large area of stromal cell–basal lamina contact. The presence of large and prominent Golgi complexes polarized to the epithelial side of stromal cells indicates that they elaborate a secretory product, perhaps an inductive molecule. Pinocytotic vesicles located on the basal epithelial surface, similar to those described by Cunha and Lung[8] in the developing vagina, may represent endocytosis of the inductive material elaborated by stromal cells. Morphometric studies of the vesicles containing basal lamina—like material indicate that they originate from basal membrane and undergo degradation as they move into the cell.

In the paramesonephric duct, epithelial-mesenchymal contact is characterized by close proximity of stromal cell bodies to the base of the paramesonephric duct cells but without the interposition of delicate and elongate cell processes. The incomplete or absent basal lamina in these areas of intimate contact may facilitate the intercellular movement of inductive molecules. In such foci, epithelial cell processes extend into the stromal compartment and make physical contact with mesenchymal cell membranes. This phenomenon resembles that of the embryonic male rat paramesonephric duct[2] where the contact between epithelial and mesenchymal cells was associated with stripping of the basal lamina as a major event in early paramesonephric (müllerian) duct regression. The occurrence of a similar but focal phenomenon in the early paramesonephric duct suggests that close epithelial-mesenchymal cellular contact may occur focally to dissolve the basal lamina and facilitate intercellular transport. The bulk of the subepithelial stromal cell cytoplasm, including most of the organelles, is polarized to the ductal side of the cell. Therefore the Golgi apparatus, presumably the site of vesicle formation, is closest to the point of egress, or exocytosis, of its secretion. That actual transfer of molecules occurs from the mesenchymal to the epithelial compartment is suggested by the close fine structural similarity of the vesicles in both types of cells.

We appreciate the expertise of Chris Charron in the editing and preparation of the manuscript.

Activation of protein kinase C stimulates collagenase production by cultured cells of the cervix of the pregnant guinea pig

Mohammad R. Rajabi, MD, PhD,[a, c] Samuel Solomon, PhD,[c] and A. Robin Poole, PhD[b]
Montreal, Quebec, Canada

OBJECTIVE: Dilatation of the uterine cervix at parturition is achieved by an estrogen-induced, collagenase-mediated degradation of type I collagen in the cervix. The objective was to test the hypothesis that collagenase production in the cervix of pregnant guinea pig in culture is mediated by activation of protein kinase C.
STUDY DESIGN: The effects of 17β-estradiol, prostaglandin $F_{2\alpha}$, or activation of protein kinase C by phorbol-12-myristate-13-acetate, 1-stearoyl-2-arachidonyl-*sn*-glycerol and phospholipase C on collagenase production was studied with primary monolayer cultures of cervical cells from Hartley guinea pigs at 50 days' gestation. Results are analyzed for statistical significance with analysis of variance.
RESULTS: Collagenase production is increased twofold to threefold by 17β-estradiol, prostaglandin $F_{2\alpha}$, or activation of protein kinase C. The observed stimulation of collagenase production by 17β-estradiol and prostaglandin $F_{2\alpha}$ was blocked by the protein kinase C inhibitor 1-(5-isoquinoline sulfonyl) 2-methylpiperazine dihydrochloride.
CONCLUSION: Collagenase production in cultured cervical cells of pregnant guinea pig is stimulated by activation of protein kinase C. (Am J Obstet Gynecol 1992;167:194-200.)

Key words: Cervical dilatation, collagenase, estrogens, prostaglandins, protein kinase C

Interstitial collagenase is a Ca^{2+} and Zn^{2+}-dependent metalloprotease, the action of which is an essential component of the overall metabolism of fibrillar collagen in the extracellular matrix. Collagenase cleaves collagen types I, II, and III, the predominant collagens of mammalian tissues. Its sole action is to cleave collagen by hydrolyzing the peptide bonds between Gly-Leu in the α_2-chain and Gly-Ile in the α_1-chain of type I collagen at a single locus in the native triple helical domain.[1] Once the collagen molecule is cleaved into two fragments (¾ length fragment TC^A and ¼ length fragment TC^B), the fragments denature and are further cleaved by gelatinase, PZ-peptidase, and dinitrophenyl-peptidase, followed by phagocytosis and further digestion by lysosomal enzymes.[1, 2]

Collagen degradation is observed in biologic processes characterized by remodeling of connective tissue, such as bone resorption, wound healing, embryogenesis, postpartum uterine involution, and ovulation and in diseases such as osteoarthritis, rheumatoid arthritis, corneal ulcers, epidermolysis bullosa, periodontal disease, and tumor invasion.[2] Rapid collagen degradation is an underlying feature of cervical dilatation at parturition in both human and guinea pig.[3-7]

We have been interested in the mechanism of cervical dilatation at parturition. We have previously shown that cervical dilatation is accompanied by a considerable increase in extractable collagenase in the uterine cervix in women and in the guinea pig at parturition.[3, 7] High levels of circulating collagenase are also present in women in premature labor.[8] Such studies have indicated that collagenase probably plays an important role in the rapid collagen degradation observed in normal parturition and in the pathophysiology of premature labor.

We have chosen primary monolayer cultures of cells isolated from the cervices of pregnant guinea pigs at 50 days' gestation to study the mechanism of signal transduction of collagenase production for the following reasons: (1) there is an inadequate supply of cervical tissue from pregnant women, (2) cervical dilatation at parturition in both species is associated with a decrease in collagen (chemically and histologically) and a significant increase in extractable levels of collagenase in the cervix,[3, 4, 7] and (3) the guinea pig's reproductive system resembles that of women in that it has a similar ovu-

lation cycle, ovulates spontaneously, and has an actively secreting corpus luteum, and most importantly continuation of pregnancy is not dependent on ovarian hormones after the first half of pregnancy.[9] These characteristics make the guinea pig an appropriate model for studies of human reproduction.[9]

Collagenase is synthesized and rapidly secreted by fibroblasts and chondrocytes.[1] Synthesis and secretion are stimulated by platelet-derived growth factor,[10] epidermal growth factor,[11] interleukin-1,[12] tumor necrosis factor,[13] and phorbol esters.[14] We have previously shown that collagenase messenger ribonucleic acid and collagenase activity are stimulated by human recombinant interleukin-1β and 17β-estradiol in monolayer cell cultures of cervixes of pregnant guinea pigs at 50 days gestation.[6] Furthermore, collagenase biosynthesis in culture is mediated by prostaglandins (PG) $F_{2\alpha}$ and E_2.[6] The mechanism of signal transduction of collagenase production in the guinea pig cervix is not known. This study examines the role of protein kinase C on collagenase production in the cervix of the pregnant guinea pig. Hydrolysis of endogenous phosphatidylinositol bisphosphate by phospholipase C results in the release of inositol triphosphate and diacylglycerol.[15] The release of inositol triphosphate and diacylglycerol results in increasing intracellular calcium concentration and activation of protein kinase C, respectively.[16] The present study extends our previous findings by providing evidence that activation of protein kinase C results in stimulation of collagenase production in cervical cell cultures of guinea pigs at 50 days' gestation.

Material and methods

Material. The following reagents were obtained from the Sigma Chemical Company, St. Louis: tamoxifen, $PGF_{2\alpha}$, 17β-estradiol, phorbol myristate acetate, 1-Stearoyl-2-arachidonyl-*sn*-glycerol, phospholipase C, bacterial collagenase type AI, deoxyribonuclease type 1, and *bis*-benzimide (Hoechst H33258). Trypsin 1:250 was obtained from Difco Laboratories, Detroit. 1-(5-Isoquinoline-sulfonyl)-2-methylpiperazine dihydrochloride (H-7) was obtained from Seikagaku America, St. Petersburg, Fla. Aquasol scintillation fluid and tritiated-methyl-thymidine were obtained from New England Nuclear, Dupont, Markham, Ontario.

Animals. Adult Hartley guinea pigs (Charles River, Montreal) were housed in guinea pig cages (three to five per cage) with a 12-hours-light and 12-hours-dark cycle and fed guinea pig chow and water as desired. Timed gestation was induced by mating animals within 12 hours of delivery. Pregnant animals at 50 days of gestation ($n = 10$) were anesthetized with intramuscular ketamine hydrochloride (50 mg/kg) and xylazine (3 mg/kg). After approximately 15 minutes they were killed by intracardiac exsanguination. With aseptic technique a midline laparotomy and a total abdominal hysterectomy were performed according to a protocol approved by the Royal Victoria Hospital Research Animal Care Sub-Committee.

Cervical cell isolation and culture. Cervices obtained from 10 pregnant guinea pigs at 50 days' gestation were cut into 2 to 4 mm pieces and digested with 0.05% trypsin 1:250/0.02% ethylenediaminetetraacetic acid (EDTA) in calcium and magnesium-free phosphate-buffered saline solution (for 15 minutes on ice, followed by digestion with bacterial collagenase type AI, 0.5 mg/ml) and deoxyribonucleas type I (0.05 mg/ml) in Dulbecco's modified Eagle medium for 4 to 6 hours at 37° C with gentle agitation. The digested mixed cervical cells were recovered by centrifugation at 365*g* for 10 minutes at room temperature every 1 to 2 hours followed by washing once with Hanks' balanced salt solution. The process was repeated until the tissue was completely digested (usually within 6 hours). The released cells were filtered twice through nylon monofilament with a pore size of 400 μmol/L (Swiss Nitex, Thompson, Montreal) and recovered by centrifugation at 365*g* for 10 minutes at room temperature. The cells were washed three times with Hanks' balanced salt solution followed by suspension in Dulbecco's modified Eagle medium containing heat-inactivated (60° C for 30 minutes) 10% fetal calf serum, penicillin G sodium (100 U/ml), streptomycin sulfate (100 μg/ml), and amphotericin B (1.25 μg/ml). Cell viability exceeded 90% as determined by the trypan blue exclusion test (approximately 3×10^6 cells per cervix). For each experiment three to four pregnant guinea pigs at 50 days of gestation were used. Cells were counted with a hemocytometer slide. Cells were plated in Limbro plates containing 96 flat-bottom wells, (Flow Laboratories, McLean, Va.) at 1×10^5 cells per well in 300 μl medium and incubated in a humidified atmosphere of 5% carbon dioxide in air at 37° C. After 3 days almost all cells had adhered. The medium and unattached cells were removed and replaced with fresh medium. Cells were then grown to confluency (usually within 3 days). Immediately before analysis of collagenase production, the cells were washed once in Hanks' balanced salt solution, followed by the addition of different concentrations of the chemicals and hormones to be tested in serum-free Dulbecco's modified Eagle medium containing penicillin, streptomycin, and amphotericin B at the concentrations described above with appropriate controls containing ethanol, which was used as the solvent at 0.1% to 0.3% final concentration of ethanol in Dulbecco's modified Eagle medium. After a further 72 hours culture media were collected and frozen at −20° C until assayed for collagenase. The cells were collected after a brief exposure to 100 μl per well of 0.05% trypsin and 0.02% EDTA in calcium and mag-

Table I. Tritiated methyl thymidine incorporation

	Incorporation	
	Counts/min (mean ± SEM)	*%*
Control Dulbecco's minimum essential medium	62,753 ± 3,393	5.76

Tritiated methyl thymidine added to each well contained 1.1×10^6 counts/min. Each value gives the mean value ± SEM for quadruplicate wells. There were no significant differences.

nesium-free phosphate buffered saline solution (5 to 10 minutes, 37° C). Representative wells were counted with a hemocytometer slide. Cells from the remaining wells were frozen at −20° C for deoxyribonucleic acid (DNA) determinations.

Collagenase assay. Acid-soluble collagen was purified from the skins of adult female Sprague-Dawley rats, and the collagenase substrate tritiated telopeptide-free collagen type I was prepared as previously described.[6] Collagenase was assayed with the specific collagenase method described by Dean and Woessner[17] with some modifications. Briefly, enzyme samples (up to 100 μl in assay buffer) were incubated with 10 μl of tritiated telopeptide-free collagen substrate (specific activity 3.1×10^6 counts/min/mg collagen at 2.24 mg/ml, in 50 mmol/L Tris hydrochloride, pH 7.6, 0.3 mol/L sodium chloride) in 1.5 ml microfuge tubes (39 × 10 mm, Sarstedt, Germany). Aminophenylmercuric acetate (0.5 mmol/L) was added to activate procollagenase. 1,10-Phenanthroline (1 mmol/L) was added to inhibit collagenase and served as a blank control. After 18 to 48 hours of incubation at 30° C, the reaction was terminated by the addition of EDTA, to a final concentration of 40 mmol/L. Collagenase cleavage products (TC^A, TC^B) were further digested by trypsin and chymotrypsin in the presence of type I collagen as a carrier protein for 2 hours at 30° C. The undigested tritiated telopeptide-free substrate was precipitated in 10% trichloroacetic acid at 0° C for 30 minutes in the presence of 250 μg bovine serum albumin (10 mg/ml assay buffer) followed by centrifugation in a fixed speed Eppendorf centrifuge 5413 (Brinkman, Westbury, N.Y.) for 15 minutes. A 100 μl aliquot of the supernatant was mixed with 5 ml Aquasol scintillation fluid and counted in a Beckman scintillation spectrometer (Beckman, Palo Alto, Calif.). Mixing of these volumes resulted in minimal quenching of radioactivity (data not shown). The percent digestion was calculated as the total counts per minute in the supernatant minus counts per minute in the 1,10-phenanthroline blanks divided by original counts in the tritiated telopeptide-free substrate (in 100 μl of 10% trichloroacetic acid in assay buffer) × 100. One unit of collagenase is defined as the amount of collagenase that digests 1 μg of tritiated telopeptide-free collagen type I in 1 minute at 30° C.

Inactivation of tissue inhibitor of metalloproteinase. To prevent the inactivation of activated collagenase by tissue inhibitor of metalloproteinase, the latter was inactivated by reduction of its six disulfide bridges in 2 mmol/L dithiothrietol at 37° C for 30 minutes. To prevent spontaneous reactivation of tissue inhibitor of metalloproteinase, the reduced form was alkylated with 5 mmol/L iodoacetamide at 37° C for 30 minutes. The samples were dialyzed against assay buffer for 18 hours at 4° C, then assayed for collagenase. This treatment increases the detection of collagenase and does not interfere with collagenase activity.[6, 7]

DNA determination. DNA was determined as previously described.[6] Briefly, cervical tissues were digested with proteinase K (0.5 mg/ml) for 24 hours at 56° C in 0.1 mol/L sodium phosphate buffer, pH 6.5, containing 0.01% EDTA. DNA standard curves were prepared from calf thymus DNA (0.1 to 1.0 μg) in 0.1 mol/L phosphate and EDTA buffer. To 100 μl of tissue digest was added 2 ml of a solution containing 1.0 μg/ml *bis*-benzimide in 0.05 mol/L sodium phosphate, pH 7.4, containing 2 mol/L sodium chloride. Fluorescence was recorded with an excitation at 356 nm and emission at 458 nm with a fluorescence spectrophotometer (model 650-IOS, Perkin-Elmer Corporation, Norwalk, Conn.).

Tritiated thymidine incorporation. Primary monolayer cell cultures of cervices from guinea pigs at 50 day's gestation were maintained in 96-well plates in Dulbecco's modified Eagle medium with 10% fetal calf serum until confluency, as described above. The cells were washed twice in Hanks' balanced salt solution followed by the addition of 75 μl of serum-free Dulbecco's modified Eagle medium (in the presence or absence of hormones and chemicals to be tested). Twenty-five microliters of serum-free Dulbecco's modified Eagle medium containing 1 μCi of tritiated methyl thymidine (6.7 Ci/mmol) were added during the last 18 hours in

culture. Cells were incubated in an atmosphere of 5% carbon dioxide in air at 37° C. Culture media were removed, and cells were suspended by brief exposure to 100 μl per well of 0.05% trypsin and 0.02% EDTA in calcium-and magnesium-free phosphate-buffered salt solution for 5 minutes at 37° C. Cells were harvested on filter mats with a cell harvester (Titertek Cell Harvester, Skraton Inc., Sterling, Va.). Filters were added to 10 ml Aquasol scintillation fluid and counted in a Beckman scintillation spectrometer.

Statistical analyses. Results are expressed as the mean ± 1 SEM unless otherwise indicated. Statistical analyses were performed by analysis of variance for multiple observations with RS/1 Statistical Tools (BBN Software Products Corporation, Cambridge, Mass.). Statistical differences were determined with Bonferroni simultaneous confidence intervals for all comparisons, when applicable. Differences between groups were considered significant when $p \leq 0.05$. Dose-response curve fitting was obtained with DeltaGraph version 1.5 with polynomial of degree setting at 3 (DeltaPoint, Inc., Monterey, Calif.).

Results

Effects of phorbol myristate acetate, diacylglycerol, phospholipase C, 17β-estradiol, and $PGF_{2\alpha}$ on DNA replications. Confluent cells were exposed to these chemicals and hormones in serum-free Dulbecco's modified Eagle medium in the presence of tritiated methyl thymidine. There was no significant effect on tritiated thymidine incorporation into DNA when compared with control under these conditions (Table I).

Stimulation of procollagenase by known activators of protein kinase C. The addition of the tumor promoter phorbol-12-myristate-13-acetate (Fig. 1, *A*) or the diacylglycerol 1-stearoyl-2-arachidonyl-*sn*-glycerol (Fig. 1, *B*) resulted in a twofold stimulation of procollagenase production. Each of these activators, at all concentrations tested, resulted in an increase in procollagenase production. Dose-response effects were observed with a maximum response at 10^{-8} mol/L for phorbol-12-myristate-13-acetate and 10^{-7} mol/L for 1-stearoyl-2-arachidonyl-*sn*-glycerol. Similarly, the addition of bacterial phospholipase C (0.01 to 10 U/ml Dulbecco's modified Eagle medium) also resulted in a threefold stimulation of procollagenase production with a maximum response at 0.1 U/ml (Fig. 2).

Evidence for role of protein kinase C in mediating procollagenase stimulation of prostaglandins and estrogen. $PGF_{2\alpha}$ (10^{-6} mol/L) (Fig. 3, *A*) and 17β-estradiol (10^{-7} mol/L) (Fig. 3, *B*) stimulate the production of procollagenase in culture. The observed stimulation by both hormones was completely blocked by 1-(5-isoquinoline sulfonyl)-2-methylpiperazine dihydrochloride, H-7, an inhibitor of protein kinase C.[18] The stimulatory effect of 17β-estradiol but not that of $PGF_{2\alpha}$ was completely abolished by the estrogen antagonist tamoxifen.

Comment

Interstitial collagenase is believed to play an important role in the cleavage of collagen during cervical dilatation at parturition in the human.[3] We have shown that the pregnant guinea pig can be used to study the regulation of this process.[4-7] In this study we have extended our previous findings to examine the mechanism of signal transduction of collagenase production in cultured cervical cells of the guinea pig at 50 days'

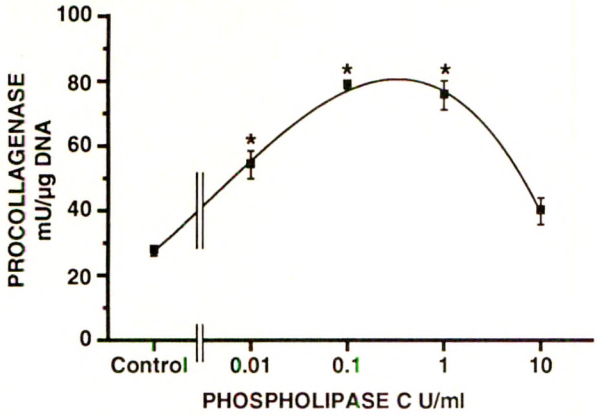

Fig. 2. Effects of hydrolysis of endogenous phosphatidylinositol bisphosphate by bacterial phospholipase C on procollagenase production from primary monolayer cervical cell cultures of three pregnant guinea pigs at 50 days' gestation. Culture medium from each well was reduced with dithiothreitol, alkylated with iodoacetamide, dialyzed, and assayed for collagenase in duplicate in the presence of aminophenylmercuric acetate (0.5 mmol/L, added to activate procollagenase). gestation. Collagenase is not stored in fibroblasts, and biosynthesis is accompanied by prompt secretion of the enzyme into the extracellular matrix.[1] Therefore secretion of the enzyme is a measure of collagenase biosynthesis.[6] Ordinarily, activated procollagenase is inactivated by available tissue inhibitor of metalloproteinase as soon as the enzyme is activated. With a recently developed sensitive and specific assay to detect latent procollagenase and a method to inactivate tissue inhibitor of metalloproteinase, it was possible to measure the total latent enzyme produced by these cells. It was also important to determine the mitogenic effect of the chemicals and hormones used in this study on cervical cells. As shown in Table I, there was no significant effect on cell division as determined by tritiated thymidine incorporation of any of the reagents tested compared with the controls when using confluent cultures and serum-free medium. The dissociation between mitogenic activity and protein synthesis under these conditions allowed us to investigate the effect of these reagents on procollagenase biosynthesis in culture.

The role of protein kinase C activation in procollagenase biosynthesis was studied. Hydrolysis of endogenous phosphatidylinositol bisphosphate by bacterial phospholipase C[15] and activation of protein kinase C by phorbol-12-myristate-13-acetate and diacylglycerol resulted in twofold to threefold stimulation of procollagenase production. These results indicate that production of procollagenase may be mediated by activation of endogenous phospholipase C resulting in hydrolysis of phosphatidylinositol biphosphate, production of diacylglycerol, and activation of protein kinase C. We have previously shown that 17β-estradiol stimulates procollagenase production in cultured cervical cells of guinea pigs at 50 days' gestation through a prostaglandin intermediate with an optimum response at 10^{-7} mol/L.[6] $PGF_{2\alpha}$ also stimulates procollagenase production with an optimum response at 10^{-6} mol/L.[6] In this study the stimulatory effect of 17β-estradiol and not that of $PGF_{2\alpha}$ was completely blocked by the estrogen antagonist tamoxifen, indicating a specific effect of estrogen. The observed stimulatory ef-

(See text for details).

fects of 17β-estradiol and $PGF_{2\alpha}$ were completely blocked by 1-(5-isoquinoline sulfonyl)-2-methylpiperazine dihydrochloride, a protein kinase C inhibitor[18] providing additional support for activation of protein kinase C in collagenase production. These findings are further supported by other reports. Estradiol-17β has been shown to stimulate renal PGE_2 production.[19] PGE_2 is converted to $PGF_{2\alpha}$ by PGE_2 9-ketoreductase that is widely distributed in several tissues.[20] Prostaglandin $F_{2\alpha}$ activates endogenous phospholipase C, resulting in hydrolysis of phosphatidylinositol bisphosphate and activation of protein kinase C.[21]

Other published evidence supports a role for protein kinase C activation in collagenase production. Phorbol myristate acetate, which mimics the effect of diacylglycerol and activates protein kinase C, is a potent stimulator of rabbit synovial cells to produce collagenase in culture.[21] Tumor necrosis factor-α also activates transcription of procollagenase messenger ribonucleic acid by a protein kinase C–mediated activation of the protooncogenes c-*fos* and c-*jun*.[13] The *trans*-acting transcription proteins of protooncogene products (AP1/P39 and FOS proteins) act on the *cis*-acting transcription elements TGAGTCA at positions −73 to −65 upstream of the procollagenase gene, resulting in its activation by a protein kinase C pathway.[13] Such studies provide strong evidence for $PGF_{2\alpha}$-induced, protein kinase–mediated activation of collagenase production. Although the effect of $PGF_{2\alpha}$ on c-*jun* and c-*fos* is not known, the most likely outcome of activation of protein kinase C by $PGF_{2\alpha}$ is an immediate activation of these protooncogenes, resulting in activation of collagenase gene. A schematic presentation of our current state of knowledge on possible $PGF_{2\alpha}$-mediated signal transduction pathways leading to an activation of collagenase gene is presented in Fig. 4.

In this study our finding of stimulation of collagenase production in cultured cervical cells of guinea pigs at 50 days' gestation by $PGF_{2\alpha}$ is in agreement with our previously published studies[5-7] and those of others.[22] With regard to the stimulatory effect of 17β-estradiol on collagenase production, findings from this study are in agreement with our previously published studies with cultured cervical cells of guinea pigs at 50 days' gestation and cultured cervical tissue of nonpregnant animals.[5-7] In the postpartum rat uterus administration

of 17β-estradiol resulted in inhibition of collagenase activity and retardation of postpartum involution of the uterus.[23] Jeffrey et al.,[24] on the other hand, have failed to demonstrate any significant effect on collagenase production by 17β-estradiol in organ culture of the postpartum rat uterus. The apparent discrepancies in the effects of 17β-estradiol on collagenase production may be due to one or more of the following: (1) different responsiveness of two different organs (i.e., uterus and cervix), (2) variation in uptake and metabolism of the administered hormones in vivo and in vitro, and (3) postpartum involuting rat uterus may respond differently from the cervix of the guinea pig at 50 days' gestation.

The finding that bacterial phospholipase C stimulates cervical collagenase production, a key enzyme in cervical dilatation at parturition, is of clinical significance in understanding the pathophysiologic parameters of preterm labor. There is a significant body of evidence suggesting a role for infection-mediated products such as interleukin-1β, platelet-activating factor, phospholipase A_2, phospholipase C, and tumor necrosis factor in the pathophysiologic features of preterm labor.[25] It is possible to speculate that phospholipase C and $PGF_{2\alpha}$ may lead to premature stimulation of cervical collagenase resulting in degradation of type I collagen, the main structural protein in the extracellular matrix of the cervix, and leading to preterm cervical dilatation. High levels of circulating collagenase are present in women at parturition and significantly higher levels are present in women in premature labor, suggesting a role for collagenase in the pathophysiologic characteristics of premature labor.[8]

In summary, collagenase production in cultured cervical cells of 50-day pregnant guinea pigs is stimulated by activation of protein kinase C. Furthermore, 17β-estradiol and $PGF_{2\alpha}$ stimulate collagenase production by activation of protein kinase C.

We thank Jane Wishart and Mark Lepik for processing the figures.

Hydrogen peroxide and reoxygenation cause prostaglandin-mediated contraction of human placental arteries and veins

Hatim A. Omar, MD,[a] Reinaldo Figueroa, MD,[b] Rawhi A. Omar, MD, PhD,[c] Nergesh Tejani, MD,[b] and Michael S. Wolin, PhD[a]

OBJECTIVE: Because our previous studies in several vascular preparations suggest that posthypoxic reoxygenation elicits tone responses by generation of hydrogen peroxide we compared the actions of reoxygenation and hydrogen peroxide on isolated human placental arteries and veins.

STUDY DESIGN: Endothelium-intact and denuded arteries and veins (1 to 2 mm diameter, from normal term deliveries), incubated under 95% oxygen/5% carbon dioxide or 5% oxygen/5% carbon dioxide (balance nitrogen) and precontracted with 1 to 10 nmol/L U46619, were exposed to hypoxia (95% nitrogen/5% carbon dioxide, P_{O_2} 8 to 10 torr) followed by reoxygenation and to 1 to 100 μmol/L hydrogen peroxide in the presence and absence of the inhibitor of prostaglandin biosynthesis, 10 μmol/L indomethacin.

RESULTS: In both arteries and veins posthypoxic reoxygenation or exposure to hydrogen peroxide produced vascular contraction that was eliminated or reversed to a modest relaxation by indomethacin, consistent with mediation by prostaglandins. Hypoxia after incubation with 5% oxygen, but not 95% oxygen, caused a modest prostaglandin-independent relaxation. Removal of the endothelium did not alter any of these responses.

CONCLUSION: Placental arteries and veins show a similar prostaglandin-mediated contraction to hydrogen peroxide and posthypoxic reoxygenation, consistent with a possible involvement of hydrogen peroxide in the response to reoxygenation. (Am J Obstet Gynecol 1992;167:201-7.)

Key words: Endothelium, hydrogen peroxide, oxygen, placental vessels, prostaglandins

Our studies of a variety of vascular preparations have suggested that reoxygenation, with physiologic or hyperoxic oxygen tensions, after a brief period of hypoxia causes vascular responses that appear to involve the generation of hydrogen peroxide.[1-3] For example, in the calf pulmonary and coronary artery reoxygenation appears to produce a hydrogen peroxide–elicited relaxation caused by the activation of guanylate cyclase, resulting in production of the intracellular mediator guanosine cyclic-3′,5′-monophosphate.[1, 2] In the rat skeletal muscle microcirculation, the reoxygenation caused by the release of a brief (15 second) arteriolar occlusion or the administration of hydrogen peroxide causes vasodilation mediated by both the generation of dilator prostaglandins and by a prostaglandin-independent mechanism, which may also involve guanosine cyclic 3′,5′-monophosphate.[3] Therefore the endogenous generation of hydrogen peroxide could contribute to responses in other vascular preparations produced by reoxygenation after exposure to hypoxia.

Changes in oxygen tension have been shown to alter vascular tone of the umbilical artery in vitro in both lamb[4] and human.[5-7] In the lamb umbilical artery both low and high P_{O_2} values were found to cause contraction mediated by acetylcholine,[4] whereas in the human umbilical artery only an increase in P_{O_2} causes contraction, which is mediated by cyclooxygenase products.[7] The human umbilical vein, however, was found to lack this oxygen-induced mechanism.[5] Other studies suggest that oxygen induces thromboxane formation in human umbilical vessels.[8] Exposure of human umbilical artery to oxygen was found to inhibit prostaglandin I_2 formation,[9, 10] whereas hypoxia stimulated its production.[9] The production rate of thromboxane A_2, prostaglandin E_2, and $F_{2\alpha}$, on the other hand, is larger at increased oxygen tension.[9] Thus an increase in P_{O_2} causes a prostaglandin-mediated contraction of human umbilical artery; however, little is known about the effects of changes in P_{O_2} on tone in blood vessels present in the placental segment of the circulation.

In the present study we investigated whether re-

sponses to changes in P_{O_2} observed in the human umbilical artery were present in isolated human placental arteries and veins and whether there are similarities between the response to reoxygenation and to exposure to hydrogen peroxide. Because the endothelium could potentially influence vascular tone by the release of mediators, all studies with changes in P_{O_2} and hydrogen peroxide were conducted in the presence and absence of the endothelium. Because of the potential importance of prostaglandins in the oxygen-elicited responses of the human umbilical artery, the involvement of prostaglandins in all observed responses was examined by inhibition of their formation with indomethacin. In addition, responses were characterized both in the presence of an atmosphere of 95% (P_{O_2} ~ 500 to 600 torr) or 5% oxygen (P_{O_2} ~ 35 torr) for comparison with the hyperoxic environment used in previous studies on isolated vascular tissue or to approximate physiologic oxygen tensions in the placental venous circulation, respectively. A nitrogen atmosphere (P_{O_2} 8 to 10 torr) was used to generate hypoxia.

Methods

Experimental techniques. Placentas from uncomplicated term pregnancies were obtained immediately

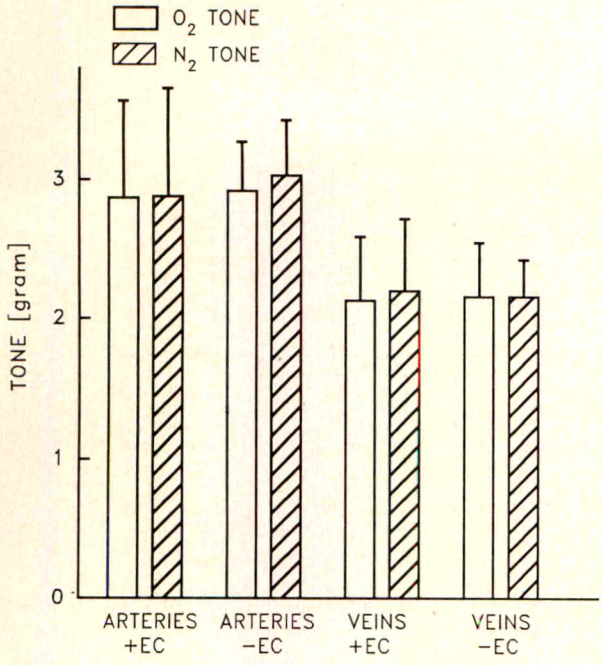

Fig. 2. Effect of brief hypoxia on tone generated by 1 to 10 nmol/L U46619 in human placental arteries (n = 5) and veins (n = 7), both endothelium intact *(+EC)* and denuded *(−EC)* after incubation under 95% oxygen *(O_2)*. Tone is increase in force produced by U46619, once tone has reached steady-state under oxygen and then after exposure to nitrogen *(N_2)* atmosphere. No alteration of tone was observed.

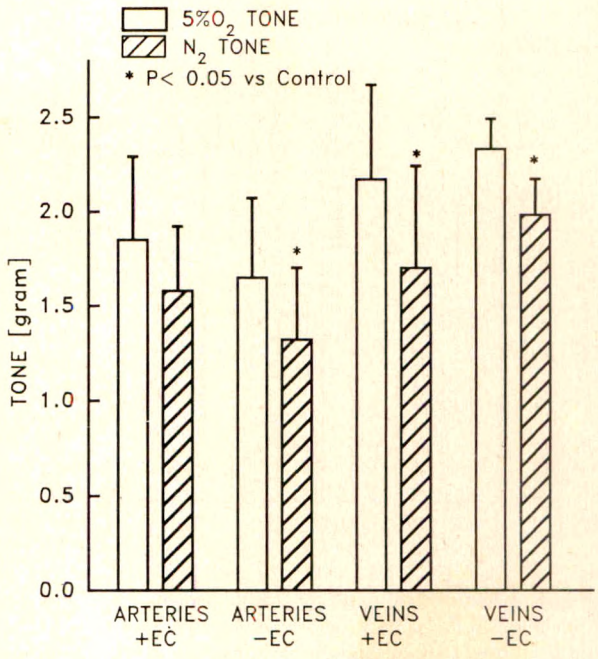

Fig. 3. Effect of brief hypoxia on tone generated by 1 to 10 nmol/L U46619 in human placental vessels (n = 6) after incubation under 5% oxygen. Modest relaxation was observed in all groups. Relaxation of endothelium-intact arteries did not reach statistical significance (p = 0.09) N_2, Nitrogen; *+EC*, Endothelium intact; *−EC*, endothelium denuded.

after vaginal delivery or cesarean section and placed in ice-cold saline solution. Placental arteries and veins were then dissected from the peripheral half of the fetal side of the chorionic plate within 1 hour of delivery and placed in ice-cold Krebs-bicarbonate buffer (pH 7.4) containing the following: sodium chloride, 118 mmol/L; potassium chloride, 4.7 mmol/L; calcium chloride, 1.5 mmol/L; sodium bicarbonate, 25 mmol/L; magnesium sulfate, 1.1 mmol/L; monopotassium phosphate, 1.2 mmol/L; and glucose, 5.6 mmol/L. The vessels were then cleaned carefully from surrounding tissue and cut, with a new scalpel, with extreme care to avoid damage to the endothelium into rings. The vessel rings, 1 to 2 mm in diameter and 2 mm in width, were mounted on wire hooks attached to Grass force displacement transducers (model FT03, Grass Instrument Co., Quincy, Mass.) for measurement of changes in isometric force. Vessels were incubated in 10 ml baths (Metro Scientific), which were temperature-controlled individually (37° C) in Krebs buffer gassed with either 95% oxygen–5% carbon dioxide or 5% oxygen–5% carbon dioxide–90% nitrogen. Tension was continuously adjusted during the equilibration period to 5 gm, which we found to be the optimal baseline force for observation of maximal contraction. The stretching of the vessels to this level of baseline force produced ~1 gm of spontaneous tone generation, on the basis of the maximal relaxation elicited by exposure to nitroglycerin. Changes in force were recorded on a Grass polygraph (model 7), and are reported as the increase in force above the 5 gm of combined passive and stretch-induced tone. Some of the rings were denuded of endothelium by gentle rubbing of the lumen of the vessel with the wooden handle of a cotton swab for about 40 seconds. After a 2-hour equilibration at the optimal passive tension, the vessels were depolarized with Krebs-bicarbonate containing potassium chloride (123 mmol/L) in place of sodium chloride. This treatment produces maximal contraction (~7 gm) and enhances the reproducibility of subsequent contractions. The vessels were then reequilibrated with Krebs-bicarbonate for 30 minutes before experiments were conducted.

The vessels were precontracted with 1 to 10 nmol/L U46619, tone was allowed to achieve a steady-state level, and the gas mixture bubbling the organ bath was then switched from 95% or 5% oxygen to 95% nitrogen (the three gas mixture contained 5% carbon dioxide, which maintained the pH at 7.4) for 5 to 7 minutes followed by rapid reoxygenation with the original gas mixture that was used before exposure to 95% nitrogen. This protocol was designed on the basis of obser-

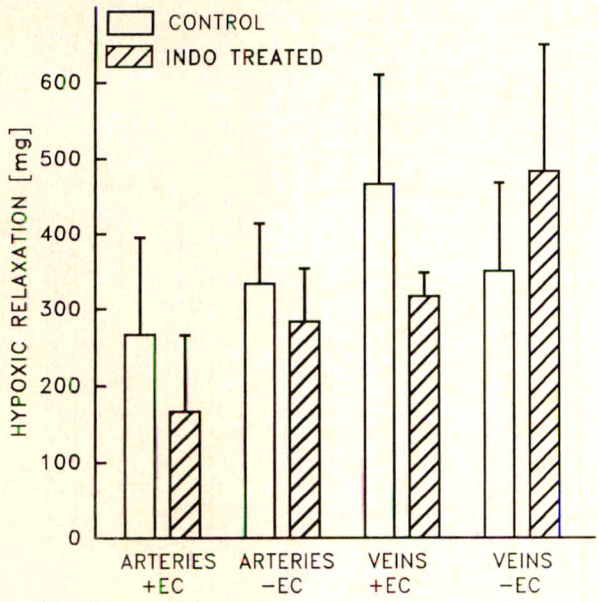

Fig. 4. Effect of indomethacin *(INDO)* treatment on hypoxic relaxation in human placental vessels ($n = 6$). No difference on level of relaxation between groups was observed, and indomethacin did not significantly alter relaxation to hypoxia in any group. *+EC,* Endothelium intact; *−EC,* endothelium denuded.

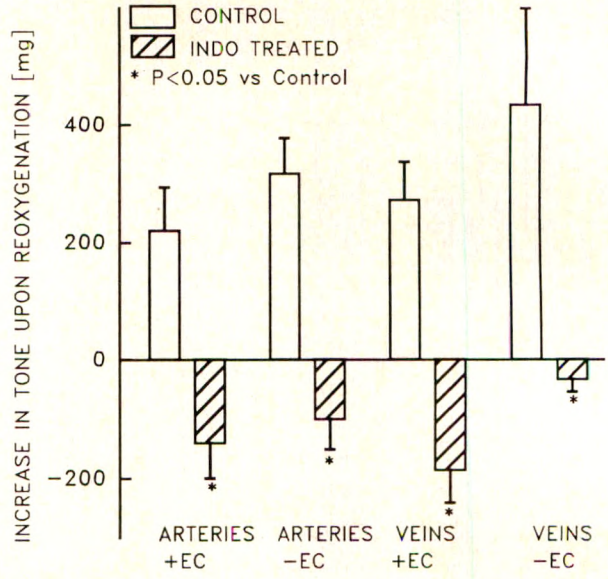

Fig. 5. Summary data showing contraction of human placental arteries ($n = 5$) and veins ($n = 7$) on reoxygenation with 95% oxygen and the effect of indomethacin *(INDO)* treatment on this contraction. No difference on level of contraction between groups was observed. In all groups contraction was reversed to modest relaxation by indomethacin. *+EC,* Endothelium intact; *−EC,* endothelium denuded.

vations from preliminary experiments, where it was found that agonist-induced tone of 1 o 4 gm and a 5-minute period of hypoxia were needed for optimal reproducible observation of the reoxygenation-elicited contraction, that U46619 produced contraction of these vessels that was very stable with time, and that changes in Po_2 produced by shifting the gas mixtures between 5% and 95% oxygen did not alter tone generation. Cumulative doses of hydrogen peroxide (1 to 100 μmol/L) were added to the organ baths when steady-state tone was reached again. A 2-minute period was allowed between doses, and after the highest dose the vessels were thoroughly washed with Krebs solution. After 30 minutes the protocol was repeated in a second experimental cycle. Some of the vessels were treated between the two cycles with 10 μmol/L indomethacin for 15 minutes and the others were used as time controls. Dilutions of U46619 and hydrogen peroxide were made in distilled-deionized water, and 10 μl aliquots were added to the 10 ml baths, as indicated. Indomethacin was dissolved in absolute ethyl alcohol and 10 μl from the solution was added to the bath. Vehicle control with 10 μl ethyl alcohol was done in the first cycle for all vessels in the indomethacin-treated group.

In most experiments both endothelium-intact and endothelium-denuded vessel rings were fixed in 10% buffered formalin, both before and after the experiment, and embedded in paraffin. Sections 5 μm thick were stained with the routine hematoxylin and eosin or immunostained for factor VIII antigen with a commercial staining kit (Dako Corp., Santa Barbara, Calif.) and with standard protocols, which we have routinely used for detection of various antigens.[11]

Material. U46619 was purchased from Cayman Chemical Company, Ann Arbor, Mich. Hydrogen peroxide (30%) and indomethacin were obtained from Sigma Chemical Company (St. Louis).

Statistical analysis. A paired Student t test was used to compare the level of tone or the change in tone between first and second cycle. A one-way analysis of variance with Duncans' multiple range test to determine significance between groups was used for multiple comparisons among different vessels to determine the effects of endothelium and comparisons between arteries versus veins on all responses to hypoxia, reoxygenation, or hydrogen peroxide. The accepted level of significance was $p < 0.05$. The number of experimental determinations in all cases is equal to the number of placentas from which a vessel ring was used for a treatment or control group. Data in the figures are depicted as means ± SE. In all experiments described, responses were found to be reproducible with time.

Results

Histologic examination of the vessels. Hematoxylin and eosin–stained sections clearly demonstrate an intact endothelial layer in control vessels, whereas that layer is almost totally (90% of intial surface) absent in

denuded vessels (not shown). Immunostaining for factor VIII antigen confirms the endothelial nature of the cells (Figs. 1A and 1B).

Effects of hypoxia. In the first group of experiments, conducted on placental arteries and veins gassed with 95% oxygen, exposure to a brief period of hypoxia (Po_2 8 to 10 torr) did not alter the level of tone in any group of vessels, as is shown in Fig. 2. Vessels incubated under 5% oxygen (Po_2 35 to 40 torr), however, underwent a relaxation of ~20% during the first 3 minutes of exposure to hypoxia (Fig. 3). This relaxation was statistically significant in all groups except the endothelium-intact arteries ($p = 0.09$). Similar results were also observed in the presence of indomethacin. Indomethacin did not significantly alter the magnitude of the hypoxic relaxation, as shown in Fig. 4.

Effect of reoxygenation. Reintroduction of 95% oxygen after 5 to 7 minutes of exposure to hypoxia elicited an increase in tone of about 15% to 20% in all vessels. This contraction started almost immediately after reoxygenation and reached maximum within 2 minutes. The duration of this contraction averaged 3 to 5 minutes and was followed by a return to the initial level of tone. Treatment with 10 μmol/L indomethacin eliminated the reoxygenation contraction or reversed it to a modest relaxation (Fig. 5). On the other hand, reoxygenation with 5% oxygen produced significant contraction only in the veins. The arteries showed a very modest increase in tone, which was not statistically significant (Fig. 6). As shown in Fig. 6, indomethacin treatment caused a complete elimination of this contraction, and in general a reversal to relaxation was observed.

Effects of hydrogen peroxide. Addition of 1 to 10 μmol/L hydrogen peroxide caused only a minor, nonsignificant increase in tone (not shown), whereas 0.1 mmol/L hydrogen peroxide elicited contraction in all vessels under both 95% and 5% oxygen (Figs. 7 and 8). There was no significant difference between arteries and veins in their response to hydrogen peroxide under 95% oxygen (Fig. 7), whereas under 5% oxygen the venous contraction to 0.1 mmol/L hydrogen peroxide was more than double that of the arteries (Fig. 8). Hydrogen peroxide addition after treatment with indomethacin, however, caused a modest relaxation in all vessels under both oxygen atmospheres (Figs. 7 and 8). Removal of the endothelium did not alter any of the responses to hypoxia, oxygen, or hydrogen peroxide as shown in Figs. 2 through 8.

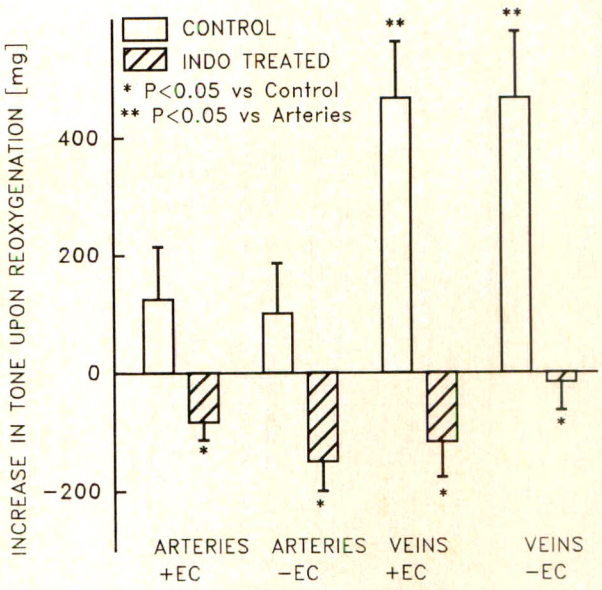

Fig. 6. Effect of reoxygenation with 5% oxygen on human placental vessels ($n = 6$). Veins contracted to significantly ($p < 0.05$) greater level than the arteries; indomethacin *(INDO)* eliminated this contraction and reversed it to modest relaxation in all groups. *+EC*, Endothelium intact; *−EC*, endothelium denuded.

Comment

Similar to findings in human umbilical artery,[5-7] this study shows that oxygen induces contraction in human placental arteries and veins. Responses to increments of Po_2 are not always maintained in human umbilical artery, and a hypoxic period before the introduction of oxygen is needed to observe a response to oxygen.[5-7] As previously described in the human umbilical artery,[5-7] the contraction to reoxygenation in the human placental vessels also seems to be mediated by cyclooxygenase products, because it was eliminated by indomethacin. This mechanism appears to be different from the oxygen-induced contraction in the sheep umbilical artery, where it was reported to be mediated by acetylcholine.[4] Unlike the human umbilical vein, which was reported to lack this oxygen-induced mechanism,[5] the human placental vein in this study was very sensitive to increases in Po_2.

The findings of this study in the human placental vessels is consistent with our previous studies in other vascular preparations[1-3] in that reoxygenation after a brief period of hypoxia leads to a response that is similar to that caused by exposure to hydrogen peroxide. In the human placental vessels hydrogen peroxide induces a prostaglandin-mediated contraction. Because reoxygenation produces a similar contraction, we hypothesize that an abrupt increase in Po_2 after exposure to hypoxia results in the generation of hydrogen peroxide. In our previous studies in other species we have shown that hydrogen peroxide produces tone responses by different mechanisms, including prostaglandins and guanosine cyclic 3′,5′-monophosphate.[1-3]

The observation that hypoxia did not alter tone of the human placental arteries and veins after incubation under 95% oxygen whereas those vessels equilibrated

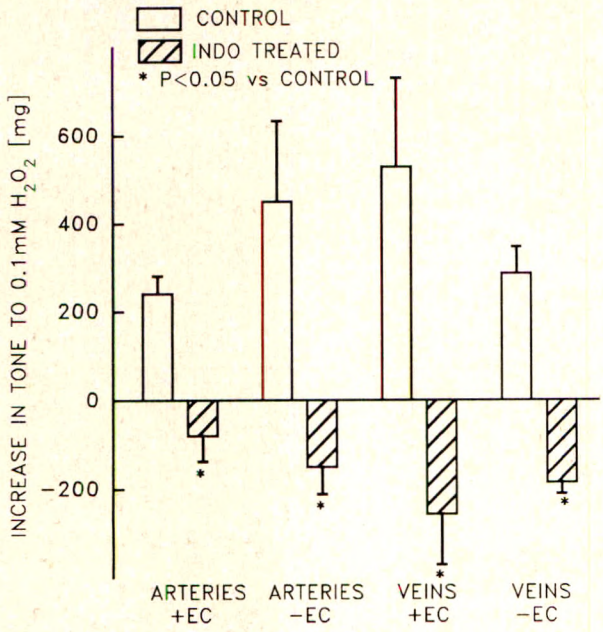

Fig. 7. Effect of topical application of 0.1 mmol/L hydrogen peroxide on human placental arteries (n = 6) and veins (n = 7) under 95% oxygen. No difference on level of contraction between groups was observed. In all groups contraction was reversed to modest relaxation by indomethacin *(INDO)*. *+EC*, Endothelium intact; *−EC*, endothelium denuded.

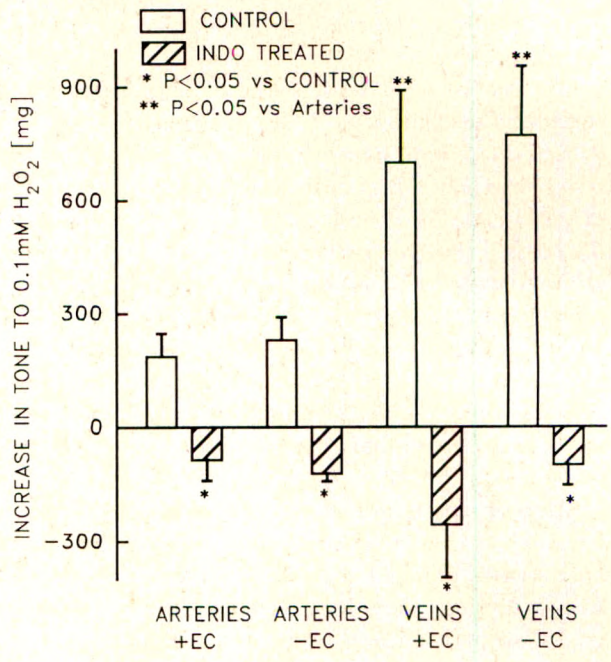

Fig. 8. Effect of 0.1 mmol/L hydrogen peroxide on human placental vessels (n = 7) under 5% oxygen. Veins contracted to significantly ($p < 0.05$) greater level than arteries. Indomethacin *(INDO)* reversed the contraction to modest relaxation. *+EC*, Endothelium intact; *−EC*, endothelium denuded.

under 5% oxygen, showed relaxation to hypoxia is similar to observations in rabbit arteries where chronic exposure to physiologic oxygen tension led to a change in the response to hypoxia.[12] This change in response was termed *adaptation*, a term used to describe previous observations that a prolonged exposure of isolated blood vessels to a certain normoxic or hypoxic oxygen tension resulted in a change in the tone response elicited by exposure to severe hypoxia, followed by reoxygenation to the original oxygen atmosphere. This is similar to the expression of the relaxation caused by exposure to nitrogen atmosphere after prolonged incubation with 5% oxygen, which was not observed in the experiments conducted with 95% oxygen. The observed hypoxic relaxation of human placental vessels in this study does not appear to be mediated by prostaglandins, because it was not significantly changed by indomethacin. However, the mechanism for these responses or adaptation to hypoxia remains to be elucidated.

Results of previous studies[5, 7] and the present study indicate that reoxygenation causes a prostaglandin-mediated contraction. We suggest that reoxygenation after a brief period of hypoxia leads to a period of increased hydrogen peroxide generation, which appears to induce prostaglandin production, leading to the observed contraction. In addition, this response does not depend on the endothelium, because it is present in endothelium-removed vessels.

Currently we do not know what possible physiologic role these oxygen-induced mechanisms may play in the placental circulation; however, the contraction to increased Po_2 has been suggested as a contributor to closure of the umbilical circulation at birth.[4, 5] Further studies are needed to determine if the reoxygenation-elicited contraction could contribute to vasospasm associated with disease processes that affect the placental circulation.

We thank the nursing staff of the labor and delivery unit at Westchester County Medical Center for their assistance.

Inhibitory effect of medroxyprogesterone acetate on angiogenesis induced by human endometrial cancer

Hiroaki Jikihara, MD,[a] Nobuyuki Terada, MD, PhD,[b] Reiko Yamamoto, CT(IAC),[c] Yoshinobu Nishikawa, MD,[a] Osamu Tanizawa, MD, PhD,[a] Keishi Matsumoto, MD, PhD,[b] and Naoki Terakawa, MD, PhD[d]

Osaka and Yonago, Japan

OBJECTIVE: The purpose of this study was to investigate the effect of medroxyprogesterone acetate on angiogenesis induced by endometrial cancer and to elucidate the possible mechanisms by which it inhibits the growth of the cancer.

STUDY DESIGN: Tumors were obtained from 29 patients with endometrial adenocarcinoma, and angiogenesis was assayed in corneas of white rabbits.

RESULTS: Transplantation of tumor tissues into rabbit corneas induced angiogenesis in 70.4% of the corneas, but their transplantation with a pellet of medroxyprogesterone acetate induced angiogenesis in only 21.5% of the corneas. This compound also inhibited angiogenesis induced by acidic fibroblast growth factor and transforming growth factor-α.

CONCLUSION: Inhibition of angiogenesis may be one mechanism by which medroxyprogesterone acetate inhibits the growth of endometrial adenocarcinoma, and its inhibition of neovascularization induced by adenocarcinoma may be through its direct action on endothelial cells. (Am J Obstet Gynecol 1992;167:207-11.)

The progressive growth of tumors is associated with neovascularization induced by an angiogenic factor(s) that is secreted by the tumors.[1, 2] Therefore inhibition of neovascularization could be effective for inhibiting tumor growth.[2]

Since Anderson[3] first reported a favorable response in patients with endometrial adenocarcinoma to the potent progestin, medroxyprogesterone acetate, many patients with advanced endometrial adenocarcinoma have been treated with this compound. Clinical studies have shown its efficacy for treatment of endometrial

cancer, although one third of patients with endometrial adenocarcinoma respond objectively to progestin therapy.[4, 5] We previously found that the growth of human endometrial adenocarcinoma cells in primary culture was significantly suppressed by medroxyprogesterone acetate[6]; a growth-inhibitory effect in a nude mouse system has been also reported.[7] On the other hand, Gross et al.[8] and Oikawa et al.[9] have shown by rabbit cornea assay that medroxyprogesterone acetate inhibits angiogenesis induced by rabbit V2 carcinoma, mouse B-16 melanoma, and rat mammary tumor. Although medroxyprogesterone acetate seems to act directly on endometrial cancer to inhibit cancer growth, these findings suggest that its inhibition of angiogenesis may be one mechanism by which it inhibits the growth of endometrial adenocarcinoma. To obtain further information on its mechanism of action in human endometrial cancer, in this study we examined its effect on angiogenesis induced by adenocarcinoma.

Material and methods

Subjects. Tumor specimens were obtained at hysterectomy from 29 patients with primary endometrial adenocarcinoma who had not received previous treatment by radiotherapy, chemotherapy, or hormone therapy. The specimens obtained were immediately immersed in Eagle's minimum essential medium (Handai Biken, Osaka) containing 200 U/ml of penicillin and 200 μg/ml of streptomycin. Each specimen was divided into three equal parts, which were used for progestin receptor assay, histopathologic examination, and angiogenic assay, respectively. The specimens for receptor assay were stored at −80° C and used for assay within a week. Tumor specimens for angiogenic assay were transplanted into rabbit corneas within 3 hours. All specimens were graded histologically as previously described.[10]

Progestin receptor assay. The procedure for assay of cytoplasmic progestin receptors was as previously reported.[10] All procedures were carried out at 0° to 4° C. The tumor tissue was rapidly thawed, and tissue without blood clots or mucus was homogenized in 4 to 10 volumes of phosphate buffer (5 mmol/L sodium phosphate, 5 mmol/L mercaptoethanol, 3 mmol/L magnesium chloride, 10 mmol/L sodium molybdate, and 20% glycerol, pH 8.0). The homogenate was centrifuged in a Hitachi RPS 65 rotor (Hitachi Sales Corp., Tokyo) at 105,000*g* for 60 minutes. Duplicate samples of 0.2 ml of the supernatant (2 to 6 mg/ml of protein) were incubated for 16 hours with a saturating concentration of 10 nmol/L tritiated promegestone (3.22 TBq/mmol; New England Nuclear, Boston) and a 200-fold excess of cortisol. Nonspecific binding was determined by parallel incubations with tritiated promegestone plus cortisol in the presence of a 200-fold excess of promegestone in a final volume of 0.25 ml. The mixture was then incubated further with 25 μl of 2.5% charcoal–0.025% dextran solution for 15 minutes. The charcoal was removed by centrifugation, and the radioactivity of a 0.1 ml aliquot of the supernatant was counted. Samples with progestin receptor levels of >10 fmol/mg protein were classified as receptor positive.

Assay of angiogenesis. Bioassay of angiogenesis with rabbit cornea was carried out as described by Gimbrone et al.[11] All procedures were performed under sterile conditions. Young female Japanese white rabbits were used in the present study. A rabbit was anesthetized by injection of pentobarbital (25 mg/kg body weight) into the marginal ear vein. The eyeball was extruded forward and fixed with a rubber sheet with a hole in it smaller than the eyeball. A 2 mm incision was made in the center of the cornea, and a 2 mm corneal pocket was created by separating the lamella of the corneal stroma with an iris spatula. The base of the pocket was about 1.5 mm from the corneal limbal junction. A 1 mm^3 pellet of ethylene vinyl acetate polymer[12] with or without medroxyprogesterone acetate (200 μg) was placed at the base of the pocket, and then a 1.5 mm^3 piece of tumor was introduced with a trocar needle. Tumor fragments obtained from a patient were transplanted into six corneas of three rabbits, one eye of each rabbit with medroxyprogesterone acetate and the other without as a control. In some experiments a pellet containing 1 μg acidic fibroblast growth factor (aFGF) or 1 μg transforming growth factor-α (TGF-α) instead of a piece of tumor was transplanted into the pocket of the cornea, with or without a pellet containing medroxyprogesterone acetate (200 μg) or progesterone (200 μg).

Ten days after the transplantation, angiogenesis from the limbus was evaluated. For this the rabbit was anesthetized and the eyeball was fixed as described above. Angiogenesis from the limbus was evaluated macroscopically, and the results were confirmed by reexamining the excised corneas under a dissection microscope (Fig. 1). Corneas with inflammatory change or those that had lost tumor fragments were excluded from the evaluation. The excised corneas were fixed in 10% buffered formalin. Sections of 5 μm thickness were prepared and stained with hematoxylin and eosin. The study was carried out according to the guidelines for the care and use of the animals approved by Osaka University Medical School.

Statistics. Results were analyzed statistically by the Mantel-Haenszel test and Breslow-Day test or χ^2 test.

Results

In the control group all tumor fragments from 29 patients with endometrial adenocarcinoma induced angiogenesis in at least one of three corneas. It was therefore considered that the effect of medroxyprogesterone acetate could be evaluated on all 29 tumors. Be-

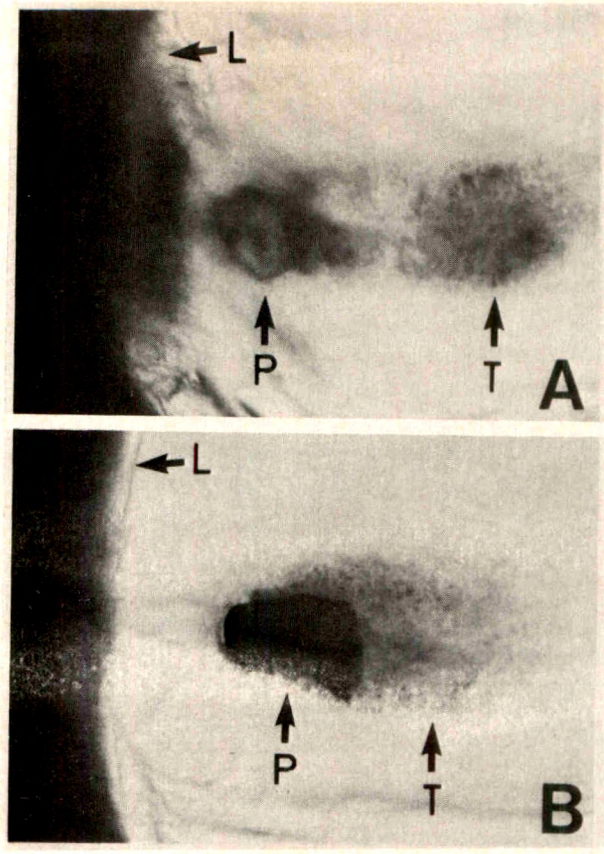

Fig. 1. Angiogenesis induced by endometrial adenocarcinoma 10 days after transplantation of tumor grafts. Eyes were examined with dissection microscope. Marked neovascularization from limbus *(L)* toward tumor graft *(T)* is seen in control eye **(A).** No angiogenesis is seen in contralateral eye in presence of medroxyprogesterone acetate **(B).** *P,* Pellet with or without medroxyprogesterone acetate in cornea.

cause corneas with inflammatory changes and those that had lost tumor fragments were omitted, the effective number of corneal grafts was 71 in the control group and 79 in the experimental group. The adenocarcinoma tissues induced angiogenesis in 50 of 71 (70.4%) control corneas but in only 17 of 79 (21.5%) corneas in the presence of medroxyprogesterone acetate (Fig. 1). The difference between these values for the control and experimental groups was statistically significant ($p < 0.01$). These results indicate that medroxyprogesterone acetate inhibited angiogenesis induced by endometrial adenocarcinoma.

We next examined whether the inhibitory action of medroxyprogesterone acetate on angiogenesis is mediated through progestin receptors in the adenocarcinomas. Of 28 adenocarcinomas examined, 17 were positive for progestin receptors. As shown in Table I, medroxyprogesterone acetate prevented induction of angiogenesis by receptor-positive and receptor-negative tumors to similar extents. In its presence angiogenesis occurred in 10 of 44 (22.7%) corneas containing receptor-positive tumors and in five of 32 (15.6%) corneas containing receptor-negative tumors. These observations suggest that the inhibitory action of medroxyprogesterone acetate on angiogenesis is not mediated through progestin receptors in adenocarcinoma.

With regard to the histologic grade of an adenocarcinoma, 22 tumors were classified as grade 1, four as grade 2, and three as grade 3. There was no apparent difference in the angiogenic activities of tumors of different grades of differentiation in the control group (Table II). In the medroxyprogesterone acetate–treated group, angiogenesis occurred in 12 of 60 (20.0%) corneas containing grade 1 adenocarcinomas and in five of 19 (26.3%) corneas containing grade 2 and 3 tumors. Thus medroxyprogesterone acetate inhibited angiogenesis regardless of the histologic grading of the adenocarcinoma.

The histologic appearance of tumor grafts 10 days after transplantation is shown in Fig. 2. In both the control (Fig. 2, *A*) and medroxyprogesterone acetate–treated (Fig. 2, *B*) group the tumor cells of grade 1 were viable, and there was no apparent difference in the histology of the grafts in the two groups.

Pellets containing the angiogenic factors, aFGF or TGF-α, without tumor tissue induced angiogenesis in all the corneas examined (Table III). Medroxyprogesterone acetate inhibited angiogenesis induced by aFGF in eight of nine corneas and prevented angiogenesis by TGF-α in all five corneas tested.

Finally we examined whether medroxyprogesterone acetate acted as progestin in inhibition of neovascularization. For this a pellet containing 200 μg of progesterone instead of the same amount of medroxyprogesterone acetate was transplanted into corneas. However, progesterone did not inhibit angiogenesis induced by aFGF in any of the nine corneas examined (Table III).

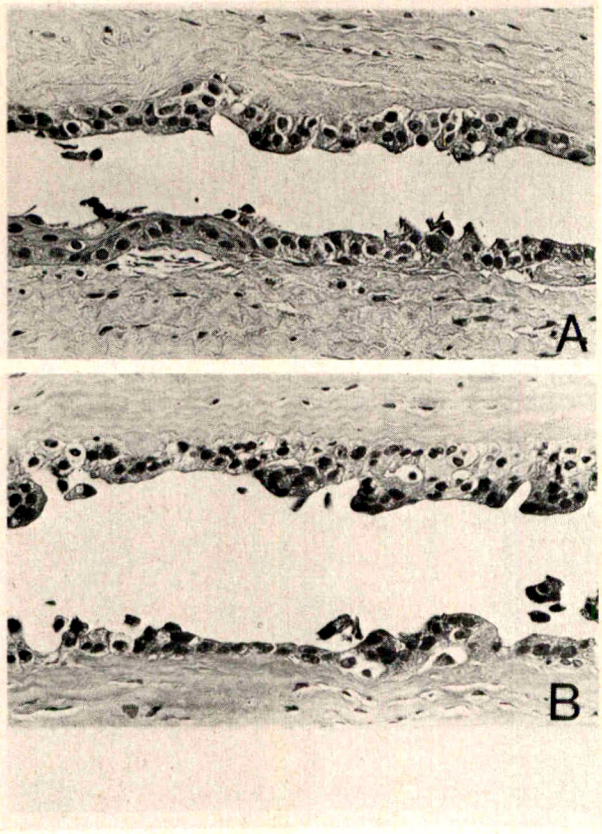

Fig. 2. Histologic appearance of grafts of endometrial adenocarcinoma of grade 1 on day 10 after transplantation. Grafts without **(A)** and with **(B)** medroxyprogesterone acetate were both viable.

Table II. Effect of medroxyprogesterone acetate on angiogenesis induced by endometrial adenocarcinomas of various histologic grades

Histologic grade	*Treatment*	*No. of corneal grafts*	*Corneas with angiogenesis*	
			No.	*%*
Grade 1 (n = 22)	Control	54	39	72.2
	Medroxyprogesterone acetate	60	12	20.2*
Grade 2 and 3 (n = 7)	Control	17	11	64.7
	Medroxyprogesterone acetate	19	5	26.3*

Comment

To our knowledge this is the first report that medroxyprogesterone acetate inhibits angiogenesis in endometrial cancer. Angiogenesis was induced by adenocarcinoma tissues in 70.4% of the rabbit corneas tested in the absence of medroxyprogesterone acetate but in only 21.5% of those tested with medroxyprogesterone acetate. We previously showed that it inhibited the growth of cultured adenocarcinoma cells,[6] and it has been shown to decrease the circulating level of estrogen, which results in regression of adenocarcinomas.[13] The antiangiogenic effect of medroxyprogesterone acetate shown in the present study may be another mechanism by which this compound inhibits the progressive growth of adenocarcinomas.

Recently several studies have shown that human endometrial adenocarcinoma cells produce an angiogenic factor(s)[14-17] and that medroxyprogesterone acetate reduced the activity of this angiogenic factor(s) in an extract of endometrial adenocarcinoma cells in vitro.[17] These results suggest that medroxyprogesterone acetate may prevent the progressive growth of endometrial adenocarcinoma by inhibiting their angiogenic factor(s). On the other hand, in rabbit cornea medroxyprogesterone acetate inhibited angiogenesis and collagenolysis induced by an extract of a human hepatoma.[8] Moreover, it significantly suppressed the activity of a plasminogen activator produced by bovine endothelial cells in vitro.[18] These findings also suggest that medroxyprogesterone acetate may act on the host endothelial cells to inhibit angiogenesis.

We have suggested that in a cell culture system the antiproliferative effect of progestin on endometrial adenocarcinoma cells is mediated through progestin receptors in the cells.[6, 19] Clinical studies have shown that endometrial adenocarcinomas that have progestin receptors are likely to respond to progestin therapy.[4, 5] In the present study, however, medroxyprogesterone acetate inhibited angiogenesis of both progestin receptor-positive and receptor-negative tumors to similar extents, suggesting that its antiangiogenic effect was not mediated through progestin receptors in the adenocarcinomas. Medroxyprogesterone acetate almost completely inhibited the neovascularization induced by the

angiogenic factors aFGF and TFG-α, but progesterone did not influence the activities of these factors. These findings support the conclusion that the antiangiogenic action of medroxyprogesterone acetate is not mediated through progestin receptors.

A statistically significant relationship has been demonstrated between tumor grading of endometrial adenocarcinomas and their response to medroxyprogesterone acetate therapy.[4, 5] A previous in vitro study showed that its cytocidal action is more pronounced in well-differentiated adenocarcinomas.[20] In the present study, however, medroxyprogesterone acetate had antiangiogenic effects on both well-differentiated and poorly differentiated adenocarcinomas. Furthermore, microscopic examination of tumor grafts showed that adenocarcinoma cells were viable in both the presence and absence of medroxyprogesterone acetate. Therefore the antiangiogenic effect on adenocarcinomas was unlikely to be due to a cytocidal action of the compound. Previous studies have shown that an antiangiogenic effect on tumors may be inactivation of the endothelial cells that cause neovascularization.[8, 18] In the current study medroxyprogesterone acetate inhibited neovascularization induced by the angiogenic factors aFGF and TGF-α. Thus these results, together with the previous findings,[8, 18] strongly suggest that medroxyprogesterone acetate acts on endothelial cells and inhibits angiogenesis in endometrial adenocarcinoma, although the possibility that it reduces the production of an angiogenic factor(s) by adenocarcinomas cannot be ruled out.

Medroxyprogesterone acetate inhibited angiogenesis induced by both progestin receptor–positive and progestin receptor–negative adenocarcinomas, and by both well-differentiated and poorly differentiated adenocarcinomas. On the other hand, most of the adenocarcinomas that respond to therapy are progestin receptor positive and well differentiated.[4, 5] This discrepancy between clinical data on medroxyprogesterone acetate therapy and experimental data on its antiangiogenic effect suggests that the antitumor effect of medroxyprogesterone acetate on adenocarcinoma cells plays an important role in the treatment of endometrial cancer, in concert with its inhibitory action on angiogenesis.

We thank Dr. T. Oikawa for advice on assay of angiogenesis.

Changes in expression of the cyclooxygenase gene in human fetal membranes and placenta with labor

Phillip R. Bennett, BSc, MD, Deborah J. Henderson, BSc, and Gudrun E. Moore, BA, PhD
London, England

OBJECTIVE: Our objective was to examine the expression of the gene coding for cyclooxygenase, the central enzyme in prostaglandin synthesis, in human placenta and fetal membranes during pregnancy and before and after labor at term.
STUDY DESIGN: Expression of the gene for cyclooxygenase was examined with Northern hybridization to ribonucleic acid from human placenta throughout pregnancy and human amnion and chorion decidua in the late third trimester.
RESULTS: Expression was undetectable in trophoblast during the first and second trimesters. Expression in amnion and trophoblast increased 3.5- and 2.5-fold, respectively, in association with labor.
CONCLUSIONS: Our results suggest that the increase in prostaglandin synthesis within the uterus that is seen with the onset of labor is associated with an increase in the expression of the gene cyclooxygenase.
(Am J Obstet Gynecol 1992;167:212-6.)

Key words: Gene, cyclooxygenase, labor, amnion, trophoblast

Recently, considerable interest has centered on the role of the fetal membranes in production of prostaglandins, and other eicosanoids in association with human parturition. Labor is associated with changes in the metabolism of the prostaglandin precursor arachidonic acid within the fetal membranes, particularly the amnion.[1] Before labor, archidonic acid metabolism in amnion is primarily through the lipoxygenase enzymes. There is little or no metabolism by cyclooxygenase enzyme pathways to prostaglandins.[2, 3] In association with labor overall arachidonic acid metabolism in amnion increases. The majority of this increase is in cyclooxygenase metabolism to prostaglandin E_2 (PGE_2). Human chorion contains large concentrations of prostaglandin dehydrogenase and is principally a site of prostaglandin inactivation.[4] Human placenta produces both cyclooxygenase and lipoxygenase metabolites of arachidonic acid and an epoxygenase product.[3, 5] Both in the first trimester and after spontaneous labor, placenta has high arachidonic acid metabolic activity, producing cyclooxygenase but principally lipoxygenase and epoxygenase products. At term, before labor, its metabolic activity is significantly reduced.[5]

A number of substances are known to stimulate prostaglandin metabolism by the fetal membranes and are considered as candidates for the control of human parturition. Platelet-activating factor stimulates prostaglandin production in amnion, probably by increasing intracellular Ca^{2+} concentrations and thereby increasing phospholipase activity. Platelet-activating factor is present in amniotic fluid during labor but not before labor. Because platelet-activating factor may be secreted by the fetal lungs, a link has been postulated between fetal lung maturation and initiation of labor.[6] Interleukins (IL) have also been postulated to be the signal for the onset of human parturition.[7] Human decidua is a source of IL-1β. IL-1β stimulates prostaglandin synthesis by amnion and decidua. There appears to be an increase in IL-1β activity in amniotic fluid in the third trimester and a further increase in association with parturition. IL-1β has been shown to stimulate prostacyclin synthesis in human umbilical vein endothelial cells by stimulating an increase in the expression of the gene coding for cyclooxygenase.[8]

It has been postulated that the increase in prostaglandin synthesis seen in the fetal membranes in association with labor is due to an increase in phospholipase activity and a consequent increase in availability of arachidonic acid. However, the accompanying change in the cyclooxygenase lipoxygenase metabolism ratio suggests that there must also be an increase in the activity of the cyclooxygenase enzyme. The complementary deoxyribonucleic acid (cDNA) sequence of cyclooxygenase has been characterized in sheep, mouse, and human.[9-11] Unfortunately, the human cDNA clone has not been made available to us. The sheep cycloox-

ygenase enzyme shows a high degree of homology to the human.[12] We have previously demonstrated that cyclooxygenase is a highly conserved gene found in a wide range of species and that the sheep cDNA may be used to detect expression of the human cyclooxygenase gene by Northern blotting.[12]

To identify whether labor is associated with increased expression of the cyclooxygenase gene we have performed experiments to examine the in vivo expression of cyclooxygenase in human placenta throughout pregnancy and in human amnion and chorion at term before and after spontaneous labor.

Methods

Tissues. Placental tissue was collected at termination of pregnancy by dilatation and suction evacuation at 5, 8, 10, and 12 weeks of amenorrhea and by dilatation and instrumental evacuation at 14 and 20 weeks. Placental tissue was identified macroscopically, and the tissue type was confirmed histologically. Fetal membranes and placenta were collected after delivery by cesarean section at 30 weeks for essential hypertension (one case) and at term, before the onset of labor, for previous cesarean section in otherwise uncomplicated pregnancies (10 cases). Fetal membranes and placenta were also collected from 10 cases of spontaneous labor and delivery at term in uncomplicated pregnancies. Labor was complete in each case within 10 hours. There was no evidence of infection in any of the cases studied.

Ribonucleic acid (RNA) isolation and Northern hybridization. To limit degradation, RNA was prepared from each of the samples immediately after collection. The amnion was carefully peeled from the chorion. The maternal surface of the term placenta was cut away and a tissue sample was taken from beneath it. All three tissues were washed thoroughly in phosphate-buffered saline solution to remove all traces of blood and were then snap-frozen dry in liquid nitrogen. Total RNA was isolated from each tissue with a guanidinium-phenol-chloroform method.[13] The yield of RNA was determined spectrophotometrically. Thirty micrograms of total RNA was denatured at 60° C in 75% formamide and 24% formaldehyde for 2 minutes. It was then loaded onto a 1.5% agarose gel containing 3% formaldehyde and then separated by electrophoresis. The RNA within the gel was denatured in 0.05 mol/L sodium hydroxide for 20 minutes and then transferred by Northern blot onto Hybond nylon filters (Amersham). Blots were baked at 80° C for 2 hours and prehybridized in 50% formamide, 0.75 mol/L sodium chloride, 0.075 mol/L sodium citrate, 50 mmol/L sodium phosphate buffer (pH 6), 250 μg/ml denatured salmon sperm DNA, and 10× Denhardt's solution at 42° C overnight.

A 1.8 kb *Eco*RI fragment of the sheep cyclooxygenase cDNA,[9] subcloned in our laboratory, was radiolabeled by the method of Feiberg and Vogelstein.[14] Hybridization to the Northern blots was performed overnight at 42° C in the same solution as that used for prehybridization. Filters were washed sequentially in 5×, 2×, 1×, and 0.5× saline solution–sodium citrate buffer. Autoradiography was undertaken for 5 days at −70° C with intensifying screens.

After autoradiography the cyclooxygenase cDNA probe was stripped from the filters. Filters were placed in double-distilled water at 98° C, and the water was allowed to cool slowly at room temperature. The filters were then prehybridized and hybridized to a radiolabeled cDNA for human β-actin with the same protocols. Filters were washed sequentially in 2×, 1×, 0.5×, and 0.1× saline solution–sodium citrate buffer. Autoradiography was undertaken for 18 hours at −70° C with intensifying screens.

Expression of cyclooxygenase and β-actin was assessed densitometrically. β-Actin expression was used to confirm uniformity of loading. To compensate for nonuniform RNA loading, the density of signal as a result of hybridization of the cyclooxygenase probe to the Northern blot is expressed as a ratio of the β-actin signal density. Statistical analysis was performed with the Student *t* test.

Results

RNA of good quality was isolated from each of the tissues. β-Actin was expressed in all of the tissues at all gestational ages.

Differences in density of the β-actin transcript band were seen where RNA loading was not uniform; otherwise there were no apparent differences in the expression of β-actin. Expression of cyclooxygenase was not detectable in trophoblast at 5, 8, 10, 12, 14, 20, or 30 weeks but was seen on positive controls on the same filter. At term before labor, cyclooxygenase expression was seen at very low levels in amnion in four cases, chorion in two cases, and trophoblast in four cases. After the spontaneous onset of labor, expression was seen in all the amnion and placental samples and in six of the 10 chorion-decidual samples. Overall there was a 3.5-fold increase in the expression of cyclooxygenase in amnion($p < 0.005$) and a 2.5-fold increase in its expression in trophoblast ($p < 0.005$) (Figs. 1 and 2). The small increase seen in expression in chorion-decidua did not reach statistical significance.

Comment

We have demonstrated that expression of cyclooxygenase is not detectable by Northern analysis in human trophoblast in the first or second trimester of pregnancy. At term, before labor, cyclooxyenase is expressed at low levels in amnion, chorion-decidua, and

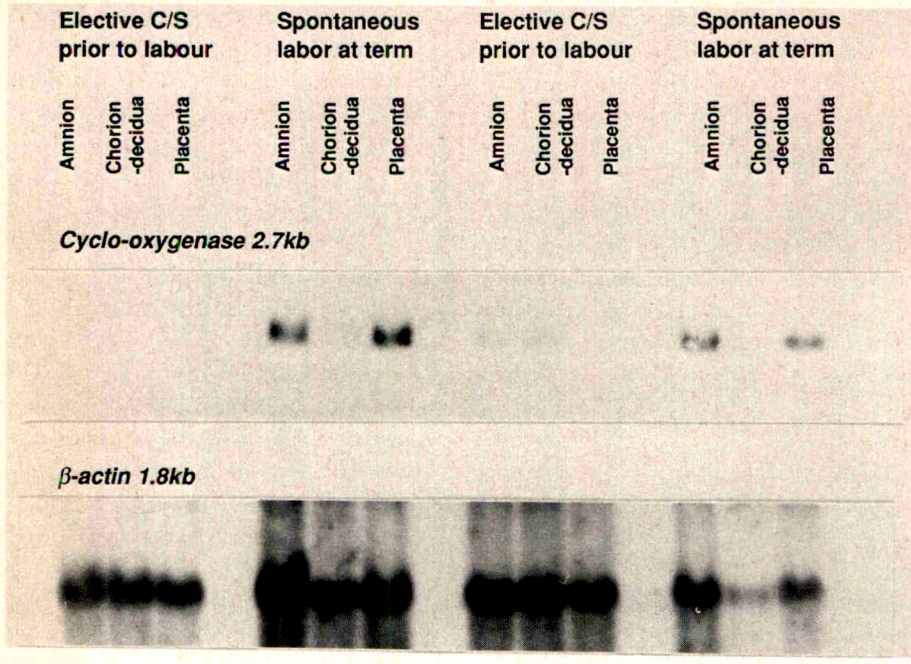

Fig. 1. Northern blot showing cyclooxygenase expression in amnion, chorion-decidua, and placenta collected at elective cesarean section *(C/S)* before onset of labor or after spontaneous onset of labor. Expression of β-actin is shown to control for uneven RNA loading.

trophoblast. In association with labor there is a large increase in expression in amnion and trophoblast. These findings are in accord with previous studies that have shown that arachidonic acid metabolism in amnion is essentially by lipoxygenase metabolic pathways until the onset of parturition, when there is a large increase in cyclooxygenase metabolism to prostaglandins.[2] It has been shown that bacterial products and inflammatory cytokines may stimulate PGE_2 production by fetal membranes.[2, 7] It is possible that the increase in cyclooxygenase expression seen in the fetal membranes after spontaneous delivery may be a response to bacterial exposure. There was, however, no evidence of either intrapartum or puerpural sepsis in any of the patients studied nor were there any associated neonatal infections.

Chorion is principally a site of prostaglandin catabolism. The cyclooxygenase expression seen in chorion-decidua is probably mostly within the decidual part of this tissue. Decidua is composed of lymphocytes, which represent 20% of cell types at term, and decidual stromal cells. An increase in decidual prostaglandin synthesis with labor has been demonstrated,[1] and it has been shown that there is an increase in cyclooxygenase enzyme levels in decidual stromal cells with labor.[15] Although we have seen a small increase in cyclooxygenase expression with labor in chorion-decidua, this did not reach statistical significance. It is probable that any increase in decidual stromal cyclooxygenase expression has been masked in our experiments by the presence of RNA from chorion and nonstromal decidual cells. This could be confirmed by in situ hybridization experiments.

We have failed to demonstrate cyclooxygenase expression in placenta during the first trimester. First-trimester placenta has been shown to produce cyclooxygenase products.[5] Therefore, there must be some expression of cyclooxygenase in first trimester trophoblast but at a level below the sensitivity of our analysis. Because we did not separate placental trophoblast from connective tissue, it is possible that the presence of non-trophoblast RNA may be diluting the trophoblast RNA and reducing the apparent expression of cyclooxygenase. Maier et al.[8] have demonstrated that unstimulated human umbilical vein endothelial cells express the cyclooxygenase messenger RNA (mRNA) at levels undetectable by Northern hybridization. Our results suggest that this may also be the case in human trophoblast in the first and second trimesters of pregnancy. It is possible that either cyclooxygenase mRNA or the protein itself has increased stability in the first trimester. We have found a large increase in cyclooxygenase expression in placenta in association with labor. This is consistant with the increase in synthesis of cyclooxygenase products seen in trophoblast with parturition.[5]

The synthesis of prostaglandins in any tissue follows well-established pathways. The substrate arachidonic acid is released from intracellular phospholipids by the

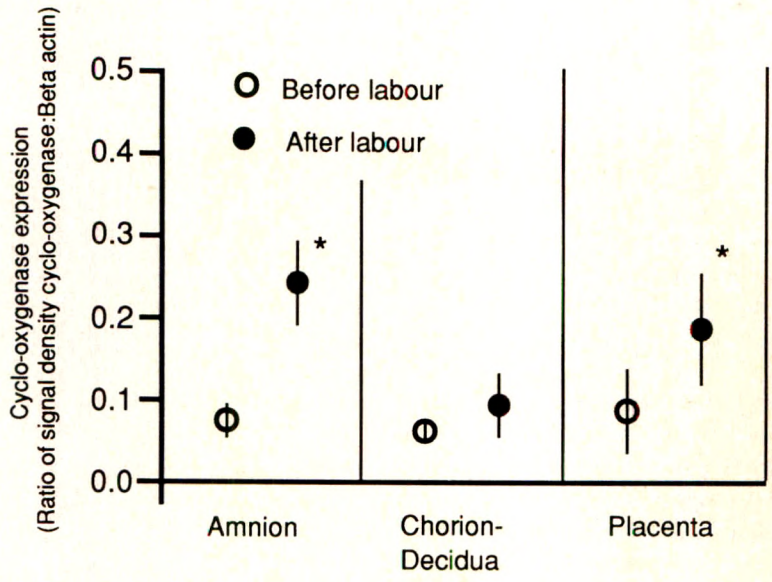

Fig. 2. Cyclooxygenase expression as ratio of signal density cyclooxygenase to that of β-actin in amnion, chorion-decidua, and placenta collected at elective cesarean section before onset of labor or after spontaneous onset of labor. Mean ± SD, $n = 10$. *Asterisk*, $p < 0.05$.

action of phospholipases. In a reaction catalyzed by cyclooxygenase, free arachidonic acid is converted to unstable prostaglandin endoperoxides. These prostaglandin endoperoxides are then converted by specific synthases to whichever prostaglandin, prostacyclin, or thromboxane is produced by the specific tissue. Recent theories of the initiation of human parturition have concentrated on phospholipase activity as the rate-limiting step in the synthesis of prostaglandins. Cyclooxygenase activity has not been considered to be rate limiting because an immediate rise in prostaglandin synthesis can be seen after addition of exogenous arachidonic acid to intrauterine tissues. However, cyclooxygenase has a very short life and undergoes a "suicide reaction" by inactivation of the apoprotein moiety of the enzyme by free radical species generated during catalysis.[16] It is highly unlikely that cyclooxygenase is simply waiting within the cell for an increase in phospholipase activity to increase its substrate availability. It is more likely that the increase in total arachidonic acid synthesis and in cyclooxygenase metabolism to PGs is caused by an increase in phospholipase activity coupled with increased synthesis of the cyclooxygenase enzyme. Our data support this theory.

There is some controversy as to which tissue within the uterus is the prime mover in the initiation of human parturition. Amniotic epithelium is a popular candidate because it contains the highest concentration of arachidonic acid of all tissues within the uterus[17] and demonstrates a significant increase in prostaglandin synthesis in association with labor.[1, 2] The chorion is principally a site of prostaglandin inactivation and does not itself synthesize prostaglandins. Several studies have investigated the intact transfer of prostaglandins from the amnion, across chorion-decidua, with conflicting results.[18-21] Because amnion is avascular and has no exogenous supply of precursor arachidonic acid, its increase in prostaglandin synthesis must involve an increase in the activity of both phospholipase and cyclooxygenase. We have demonstrated that the increased cyclooxygenase activity is associated with increased gene expression and therefore presumably increased enzyme synthesis. Whether this increase in cyclooxygenase expression is due solely to increased substrate availability or stimulated by other factors remains to be demonstrated. It does appear that IL-1β may directly stimulate increased expression of cyclooxygenase,[8] and this may be part of the mechanism by which this cytokine may initiate labor.

Decidua is a vascular tissue and may have a continuous exogenous supply of arachidonic acid. Control of prostaglandin synthesis in decidua is likely to be through the activity of the cyclooxygenase enzyme and, therefore, because it has a very short half-life, through the expression of the cyclooxygenase gene. Examination of the expression of cyclooxygenase in decidua will require either cell separation techniques or in situ hybridization.

Placenta is not thought to play a central role in the prostaglandin synthesis of early parturition. Nevertheless, its increase in cyclooxygenase activity after labor mirrors its overall increase in the metabolism of arachidonic acid. Like decidua, placenta has an available extracellular source of arachidonic acid. Experiments

by Rose et al.[5] have demonstrated that placenta will only synthesize cyclooxygenase products from exogenous arachidonic acid. Metabolism of endogenous substrate is only by lipoxygenase and epoxygenase pathways. Furthermore, addition of exogenous arachidonic acid to placental cells obtained before labor does not yield cyclooxygenase products. This suggests that cyclooxygenase expression in trophoblast is not controlled simply by the availability of substrate and may represent an important factor in the control of prostaglandin synthesis in this tissue.

Whichever tissue is of greatest importance in producing the prostaglandins that initiate human labor, it appears that the increase in prostaglandin synthesis must be a consequence of both substrate availability and cyclooxygenase expression. In amnion, which is avascular, this must mean an increase in mobilization of stored arachidonic acid together with an increase in cyclooxygenase expression. In tissues with a good vascular supply and therefore an exogenous supply of archidonic acid, decidua, and placenta, it is likely that prostaglandin synthesis is controlled principally by cyclooxygenase expression. An understanding of the factors that control the expression of cyclooxygenase will provide valuable information about the mechanisms of parturition in humans.

A novel change in cytologic localization of human chorionic gonadotropin and human placental lactogen in first-trimester placenta in the course of gestation

Takeshi Maruo, MD,[a] Cecilia A. Ladines-Llave, MD,[b] Hiroya Matsuo, MD,[a] Augusto S. Manalo, MD,[b] and Matsuto Mochizuki, MD[a]

Kobe, Japan, and Manila, Philippines

Cytologic localization of human chorionic gonadotropin and human placental lactogen in developing human early placenta was analyzed by avidin-biotin immunoperoxidase techniques with an affinity-purified polyclonal antibody to β-human chorionic gonadotropin carboxyl terminal peptide and a polyclonal antibody to human placental lactogen. In 4- to 5-week placentas human chorionic gonadotropin and human placental lactogen were found to be primarily localized to cytotrophoblasts, whereas in 6- to 12-week placentas these substances were exclusively localized to syncytiotrophoblast. We previously reported that a similar change in cytologic localization of epidermal growth factor and its receptor from cytotrophoblasts to syncytiotrophoblast in first-trimester placenta appeared between 5 and 6 weeks of gestation. Because epidermal growth factor was demonstrated to stimulate human chorionic gonadotropin and human placental lactogen production by early placental tissues, their simultaneous expression, as well as epidermal growth factor and its receptor in the cytotrophoblast of 4- to 5-week placenta and in the syncytiotrophoblast of 6- to 12-week placenta, implies that human chorionic gonadotropin and human placental lactogen production by first-trimester placenta may be regulated in an autocrine manner, wherein epidermal growth factor may serve as the signal. These findings suggest that in very early placenta, before 6 weeks of gestation, no sequential expression of human chorionic gonadotropin and human placental lactogen closely linked to syncytia formation may exist and that both can be expressed in the cytotrophoblast or undifferentiated stem cell of villous trophoblast in very early placenta. (Am J Obstet Gynecol 1992;167:217-22.)

Key words: Placenta, cytotrophoblast, human chorionic gonadotropin, human placental lactogen, immunohistochemistry

The villous trophoblast of human placenta is composed of two distinct layers: an inner cell layer of mononuclear cytotrophoblast and an outer cell layer of multinuclear syncytiotrophoblast. It is generally accepted that the cytotrophoblast is the undifferentiated stem cell of the villous trophoblast and that the syncytiotrophoblast is the fully differentiated, end-stage cell derived from cytotrophoblast.[1-6]

The human placental trophoblast elaborates at least two peptide hormones, human chorionic gonadotropin (hCG) and human placental lactogen (hPL). A number of immunohistochemical studies,[7-10] including ours,[11] have indicated that immunoreactive β-hCG, hCG, and hPL are exclusively localized to the syncytiotrophoblast, whereas other immunohistochemical studies[12, 13] have suggested that the cytotrophoblast may contain immunoreactive α-hCG. Consistent with the immunohistochemical findings, Hoshina et al.,[14, 15] using in situ hybridization techniques to localize hCG (α and β) and hPL messenger ribonucleic acids in placental tissue sections, showed that the expression of α-hCG messenger ribonucleic acid is initiated in some differentiating cytotrophoblasts, whereas the expression of β-hCG messenger ribonucleic acid starts during the process of differentiation of syncytial trophoblast and hPL messenger ribonucleic acid is expressed only in the fully differentiated syncytiotrophoblast. However, it must be pointed out that the placental tissue materials used in the studies reported have been obtained at a gestational age later than 6 weeks, probably because of the greater availability of placental materials between 6 and 12 weeks of gestation and at term. Thus the claim that the ability of human trophoblast to synthesize hCG and hPL is tied to syncytia formation may be limited to the

placenta with a gestational age >6 weeks. Nevertheless, it is known that hPL exerts a lipolytic and glucose-sparing effect on the mother to ensure that the nutritional demands of the fetus are met,[16, 17] whereas hCG is responsible for the rescue of the corpus luteum, which is indispensable for the maintenance of very early pregnancy during the first 4 to 6 weeks of gestation.[18] Thus it is of great importance to provide insight into the expression of hCG and hPL in very early placenta before 6 weeks of gestation.

On the other hand, epidermal growth factor (EGF) has been demonstrated to stimulate the production of hCG and hPL by early placental tissues through the binding to EGF receptor.[19] Furthermore, we have recently found that EGF and EGF receptor are initially expressed in the cytotrophoblasts in very early placenta before 6 weeks of gestation and thereafter expressed in the syncytiotrophoblast of 6- to 12-week placenta.[20] A remarkable change in cytologic localization of EGF and EGF receptor in very early placenta appeared between 5 and 6 weeks of gestation. Thus it seems interesting to investigate whether cytologic localization of hCG and hPL in very early placenta may also change during the course of early gestation in association with the shift of cytologic localization of EGF and EGF receptor in first-trimester placenta. Hence in the current study attention was focused on the expression of hCG and hPL in very early placenta, before 6 weeks of gestation, and the possible change in cytologic localization of hCG and hPL in first-trimester placenta over the course of early gestation was examined.

Material and methods

Material. First-trimester placentas were obtained from 12 patients who underwent elective abortion at 4 to 5 weeks (three cases), 6 to 7 weeks (three cases), and 8 to 12 weeks (six cases) of gestation. Third-trimester placentas were obtained from four patients who had cesarean section between 38 and 40 weeks of gestation. The gestational age of the placenta was determined by the known date of conception or estimation from the date of the patient's last menstrual period. In all cases gestational age was further evaluated by ultrasonographic examination. Informed consent for the use of placental tissues for immunohistochemical studies was obtained from the patients before operation.

Immunohistochemical staining. Placental tissues obtained were fixed in 4% buffered neutral formalin, dehydrated, and embedded in paraffin. Sections, 5 to 6 μm in thickness, were deparaffinized and followed by standard histologic techniques.

Immunohistochemical staining was performed by avidin/biotin immunoperoxide techniques with a polyvalent immunoperoxidase kit (Omnitags, Lipshaw, Mich.) as previously described by Maruo and Mochizuki.[11] An affinity-purified sheep polyclonal antibody against β-hCG carboxyl terminal peptide (Takeda Chemical Industries, Osaka) and a rabbit polyclonal antibody against hPL (Dako Corp., Santa Barbara, Calif.) were used, respectively, as the primary antibodies in this study. The anti-β-hCGβ carboxyl terminal peptide antibody and anti-hPL antibody were diluted 1:100 and 1:1000 before use, respectively.

To assure specificity of the immunologic reactions, adjacent control sections were subjected to the same immunoperoxidase method, except that the primary antibodies to β-hCG carboxyl terminal peptide or hPL were respectively replaced by nonimmune sheep immunoglobulin G (Miles, Elkhart, Ind.) or nonimmune rabbit immunoglobulin G (Miles). In the controls no positive staining was observed.

Results

Fig. 1, *A* and *B*, shows the immunohistochemical staining for β-hCG carboxyl terminal peptide and hPL, respectively, in very early placenta obtained at 4 weeks

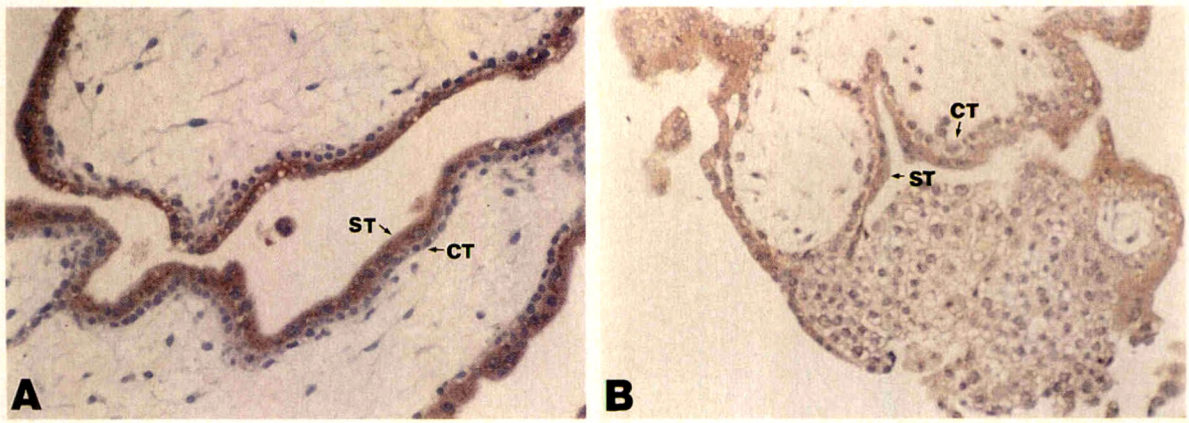

Fig. 2. Immunohistochemical localization of β-hCG-CTP and hPL in early first trimester placenta. Formalin-fixed, paraffin-embedded sections of 6-week placenta were stained with anti-β-CTP antibody **(A)** and anti-hPL antibody **(B)**. Pronounced staining for β-hCG-CTP and hPL was observed in syncytiotrophoblast *(ST)*, whereas cytotrophoblastic cells *(CT)* were negative for appreciable staining. (Original magnification ×200.)

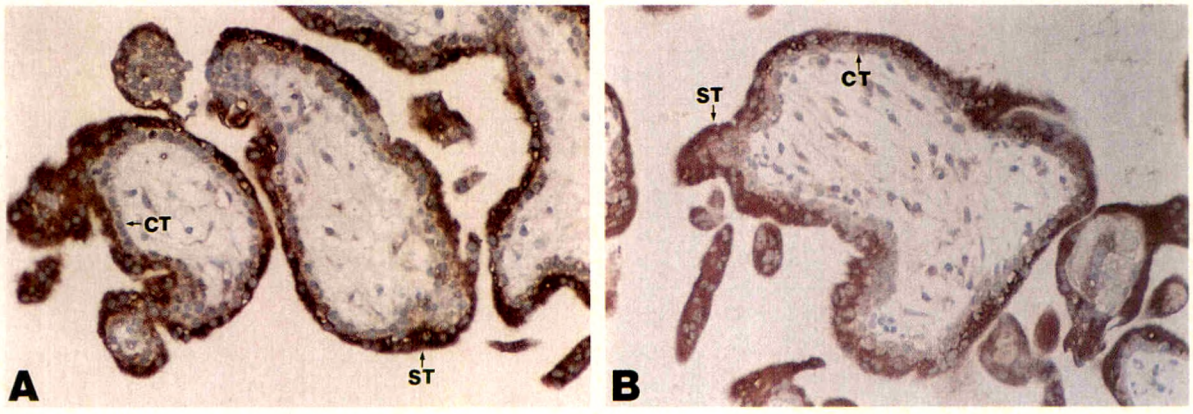

Fig. 3. Immunohistochemical localization of β-hCG-CTP and hPL in first trimester placenta. Formalin-fixed, paraffin-embedded sections of 9-week placenta were stained with anti-β-hCG-CTP antibody **(A)** and anti-hPL antibody **(B)**. Prominent staining for β-hCG-CTP and hPL was observed with maximal intensity in syncytiotrophoblast *(ST)*, whereas cytotrophoblastic cells *(CT)* were negative for appreciable staining. (Original magnification ×200.)

of gestation. Both immunostaining with anti-β-hCG carboxyl terminal peptide and anti-hPL antibody were prominent in cytotrophoblasts, whereas syncytiotrophoblast showed scarce staining for β-hCG carboxyl terminal peptide and hPL. A similar pattern of immunostaining for β-hCG carboxyl terminal peptide and hPL was observed in tissue sections of 5-week placenta.

Fig. 2, *A* and *B*, represents the immunohistochemical staining for β-hCG carboxyl terminal peptide and hPL, respectively, in early placenta obtained at 6 weeks of gestation. Unlike the very early placenta obtained at 4 to 5 weeks of gestation, both immunostaining with anti-β-hCG carboxyl terminal peptide antibody and anti-hPL antibody were exclusively localized to syncytiotrophoblast. No appreciable staining for β-hCG carboxyl terminal peptide and hPL was found in cytotrophoblasts. In the case of 8- to 12-week placenta (Fig. 3, *A* and *B*), the pattern of cytologic localization of β-hCG carboxyl terminal peptide and hPL was similar to that in 6-week placenta, but the staining intensity for β-hCG carboxyl terminal peptide and hPL of the syncytiotrophoblast was more prominent compared with that of 6-week placenta.

Fig. 4, *A* and *B*, shows the immunohistochemical staining for β-hCG carboxyl terminal peptide and hPL, respectively, in term placenta obtained at 40 weeks of gestation. Both immunostaining with anti-β-hCG carboxyl terminal peptide antibody and anti-hPL antibody were focally observed with the exclusive localization in syncytiotrophoblast.

The results of cytologic localization of β-hCG carboxyl terminal peptide and hPL in first-trimester placenta according to the type of villous trophoblast and the gestational age are summarized in Table I. A remarkable shift in cytologic localization of β-hCG carboxyl terminal peptide and hPL from cytotrophoblast

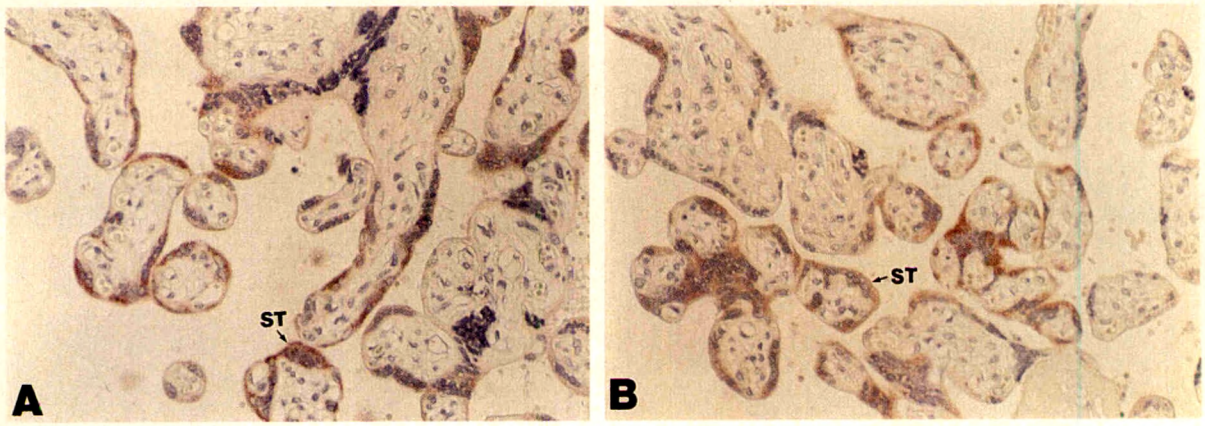

Fig. 4. Immunohistochemical localization of β-hCG-CTP and hPL in term placenta. Formalin-fixed, paraffin-embedded sections of 40-week placenta were stained with anti-β-hCG-CTP antibody **(A)** and anti-hPL antibody **(B)**. Pronounced staining for β-hCG-CTP and hPL was focally observed with exclusive localization in syncytiotrophoblast *(ST)*. (Original magnification ×200.)

to syncytiotrophoblast was found to appear between 5 and 6 weeks of gestation.

Comment

The current study demonstrated that cytologic localization of hCG and hPL in human first trimester placenta changes in the advancing course of gestation. In the very early placenta obtained at 4 to 5 weeks of gestation, hCG and hPL were primarily localized to cytotrophoblasts, whereas in early placenta obtained later than 6 weeks of gestation they were exclusively localized to syncytiotrophoblast. These findings suggest that both are initially expressed in cytotrophoblasts in very early placenta before 6 weeks of gestation and thereafter expressed in syncytiotrophoblast in the placenta during the remainder of gestation. To our knowledge, the current study is the first to demonstrate the change in cytologic localization of hCG and hPL in developing human placenta in the course of early gestation.

The change in cytologic localization of hCG and hPL from cytotrophoblasts to syncytiotrophoblast in very early placenta is of great interest considering the established finding that syncytiotrophoblast is formed from cytotrophoblasts by a process of proliferation followed by cell fusion.[4, 5] In situ hybridization studies[14, 15] with α-hCG, β-hCG, and hPL probes on tissue sections of the placenta obtained later than 6 weeks of gestation have demonstrated that the villous trophoblast acquires the ability to elaborate these substances in association with the morphologic transformation from cytotrophoblasts to syncytiotrophoblast and that the biochemical differentiation of the villous trophoblast occurs only after syncytia formation. Thus it seems evident that in the placenta with gestational age later than 6 weeks there is a sequential expression of α-hCG, β-hCG, and hPL closely correlated with the differentiation of the villous trophoblast. However, when Kao et al.[21] grew purified human placental cytotrophoblasts under serum-free conditions to elucidate whether syncytia formation is a prerequisite for the biochemical differentiation of the villous trophoblast, they found that the formation of syncytiotrophoblast is not a prerequisite for the acquisition of the ability to elaborate hCG but is only one of the consequences of the differentiation program of the trophoblast. They demon-

strated that purified human placental cytotrophoblasts in culture could secrete hCG at the same rate under serum-free conditions whether they were plated on plastic only, which prevented syncytia formation, or fibronectin laminin or type IV collagen, which allowed syncytia formation to occur. Our results obtained with the tissue sections of very early human placenta support the notion that syncytia formation is not a prerequisite for the acquisition of a specific endocrine function of the placenta. In the case of very early placenta before 6 weeks of gestation, both hCG and hPL can be expressed in cytotrophoblasts.

In this regard, our recent findings in an earlier study are of considerable interest. We have demonstrated that cytologic localization of EGF and EGF receptor in developing human placenta varies over the course of gestation and that even in first-trimester placenta there is a remarkable change in the cytologic localization from cytotrophoblasts to syncytiotrophoblast at the sixth week of gestation.[20] Thus the change in cytologic localization of hCG and hPL in very early placenta observed in the course of early gestation is closely coincident with the change in cytolocalization of EGF and EGF receptor. Because EGF has been demonstrated to exert a stimulatory effect on hCG and hPL production by early placental tissues through the binding to EGF receptor,[19] the simultaneous expression of EGF and EGF receptor and hCG and hPL in the cytotrophoblast of 4- to 5-week placentas and in the syncytiotrophoblast of 6- to 12-week placentas implies that the production of hCG and hPL by first-trimester placenta may be regulated by an autocrine system, wherein EGF may serve as the signal.

It is evident that increasing amounts of hCG produced by the chorion around the time of implantation play an important role in rescuing the corpus luteum. The placenta is known to take over the corpus luteum function at the sixth week of gestation in producing progesterone and estrogen necessary for the maintenance of early gestation. It is of interest that the dynamic change in cytologic localization of hCG and hPL and EGF and EGF receptor from cytotrophoblast to syncytiotrophoblast in very early placenta also occurs at the sixth week of gestation. Taking these findings into account, the sixth week of gestation seems to be critical in the functional development of the early placenta.

These findings suggest that in very early placenta, before the sixth week of gestation, hCG and hPL can be expressed in the cytotrophoblast (the undifferentiated stem cell of the villous trophoblast) and that there is a shift in cytologic localization of hCG and hPL from cytotrophoblast to syncytiotrophoblast around the sixth week of gestation. It is therefore likely that the program of the sequential expression of the genes coding for hCG (α and β) and hPL correlated with the differentiation of the villous trophoblast may be established in the placenta at the sixth week of gestation. Before that time no sequential expression of hCG and hPL correlated with trophoblast differentiation may exist in the placenta. Further studies with in situ hybridization with hCG (α and β) and hPL probes on very early placental tissues will be needed to reinforce this notion.

Transforming growth factor-β opposes the stimulatory effects of interleukin-1 and tumor necrosis factor on amnion cell prostaglandin E_2 production: Implication for preterm labor

Kristina Bry, MD, and Mikko Hallman, MD

Irvine, California, and Helsinki, Finland

OBJECTIVE: In preterm labor increased concentrations of interleukin-1 and tumor necrosis factor are present in amniotic fluid. These cytokines may promote labor by stimulating the production of prostaglandins by intrauterine tissues. In many biologic processes, transforming growth factor-β modifies the actions of cytokines. We studied the effect of transforming growth factor-β on the cytokine-induced prostaglandin E_2 production by amnion cells.

STUDY DESIGN: Human amnion cells in monolayer culture were treated with interleukin-1, tumor necrosis factor, or vehicle in the presence or absence of transforming growth factor-β. The prostaglandin E_2 production was measured.

RESULTS: Transforming growth factor-β decreased the interleukin-1- or tumor necrosis factor–induced prostaglandin E_2 production by 70% to 80% and the basal prostaglandin E_2 synthesis by 27%. The synergistic stimulation of prostaglandin E_2 production by the combination of interleukin-1 with tumor necrosis factor was inhibited by 80% in cells treated with transforming growth factor-β. Transforming growth factor-β1, -β2, and -β1,2 were equipotent.

CONCLUSION: Transforming growth factor-β suppresses the cytokine-induced prostaglandin E_2 production by amnion cells and may be an important factor in maintaining pregnancy in the face of labor-promoting cytokines. (Am J Obstet Gynecol 1992;167:222-6.)

Key words: Preterm labor, prostaglandins, interleukin-1, tumor necrosis factor, transforming growth factor-β, fetal membranes

Preterm labor often occurs in the setting of intrauterine infection.[1] The concentrations of cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF) increase in amniotic fluid in preterm labor.[2-4] Prostaglandins, major inducers of uterine contractions, are produced by intrauterine tissues in response to these cytokines.[3, 5-7] The amnion, which produces almost exclusively prostaglandin E_2 (PGE_2),[8] is an important intrauterine source of prostaglandin. The combination of IL-1 with TNF has a synergistic stimulator effect on the PGE_2 production by human amnion cells in culture.[9] IL-1 and TNF have been implicated in the induction of preterm labor associated with infections.[2, 3, 10]

Transforming growth factor-β (TGF-β) represents a family of multifunctional factors that influence cell growth, differentiation, immunity, and extracellular matrix formation.[11] Several forms of TGF-β and of

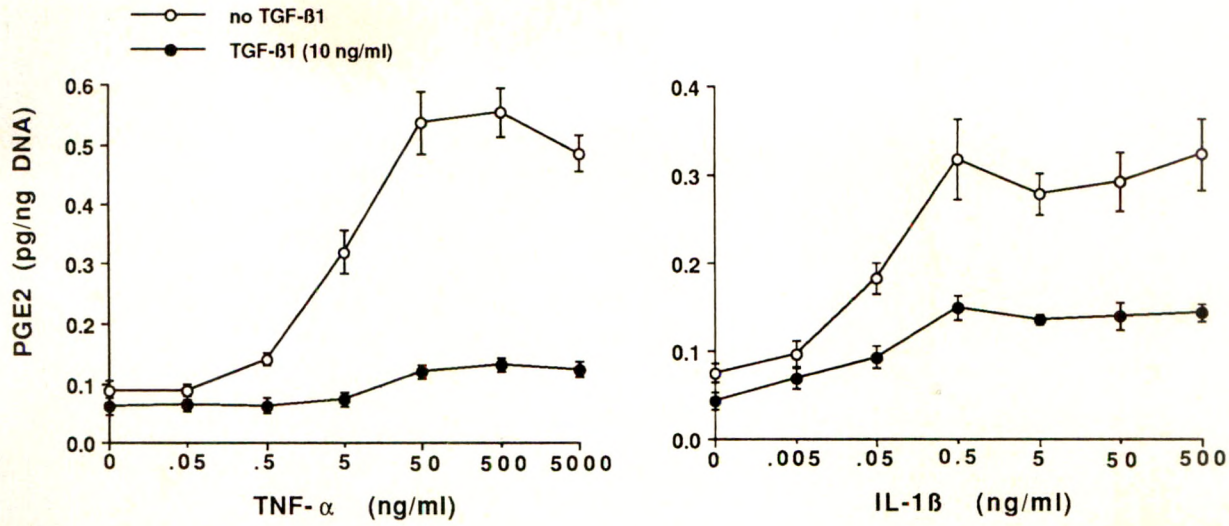

Fig. 1. Effect of TGF-β on amnion cells stimulated with different concentrations of TNF-α or IL-1β. Human amnion cells were treated with indicated concentrations of TNF-α or IL-1β in presence (●) or absence (○) of human TGF-β1 (10 ng/ml). PGE_2 production (picograms per nanogram DNA) was measured after 42-hour incubation. Results are means ± SE (n = 4) of one representative experiment.

their receptors have been identified. TGF-β1 and TGF-β2 are homodimers, and TGF-β1,2 is a heterodimer containing one polypeptide chain each from TGF-β1 and TGF-β2. Most tissues found at the maternal-fetal interface contain TGF-β and express TGF-β messenger ribonucleic acid.[12] In many biologic processes, TGF-β acts as a biologic switch, antagonizing or modifying the action of other growth factors or cytokines.[13] We therefore studied the effect of TGF-β on the cytokine-induced PGE_2 production by human amnion cells in culture. In this report we show that TGF-β suppresses the IL-1– or TNF-stimulated PGE_2 production by amnion cells.

Material and methods

Chemicals. Recombinant human TNF-α (specific activity 4.8×10^7 U/mg, endotoxin content <0.13 endotoxin unit [EU]/mg) and TNF-β (specific activity 2.1×10^8 U/mg, endotoxin 3.1 EU/mg) were generously provided by Genentech, South San Francisco. Recombinant human IL-1β (specific activity 1.8×10^7 U/mg, endotoxin 2.5 EU/mg) was a generous gift from the National Cancer Institute. Recombinant human IL-1α (specific activity 3×10^8 U/mg, endotoxin 0.7 EU/mg) was a kind gift from Hoffmann-La Roche, Inc., Nutley, N.J. The PGE_2 kit was from New England Nuclear, Boston. Human TGF-β1 and porcine TGF-β1, TGF-β2, and TGF-β1,2 were from R&D Systems, Minneapolis.

Preparation and culture of human amnion cells. Human fetal membranes were obtained from normal pregnancies at cesarean sections conducted at term before the onset of labor. Cells from the reflected amnion were isolated as described.[14] The cells were seeded in tissue culture plates at a density of 1.4×10^5 cells/cm² and maintained at 37° C in an atmosphere of air and 5% carbon dioxide in Eagle's minimum essential medium with Earle's salts supplemented with glutamine, 10% fetal calf serum, antibiotics, and antimycotics. After 24 hours the wells were washed with minimum essential medium, and the medium was changed to the culture medium supplemented with cytokines, TGF-β, or the appropriate vehicle. The cells were incubated for 42 hours before the culture media were removed

Table I. Effect of TGF-β on PGE_2 production by amnion cells stimulated with IL-1 or TNF

	PGE_2 production (fractions of control)		*Inhibition (%) in PGE_2 production caused by TGF-β1*
	Without TGF-β1	*With TGF-β1*	
Control	1	0.7 ± 0.1	27 ± 9
IL-1α	25.5 ± 9.6	4.1 ± 1.8	77 ± 4
IL-1β	27.3 ± 10.6	4.4 ± 2.0	75 ± 5
TNF-α	48.4 ± 7.9	9.7 ± 3.1	75 ± 8
TNF-β	9.6 ± 2.6	1.4 ± 0.3	71 ± 9

Amnion cells were treated with IL-1α (6.8 ng/ml), IL-1β (5 ng/ml). TNF-α (50 ng/ml), TNF-β (10 ng/ml), or vehicle (control) in the presence or absence of human TGF-β1 (10 ng/ml). After 42 hours of incubation, the media were removed and analyzed for PGE_2. PGE_2 production is shown as fractions of production in untreated (control) cells; in these cells PGE_2 production was 0.031 ± 0.008 pg/ng DNA. The inhibition in percent caused by TGF-β in each experiment was calculated. The means ± SE of six separate experiments are shown.

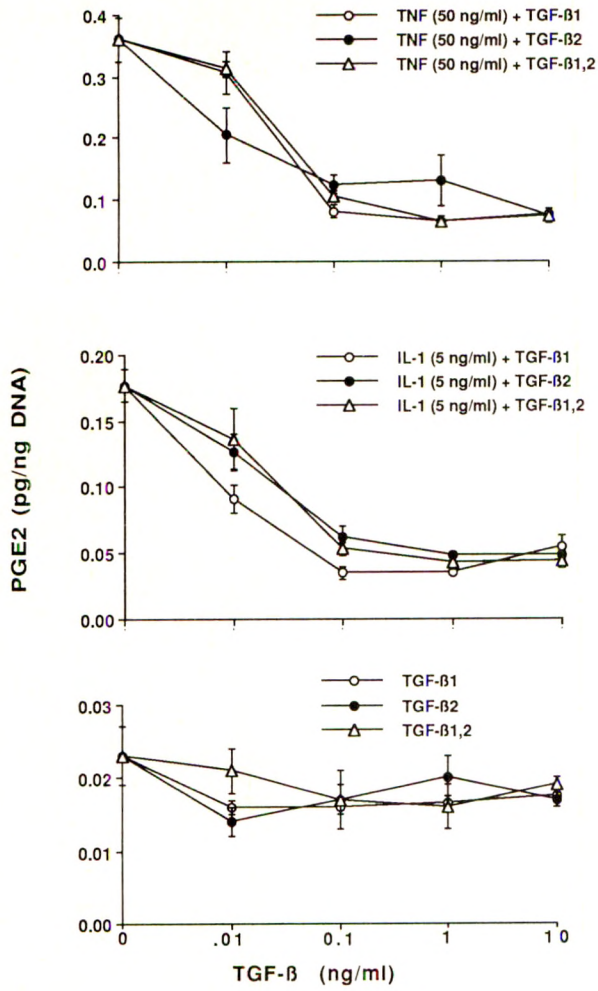

Fig. 2. Comparison of effects of TGF-β1, TGF-β2, and TGF-β1,2 on PGE_2 production by amnion cells. Human amnion cells were treated with TNF-α (50 ng/ml) *(upper panel)*, IL-1β (5 ng/ml) *(middle panel)*, or vehicle *(lower panel)*, in presence of indicated concentrations of porcine TGF-β1 (○), TGF-β2 (●), or TGF-β1,2 (Δ). The PGE_2 production (picograms per nanogram DNA) was measured after 42-hour incubation. Results are means ± SE (n = 4) of one representative experiment.

and then centrifuged at 600 g for 10 minutes to eliminate cell debris. The supernatants were stored at −70° C until assayed for PGE_2. The cells were recovered from the wells with trypsin. More than 90% of the cells excluded trypan blue.

Measurement of PGE_2. PGE_2 was measured by radioimmunoassay directly from the media. The concentrations of PGE_2 in the media incubated in the same conditions but without amnion cells were used as blanks. PGE_2 formation was calculated per nanogram of amnion cell deoxyribonucleic acid (DNA); DNA analysis was done as described.[15] The different treatments with cytokines or TGF-β did not significantly affect the DNA content of the wells.

Statistics. The test used was the Wilcoxon signed-rank test.

Results

Effect of TGF-β on PGE_2 production by amnion cells stimulated with IL-1 or TNF. Human amnion cells were treated with IL-1α (6.8 ng/ml), IL-1β (5 ng/ml), TNF-α (50 ng/ml), TNF-β (10 ng/ml), or vehicle in the presence or absence of human TGF-β1 (10 ng/ml). Because amnion cells do not metabolize PGE_2, the concentration of PGE_2 in the medium at the end of the 42-hour incubation represents the total PGE_2 released during that time.[8] For each cytokine the PGE_2 production was lower in the presence of TGF-β in each of the six separate experiments performed (p = 0.028) (Table I). The decrease caused by TGF-β in the basal PGE_2 production was 27% ± 9%. However, in cells stimulated by IL-1 or TNF, the decrease in total PGE_2 production occurring in the presence of TGF-β1 ranged from 71% ± 9% to 77% + 4% (Table I).

Effect of TGF-β on stimulation of amnion cell PGE_2 production by combination of IL-1 and TNF. Amnion cells were incubated for 42 hours with IL-1β (5 ng/ml), IL-1α (6.8 ng/ml), or TNF-α (5 μg/ml) in the presence or absence of human TGF-β1 (10 ng/ml). IL-1 acts synergistically with TNF to stimulate amnion cell PGE_2 production.[9] Nevertheless, the degree of inhibition due to TGF-β1 was approximately the same as was obtained in cells treated with only one cytokine (Table II). Similar results were obtained with TNF-β (10 ng/ml) instead of TNF-α (results not shown).

Effect of TGF-β as a function of IL-1 and TNF concentration. Amnion cells were incubated with different concentrations of IL-1β (0 to 500 ng/ml) or TNF-α (0 to 5 μg/ml) with or without TGF-β1 (10 ng/ml). The PGE_2 release was assayed after incubation for 42 hours. IL-1β and TNF-α stimulated the PGE_2 production in a concentration-dependent manner; the saturating concentrations for IL-1β and TNF-α were 0.5 and 50 ng/ml, respectively. At each concentration of IL-1β and of TNF-α, TGF-β1 inhibited the PGE_2 production as seen in Fig. 1.

Effect of different concentrations of TGF-β1, TGF-β2, or TGF-β1,2 on PGE_2 production by amnion cells. Cells were treated for 42 hours with IL-1β (5 ng/ml) or TNF (50 ng/ml), together with different concentrations (0 to 10 ng/ml) of porcine TGF-β1, TGF-β2, or TGF-β1,2. The potencies of TGF-β1, TGF-β2, and TGF-β1,2 in inhibiting the PGE_2 production were similar at each concentration tested (Fig. 2). In each case maximal inhibition was obtained with TGF-β concentrations ≥0.1 ng/ml (Fig. 2). The effects of porcine TGF-β1 were indistinguishable from those of human TGF-β1 (data not shown).

In amnion cells not treated with cytokines, TGF-β1,

Table II. Effect of TGF-β1 on amnion cell PGE_2 production stimulated by combination of IL-1 and TNF

	PGE_2 production		*Inhibition caused by TGF-β1 (%)*
	Without TGF-β1	*With TGF-β1*	
Control	0.046 ± 0.002	0.029 ± 0.001	40.0 ± 1.7
IL-1α (6.8 ng/ml)	1.55 ± 0.035	0.237 ± 0.024	84.7 ± 1.6
IL-1β (5 ng/ml)	1.83 ± 0.029	0.195 ± 0.013	89.3 ± 0.8
TNF-α (50 ng/ml)	2.83 ± 0.034	0.312 ± 0.025	89.0 ± 0.8
IL-1α (6.8 ng/ml) + TNF-α (50 ng/ml)	9.006 ± 0.323	1.678 ± 0.051	81.3 ± 0.8
IL-1β (5 ng/ml) + TNF-α (50 ng/ml)	8.671 ± 0.312	1.71 ± 0.077	80.2 ± 1.2

Amnion cells were treated with indicated cytokines or cytokine combinations in presence or absence of human TGF-β1 (10 ng/ml). Total release of PGE_2 (picograms per nanogram DNA) during 42-hour incubation was measured. Data are results (means ± SE, $n = 4$) of one representative experiment.

TGF-β2, and TGF-β1,2 also appeared equipotent, but the degree of inhibition was smaller than that obtained in cells stimulated with cytokines (Fig. 2).

Comment

In this report we show for the first time that TGF-β strikingly opposes the IL-1– or TNF-stimulated PGE_2 production by human amnion cells. It also suppressed the synergistic PGE_2-stimulatory effect of the combination of IL-1 with TNF. The basal PGE_2 production by amnion cells was also inhibited by TGF-β but to a smaller extent.[16] According to the present results, TGF-β may play a role in limiting or terminating the prostaglandin production induced by proinflammatory cytokines in the setting of intrauterine infection.

At all concentrations tested the effects of TGF-β1, TGF-β2, and TGF-β1,2 on amnion cell PGE_2 production were similar. TGF-β1 and TGF-β2 differ from each other by 32-amino-acid substitutions and have 71% sequence identity. In many cell systems TGF-β1 and TGF-β2 are biologically equipotent; however, they show marked differences in certain cells.[10]

In contrast to its effects on amnion cells, TGF-β has a stimulatory effect on the production of prostaglandins in many cells. Thus it stimulates the PGE_2 production in neonatal mouse calvaria[17] and in lung fibroblasts,[18] as well as prostacyclin production in human vascular endothelial cells.[19] In addition, TGF-β potently synergizes with IL-1β and TNF-α in stimulating the PGE_2 production in rat renal mesangial cells.[20]

TGF-β–like activity is present in many cells at the fetomaternal interface.[12] TGF-β1 antibody reacts with cells in the chorion and with extracellular matrix components in the placenta and uterus.[21] TGF-β1 messenger ribonucleic acid is present in the placenta, decidua, and placental membranes.[12] A TGF-β2–like factor has been described in murine amniotic fluid.[22] High levels of TGF-β2 messenger ribonucleic acid are present in the uterus of the pregnant mouse; they fall rapidly as birth approaches.[22]

Besides the observed effect of TGF-β on PGE_2 synthesis, there is additional evidence suggesting the importance of TGF-β to the maintenance of pregnancy. TGF-β is a potent immunosuppressant both in vivo and in vitro.[23] Murine decidual cells secrete an immunosuppressive TGF-β2–like molecule.[24] TGF-β may be essential in the maintenance of pregnancy by preventing rejection of the fetus.[24]

TGF-β induces the accumulation of extracellular matrix by several mechanisms. It stimulates the synthesis of many extracellular matrix components.[25] It also enhances the adhesion of extracellular matrix on cells.[26] In addition, TGF-β up-regulates inhibitors of extracellular matrix–degrading enzymes[27,28] and inhibits enzymes (such as collagenase) that degrade extracellular matrix components.[28] The effect of TGF-β on cell adhesion receptors may be of importance in the attachment of the fetoplacental unit to the uterine wall. Because of its effects on extracellular matrix, TGF-β has the potential of inhibiting processes required for both term and preterm labor. These include softening and dilatation of the cervix, which is associated with a decrease in collagen content and an increase in collagenolytic activity.[29] The biologic activity of TGF-β and its regulation during pregnancy remain to be clarified.

From the current results we propose that TGF-β plays an important role in the modulation of processes that regulate the initiation of preterm labor. In cases of intrauterine inflammation, increased production of cytokines threaten pregnancy. The continuation of pregnancy may depend on the balance of the activities of labor-promoting agents, such as IL-1 and TNF, and of agents, such as TGF-β, that favor the continuation of pregnancy. It remains to be seen whether TGF-β has therapeutic potential in the prevention of preterm labor.

OBJECTIVE: The purpose of this study was to assess the extent of involvement of the *ras* oncogene in endometrial carcinoma.

STUDY DESIGN: Genomic deoxyribonucleic acid from 30 samples of endometrial carcinoma was examined for point mutations in codons 12, 13, and 61 from the Ha-*ras*, Ki-*ras*, and N-*ras* genes by means of the polymerase chain reaction, slot-blotting, and deoxyribonucleic acid sequencing procedures.

RESULTS: An apparent somatic mutation of Ki-*ras* codon 12 in one of 10 paraffin-embedded tumors was confirmed by deoxyribonucleic acid sequence analysis. Two of 20 frozen endometrial carcinoma specimens were also shown to contain a point mutation in Ki-*ras* codon 12. No correlation between *ras* mutation and a number of histologic or clinical parameters was observed.

CONCLUSIONS: These data suggest a potential role for Ki-*ras* codon 12 mutations in the development of some (10%) endometrial cancers. (Am J Obstet Gynecol 1992;167:227-32.)

Key words: Endometrial carcinoma, oncogene, *ras*, polymerase chain reaction

Carcinoma of the uterine endometrium is the most frequently diagnosed gynecologic malignancy in the United States, but few data on the molecular genetic features of this tumor exist. We believe that a series of genetic alterations involving both protooncogenes and tumor suppressor genes plays a role in the development of endometrial carcinomas as it does in other human cancers.[1] The variable nature of these genetic events can be noted in the clinical observation of two distinct forms of endometrial carcinoma.[2, 3] Type I tumors are frequently associated with a history of unopposed estrogen exposure or other hyperestrogenic condition such as obesity. They occur in perimenopausal women, are typically of low grade and good prognosis, and are often associated with or preceded by endometrial hyperplasia. In contrast, type II tumors, which have a poorer prognosis, appear unrelated to estrogenic stimulation, manifest at a later age (>60), and are generally of higher grade and/or uncommon histologic subtype. The clustering of endometrial carcinoma in certain families[4] and the occurrence in patients with multiple primary tumors (especially those of the colon)[4-7] suggest genetic transmission of endometrial cancer risk.

The potential role of protooncogenes in the cause of endometrial carcinoma has only recently been addressed, unlike the etiologic factors of the more well-characterized female cancers of the breast, ovary, and uterine cervix. Amplification and/or overexpression of the c-*erb*B2 protooncogene may occur in a subset of tumors, although the extent of this phenomenon is still unclear.[8-10] In addition, the inappropriate expression of colony stimulating factor-1 and its receptor, the c-*fms* protooncogene, has been implicated as a potential autocrine growth stimulatory pathway in endometrial carcinoma.[11, 12]

Activating point mutations in members of the *ras* gene family represent the most frequent oncogene abnormality in human tumors.[13] Several recent reports suggest that *ras* mutations may play a role in some endometrial carcinomas; specifically, a total of 6 of 12 human endometrial carcinoma cell lines in two studies[10, 14] and 13 of 41 primary tumors in three studies[14-16] exhibit point mutations in Ki-*ras* codon 12. In the three previous studies of primary tumor specimens, however, a relatively small number of cases were examined in each study (10, 12, and 19, respectively), and a majority of the mutations (11 of 13) were found in endometrial carcinomas from Japan[14, 16]; the remaining two were from Australia.[15] Additional studies are needed to define the extent of involvement of the *ras* gene family in endometrial carcinomas from the United States, where the incidence of endometrial carcinoma is the highest in the world and where a majority of tumors are of the type I variety, in contrast to Japan, where the incidence of endometrial carcinoma is the lowest in the world and where a significantly higher fraction of tumors are of the type II classification.[17]

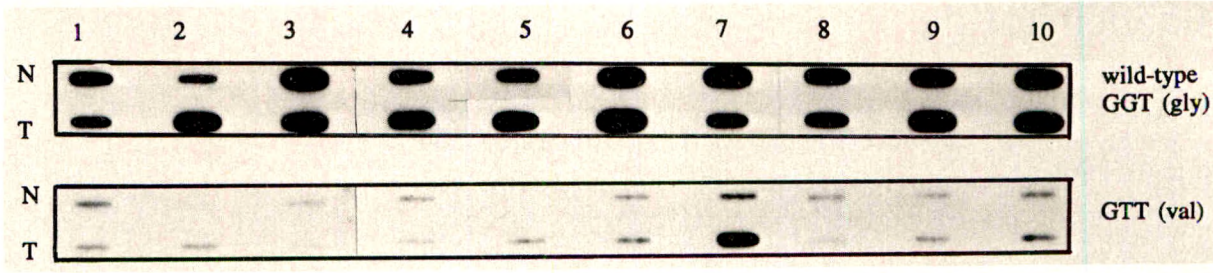

Fig. 1. Somatic mutation of Ki-*ras* codon 12 as detected by oligonucleotide hybridization with polymerase chain reaction–amplified DNA. DNA samples from normal *(N)* and tumor *(T)* tissue from 10 cases of formalin-fixed, paraffin-embedded endometrial carcinoma were analyzed for all possible activating point mutations in codons 12, 13, and 61 of Ha-*ras*, Ki-*ras*, and N-*ras* genes. Tumor but not normal tissue DNA from case 7 exhibited positive hybridization with mutant probe GTT for Ki-*ras* codon 12.

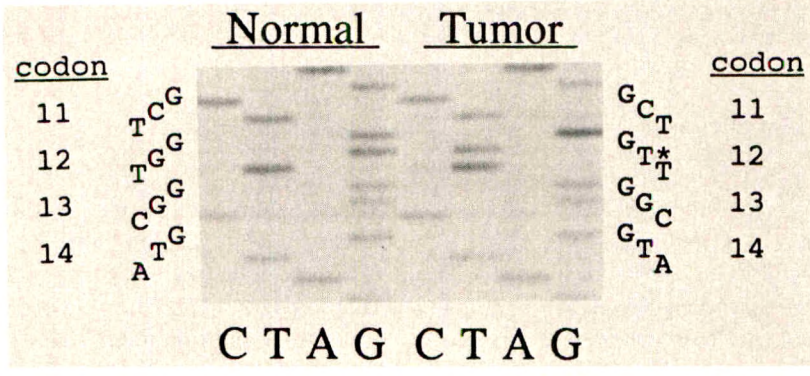

Fig. 2. Autoradiogram of sequencing gel for endometrial carcinoma case 7 in Fig. 1. The slot-blotting data indicating a point mutation of Ki-*ras* codon 12 was confirmed by DNA sequence analysis; clone of polymerase chain reaction–amplified DNA from normal tissue contained wild-type sequence GGT *(gly)*, and clone of polymerase chain reaction–amplified DNA from tumor tissue contained mutant sequence GTT *(val)*. *Asterisk*, Mutant codon.

The primary goal of this study was to examine a sufficiently large sample of endometrial carcinomas from the United States so that the extent of involvement of the *ras* oncogene in tumors from this population could be assessed. We then wished to determine if the presence of *ras* mutations correlated with parameters such as histologic factors, grade, stage, and receptor status.

Material and methods

Tumor samples and DNA isolation. Ten formalin-fixed, paraffin-embedded endometrial carcinoma specimens from the year 1990 were retrieved at random from the surgical pathology archives at the North Carolina Memorial Hospital. Genomic deoxyribonucleic acid (DNA) was extracted and was purified with a modification of a procedure described by Goelz et al.[18] Histopathologic sections 10 μm thick were cut and placed on untreated glass slides; 10 to 30 sections were cut for each tumor. One slide stained with hematoxylin and eosin stain was used to discriminate areas of tumor from normal tissue, and the bottom of each unstained slide was marked accordingly. Normal and tumor tissue were scraped separately from the slides with a straight-edged scalpel blade, were minced into small pieces, and were collected in separate 15 ml polypropylene conical tubes. DNA was then extracted and purified as described,[18] with the exception that samples were not sheared through a syringe needle (this step was found to decrease the size of genomic DNA without increasing the yield appreciably).

Twenty fresh-frozen endometrial carcinoma samples, obtained between 1989 and 1991 at the Duke University Medical Center, were processed for genomic DNA by means of standard procedures.[19]

Polymerase chain reaction and slot-blotting procedures. DNA was screened for *ras* mutations by means of polymerase chain reaction amplification, slot-blotting, and hybridization with oligodeoxynucleotides, as described previously.[10, 20] A panel of 66 oligonucleotide probes that were specific for wild-type or mutant sequences at codons 12, 13, and 61 of the Ha-*ras*,

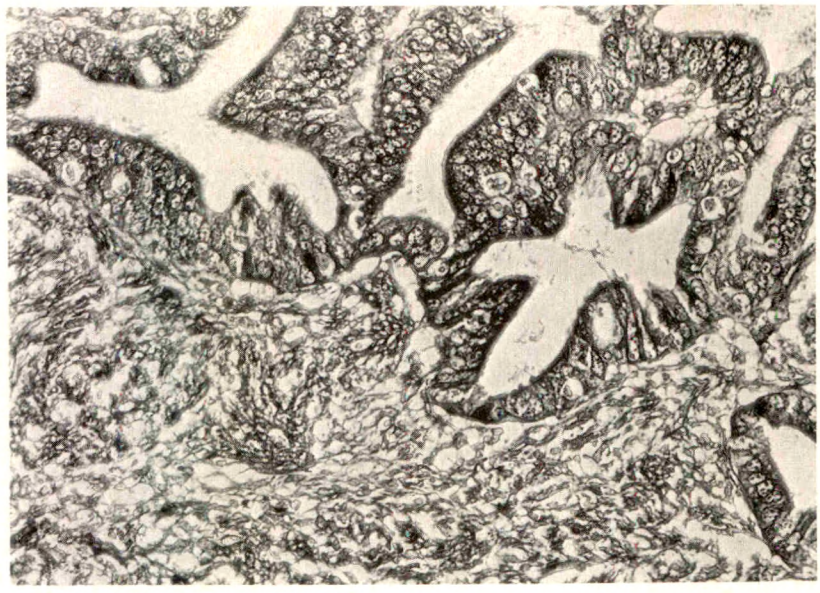

Fig. 3. Histologic photomicrograph of stained section from endometrial carcinoma case 7. The junction of carcinoma with normal myometrium illustrates the distinction of "tumor" versus "normal" in separating paraffinized tissue for DNA extraction; glandular organization indicates moderately differentiated endometrioid adenocarcinoma. (Hematoxylin and eosin. Original magnification ×200.)

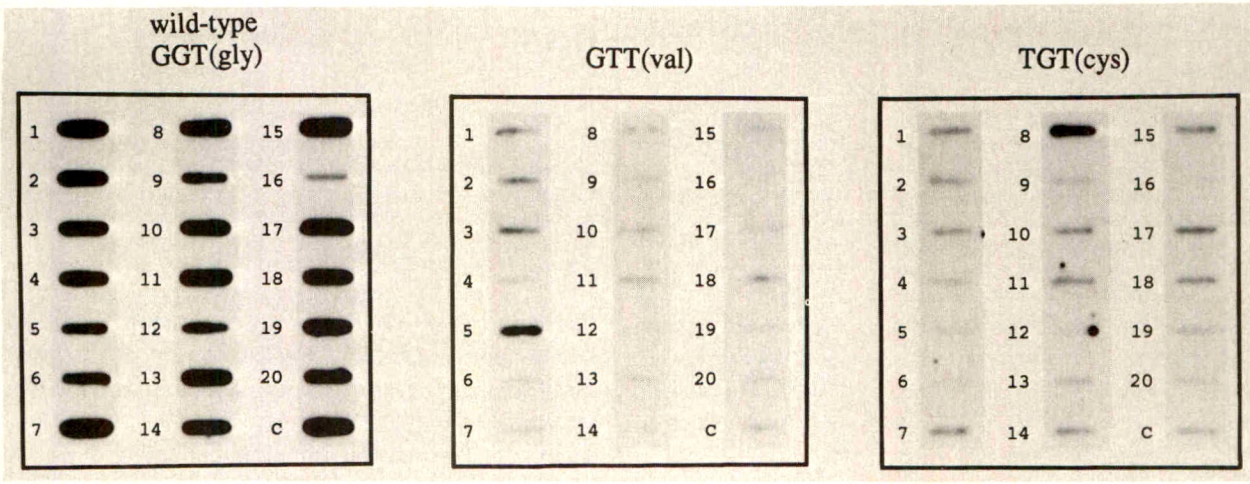

Fig. 4. Mutation of Ki-*ras* codon 12 in fresh-frozen endometrial carcinoma samples as detected by oligonucleotide hybridization with polymerase chain reaction–amplified DNA. Cases 5 and 8 exhibit mutations of wild-type GGT *(gly)* to GTT *(val)* and TGT *(cys)*, respectively.

Ki-*ras*, and N-*ras* genes was used to analyze DNA from normal and tumor tissue from each of the 10 archival endometrial carcinoma cases. The 20 fresh-frozen cases were analyzed only for mutations at Ki-*ras* codon 12. Before slot-blotting was performed, all samples were analyzed by agarose gel electrophoresis to ensure success of the polymerase chain reaction; in addition, all experiments were carried out with positive controls (DNA from previously characterized endometrial carcinoma cell lines[10]) and negative controls (plasmid DNA).

Sequence analysis. For cases determined to be harboring probable *ras* mutations, polymerase chain reaction amplified DNA fragments were subcloned and sequenced with the dideoxy chain termination method. After amplification, polymerase chain reaction products were purified by centrifugation in a Centricon-30 microconcentrator (Amicon, Danvers, Mass.) and were subcloned into the *Sma*I site of pBluescript SKII$^+$ (Stratagene, La Jolla, Calif.). Clones were sequenced with polymerase chain reaction primers according to the manufacturer's protocol for Sequenase version 2.0. Se-

quencing reactions were subjected to electrophoresis in 7 mol/L urea–6% polyacrylamide gels at 65 W constant power, were fixed in 10% methanol–10% acetic acid, were dried, and were exposed to Kodak X-Omat AR x-ray film for 1 to 3 days.

Results

All 10 of the formalin-fixed, paraffin-embedded tissue specimens analyzed yielded both normal and tumor DNA of sufficient quality and quantity for subsequent genetic analysis. The paraffin blocks invariably contained enough tumor and normal tissue so that from 30 to several hundred micrograms of genomic DNA was isolated from all cases. For each sample, the DNA migrated on ethidium bromide–stained agarose gels as a single high-molecular-weight band (>23 kb) with a smear of degraded, lower-molecular-weight DNA. Although the tumors described in this paper were all <2 years old, we have obtained DNA of sufficient quality for polymerase chain reaction procedures from fixed and embedded human tumors as old as 20 years.

DNA from these 10 cases was examined by means of polymerase chain reaction and slot-blotting procedures for all possible activating point mutations of codons 12, 13, and 61 of the Ha-*ras*, Ki-*ras*, and N-*ras* genes. One tumor contained an apparent mutation in one allele of Ki-*ras* codon 12 that was not evident in the surrounding normal tissue from this case, which indicated the somatic nature of this event (Fig. 1). A GGT→GTT (Gly→Val) transversion in codon 12 of Ki-*ras* was confirmed by sequencing of the polymerase chain reaction product; only the wild-type sequence was evident in DNA from the normal tissue of this case (Fig. 2). This tumor was classified with respect to histologic factors as a moderately differentiated endometrioid adenocarcinoma; a hematoxylin and eosin stained photomicrograph of the tumor and myometrial border is shown in Fig. 3.

Twenty additional specimens of fresh-frozen endometrial carcinoma were examined for mutations in Ki-*ras* codon 12. Two of these tumors, a moderately differentiated endometrioid adenocarcinoma and a

poorly differentiated endometrioid adenocarcinoma, exhibited activating point mutations: One contained the same GGT→GTT transversion described above, and the other contained a GGT→TGT (Gly→Cys) transversion in the first nucleotide of this codon (Fig. 4). These mutations were also heterozygous in nature; the tumors contained both a mutant and wild-type allele.

The mutations and histopathologic data for the 30 tumors described in this report are summarized in Table I in which no correlation between Ki-*ras* mutation and any of the clinical, pathologic, or histologic criteria was reported.

Comment

These data indicate that somatic point mutation of a *ras* oncogene occurs at a significant but relatively low (10%) frequency in endometrial carcinomas in the United States. Two previous studies[14, 16] showed that *ras* mutation occurs in endometrial carcinomas from Japan at about a threefold higher frequency than that observed here. These data suggest that *ras* mutation may be a more frequent occurrence in the type II tumors more prevalent in Japan than in the type I estrogen-related tumors that are more prevalent in the United States. The higher incidence of *ras* mutation that we had observed in endometrial carcinoma cell lines[10] may reflect spontaneous mutation and/or clonal selection of mutant *ras* genes during establishment and culture of these cells. All the existing data, however, implicate Ki-*ras* codon 12 as the most frequently altered *ras* site in endometrial carcinoma.

The *ras* family of protooncogenes encodes a unique form of GTPase molecule that appears to play a central role in cell proliferation as a result of its regulation of signal transduction. Point mutations in codons 12, 13, or 61 appear to inactivate this GTPase activity, which leaves the mutant protein in a constitutively activated state.[21] A large number and variety of human tumors contain point-mutated *ras* oncogenes,[13] which suggest a generalized role for *ras* in the proliferation of diverse tissues. Other solid tumors that contain mutations of Ki-*ras* at significant frequencies include carcinomas of the lung (20% to 30%), pancreas (70% to 90%), thyroid (20% to 60%), and colon (40% to 50%).[13] Endometrial carcinomas, like those of the lung, pancreas, and colon, exhibit a predominance of Ki-*ras* codon 12 mutations; thus a similar role for Ki-*ras* in the regulation of cell proliferation in these tissues or perhaps similar molecular pathways of neoplastic development or progression in these tissues.

Mutated *ras* genes have been strongly implicated in experimental chemical carcinogenesis[22]; this suggests that *ras* mutations in endometrial tumors may arise from chemical (including hormonal) mutagenesis. Alternatively, because cyclical cell proliferation is a prominent and somewhat unique feature of the mammalian endometrium, spontaneous DNA aberrations would be subject to a greater probability of conversion to permanent mutations in this tissue. Estrogen may thus act indirectly to stimulate tumorigenesis, by increasing the proliferative index of endometrial tissue.[23] The Ki-*ras* mutations reported in this paper whether they were spontaneous or chemically induced, did not appear to be associated with any histopathologic or clinical criteria. This suggests a sporadic induction and random distribution in endometrial carcinoma.

To extend these findings it will be necessary to examine a larger number of tumors, especially those of the more uncommon histologic (type II) variants. In particular, it would be instructive to compare a larger number of tumor samples from the United States with those from Japan, where estrogen-related risk factors and the incidence of endometrial carcinoma are much lower than those in the United States.[3, 17] That comparison might indicate a dramatically different ratio of type II to type I tumors. In addition, it would be of interest to analyze premalignant hyperplastic lesions of the endometrium for *ras* mutations to determine if that mutation is an early event in the development of some endometrial cancers as it is in colon carcinoma.

Effect of maternal oxygen administration on fetal oxygenation during graded reduction of umbilical or uterine blood flow in fetal sheep

Rene P. Paulick, MD,[a] Rebecka L. Meyers, MD,[a, c, d] and Abraham M. Rudolph, MD[a, b]
San Francisco, California

OBJECTIVE: Effects of maternal oxygen administration on fetal blood gases and on oxygen delivery and consumption during reduced uterine and reduced umbilical blood flows were examined.
STUDY DESIGN: In eight pregnant sheep (gestational age 133 ± 4 days) flow transducers were applied to a uterine and the common umbilical artery. Graded reductions in uterine and umbilical blood flows were achieved by a hypogastric artery snare and a balloon cuff encircling the umbilical cord. Fetal femoral arterial and umbilical venous oxygen contents and flows were measured at varying flow reductions with the ewe breathing air or oxygen.
RESULTS: During 75% reduction in umbilical blood flow maternal oxygen administration significantly increased fetal oxygen delivery (6.4 ± 2.5 to 7.7 ± 2.3 ml/min/kg) and oxygen consumption (4.3 ± 1.2 to 5.0 ± 0.8 ml/min/kg). With similar reduction of uterine flow oxygen administration increased oxygen delivery from 8.3 ± 2.4 to 12.3 ± 3.6 and oxygen consumption from 3.3 ± 0.8 to 4.7 ± 1.6 ml/min/kg.
CONCLUSION: Maternal oxygen inhalation improves fetal oxygenation during umbilical but especially during uterine blood flow reduction. (Am J Obstet Gynecol 1992;167:233-9.)

Key words: Umbilical blood flow, fetal oxygen delivery, fetal oxygen consumption

The effect of maternal oxygen administration during labor on fetal oxygenation is controversial. In one clinical study maternal oxygen administration increased fetal arterial P_{O_2} from 15 to 21 mm Hg.[1] In long-term, growth-retarded human fetuses maternal oxygen administration increased umbilical venous P_{O_2}.[2] On the other hand, it has been argued that maternal oxygen administration will have no major effect on fetal oxygenation because maternal arterial blood is almost completely saturated with oxygen; therefore, increasing the maternal arterial P_{O_2} above 100 mm Hg will increase only the amount of oxygen physically dissolved, which is relatively small compared with that attached to hemoglobin.[3]

During labor fetal oxygenation may need to be improved for reduction of uterine or umbilical blood flow. In fetal sheep maternal oxygen administration during reduction of umbilical blood flow improved fetal oxygenation by a modest degree.[4] Uterine blood flow may be markedly reduced in long-term, growth-retarded sheep fetuses, and maternal oxygen administration resulted in a significant improvement of fetal oxygenation.[5] However, the effect of maternal oxygen administration on fetal oxygenation during reductions of uterine blood flow has not been investigated systematically.

The aim of the present study was to assess the effect of maternal oxygen administration on fetal blood gases, oxygen delivery, and oxygen consumption during graded reductions of uterine blood flow. Furthermore, the effect of maternal oxygen administration during reduction of uterine blood flow was compared with that during reduction of umbilical blood flow of similar degree.

Material and methods

Animal preparation. Animal care and experimental procedures were approved by the Committee on Animal Research at the University of California, San Francisco.

Eight mixed-breed Western ewes with time-dated singleton gestations of 133 ± 4 days at the time of study (term 145 days) were fasted 24 hours, given spinal anesthesia with 4 ml 1% tetracaine hydrochloride (Pontocaine, Winthrop Laboratories, Murray Hill Station, N.Y.), and placed supine on the operating table. Polyvinyl catheters (inner diameter 0.05 inches) were inserted into pedal branches of a maternal femoral artery and vein and advanced to the descending aorta and

inferior vena cava, respectively. A continuous intravenous infusion of 0.9% saline solution (500 to 1000 ml) was administered to the ewe throughout the surgical procedure. Ketamine hydrochloride, 50 to 100 mg, was injected intravenously as necessary to maintain sedation. The ewe's abdomen was opened in the midline, and a snare was placed around the common segment of the uterine artery so that uterine blood flow could be controlled. In addition, a precalibrated electromagnetic flow transducer of appropriate size was placed around the main uterine artery supplying the pregnant horn.

The fetal hindlimbs were exposed through a small uterine incision. Anesthesia for the placement of all fetal catheters was provided locally with 0.5% lidocaine hydrochloride and systemically with 15 to 25 mg intramuscular ketamine hydrochloride given to the fetus. Polyvinyl catheters (inner diameter 0.03 inches) were inserted through pedal branches into the descending aorta and the inferior vena cava. A 3.5 Fr multiple sidehole catheter was inserted through a cotyledonary tributary into one of the two main umbilical veins. After placing an inflatable cuff occluder around the umbilical cord, an amniotic catheter was inserted to lie adjacent to the fetal trunk. Through a separate uterine incision, the common umbilical artery was isolated by a retroperitoneal approach as described previously.[6] The diameter of the common umbilical artery was measured, ranging from 4.5 to 5.5 mm, and a precalibrated electromagnetic flow transducer of appropriate size was placed around it.

The fetal and uterine incisions were closed, and amniotic fluid lost during surgery was replaced with warm saline solution. All catheters were filled with heparin (1000 IU/ml) and plugged. Together with the transducer cables of the flow probes and the snare, they were then directed subcutaneously to the ewe's flank, exteriorized, and stored in a vinyl pouch. On the day of surgery and each day afterward the ewe received 2 million IU penicillin G and 100 mg gentamicin, half intravenously and half into the amniotic cavity. Catheters were flushed daily and refilled with heparin.

Experimental protocol and measurements. Experiments were performed 1 to 3 days after surgery while the ewe stood quietly in a study cage. Pressures in the fetal descending aorta, umbilical vein, inferior vena cava, and amniotic cavity were measured with carefully calibrated Statham P23Db pressure transducers (Gould Inc., Oxnard, Calif.). Amniotic pressure was used as the zero pressure reference. Fetal heart rate was measured with a cardiotrachometer triggered by the arterial pulse pressure. Readings of uterine and umbilical blood flow were made on Statham SP 2202 electromagnetic blood flow meters. Mean blood flows, fetal heart rate, and pressures were recorded continuously on an Astro-Med MT-8800 direct writing recorder (West Warwick, R.I.).

Baseline blood samples were withdrawn simultaneously from the fetal descending aorta and the umbilical vein while the ewe was breathing room air or 100% oxygen for at least 15 minutes. The oxygen was administered to the ewe through a loosely fitting plastic bag at a rate of 15 L/min. Blood gases and pH were

§$p < 0.05$ compared with baseline.

measured by a Corning 175 Blood Gas Analyzer (Medfield, Mass.). Hemoglobin concentration and oxygen saturation were measured photometrically in duplicate (Hemoximeter OSM 2, Radiometer, Copenhagen).

After baseline blood samples were obtained, either umbilical or uterine blood flow was reduced in a stepwise fashion. We aimed for 30%, 50%, and 75% reductions of blood flow. At least 10 minutes after the flow remained stable at each grade of reduction, a 0.6 ml blood sample was obtained from the descending aorta and umbilical vein, and fetal heart rate, blood pressures, and blood flows were measured. Measurements were then repeated while the ewe breathed 100% oxygen for 15 minutes. Between each grade of reduction we waited at least 20 to 30 minutes or until pressures and blood flows had returned to baseline values. On each day only one type of blood flow reduction was performed; each type of blood flow reduction was performed only once per animal.

At the end of the studies the ewe was killed with an overdose of pentobarbital sodium (Euthanasia-6, Veterinary Laboratories, Lexena, Kan.) followed by an intravenous injection of 10 ml saturated potassium chloride solution. The fetus was weighed and the correct positions of the catheters, flow probes, and snare were confirmed.

Calculations. The oxygen content in the umbilical vein and the descending aorta, fetal oxygen delivery, and fetal oxygen consumption were calculated as follows:

$$\text{Oxygen content (ml/dl)} = 0.0134 \times \text{Hemoglobin (gm/dl)} \times \text{Oxygen saturation (\%)}$$

$$\text{Oxygen delivery (ml/min)} = \text{Oxygen content}_{UV} \text{ (ml/dl)} \times \text{Placental blood flow (ml/min)}/100$$

$$\text{Oxygen consumption (ml/min)} = \text{Oxygen content}_{UV-DA} \text{ (ml/dl)} \times \text{Placental blood flow (ml/min)}/100$$

where UV is umbilical vein and DA is descending aorta.

Statistical analysis. Data analysis was performed with a computerized statistical program (SuperANOVA, Abacus Concepts, Berkeley, Calif.). Data are expressed as mean ± SD. The effect of blood flow reduction and maternal oxygen administration was analyzed by an analysis of variance for repeated measurements with two within factors. Furthermore, the program tested whether a significant interaction between the two within factors (blood flow reduction and maternal oxygen administration) was present. No post hoc multiple comparison testing was performed because only within-factors and no between-factors variations were present. For all tests, after degree of freedom adjustment, $p < 0.05$ was considered statistically significant.

Results

Fetal weight averaged 3.6 kg (range 3.0 to 4.5 kg). At baseline, while the ewe was breathing room air, fetal blood gases, umbilical blood flow, oxygen delivery, and oxygen consumption were within the normal range of values measured in our laboratory (Tables I to IV).

At baseline maternal oxygen administration increased umbilical venous oxygen saturation to nearly 100%. Because umbilical blood flow did not change, maternal oxygen administration increased fetal oxygen delivery by about 4.5 ml/min/kg, representing a 20%

§$p < 0.05$ compared with baseline.

increase compared with room air (Tables II, IV). Fetal oxygen consumption remained unchanged.

Graded reductions of umbilical blood flow resulted in a significant increase in fetal hemoglobin concentration (Table I). Fetal descending aortic oxygen saturation decreased significantly, whereas umbilical venous oxygen saturation remained unchanged. Fetal oxygen delivery decreased in proportion to the grade of umbilical blood flow reduction (Table II). With a reduction of fetal oxygen delivery below 12 ml/min/kg, fetal oxygen consumption began to decrease.

Maternal oxygen administration during graded reductions of umbilical blood flow decreased umbilical venous pH and increased umbilical venous P_{CO_2} significantly (Table I), probably due to maternal hypercapnia. Umbilical venous P_{CO_2} and oxygen saturation

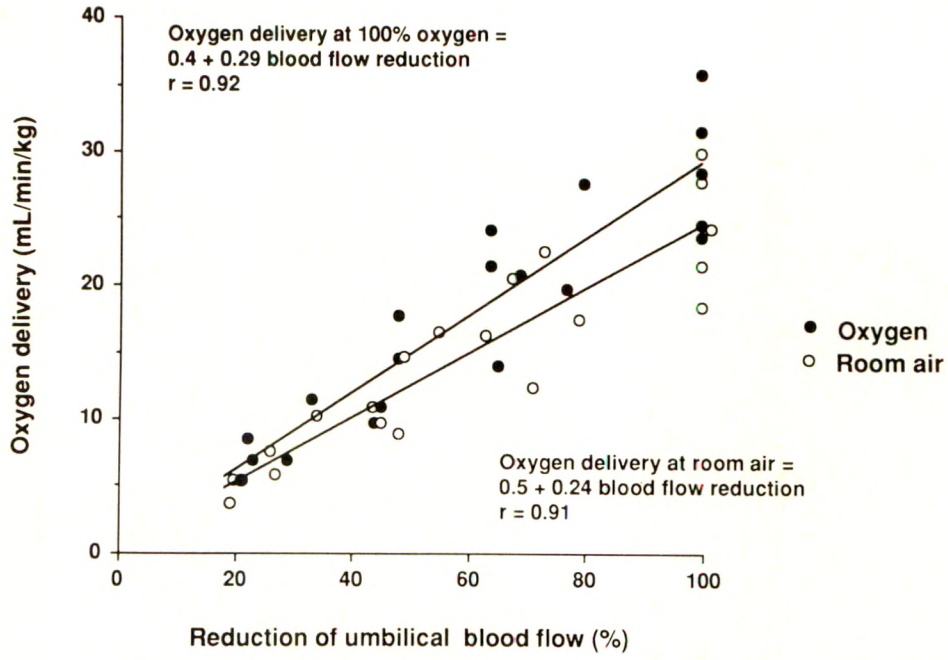

Fig. 1. Effect of maternal oxygen administration on fetal oxygen delivery during graded reductions of umbilical blood flow.

increased significantly. As a result, umbilical venous oxygen content increased to about 15.5 ml/min/kg at all grades of blood flow reduction (Table II). Thus maternal oxygen administration increased fetal oxygen delivery by 20% compared with the corresponding room air values. There was a significant interaction between the effect of maternal oxygen administration and blood flow reduction; although oxygen administration increased fetal oxygen delivery by 4.4 ml/min/kg at baseline, increases were 3.4, 2.7, and 1.3 ml/min/kg with a 30%, 50%, and 75% reduction of umbilical blood flow. Thus the beneficial effect of maternal oxygen administration on fetal oxygen delivery diminished with the severity of blood flow reduction. Maternal oxygen administration did not increase fetal oxygen consumption significantly.

Fig. 1 illustrates the relationship of fetal oxygen delivery to umbilical blood flow. In both room air– and oxygen-treated fetuses oxygen delivery was linearly related to umbilical blood flow. Fetal oxygen delivery was significantly greater in fetuses treated with oxygen. However, this increase was related to umbilical blood flow and diminished with the severity of blood flow reduction.

Graded reductions of uterine blood flow resulted in a significant increase in fetal hemoglobin concentration (Table III). Fetal arterial and umbilical venous oxygen saturation decreased significantly; umbilical blood flow increased by a modest degree. Fetal oxygen delivery decreased when uterine blood flow fell below 60% of baseline values (Table IV). With a reduction of fetal oxygen delivery below 15 ml/min/kg, fetal oxygen consumption began to decrease.

Maternal oxygen administration during reductions of uterine blood flow decreased umbilical venous pH and increased umbilical venous P_{CO_2} significantly (Table III), indicating maternal hypercapnia. Umbilical venous P_{CO_2} and oxygen saturation increased significantly. As a result, maternal oxygen administration increased umbilical venous oxygen content by about 2 ml/dl at all grades of blood flow reduction (Table IV). Because umbilical blood flow remained unchanged, maternal oxygen administration increased fetal oxygen delivery by about 4 ml/min/kg at all grades of uterine blood flow reduction. There was no significant interaction between the effect of maternal oxygen administration and blood flow reduction; thus the beneficial effect of maternal oxygen administration on fetal oxygen delivery was about the same at baseline and at 30%, 50%, and 70% reductions of uterine blood flow. Maternal oxygen administration increased fetal oxygen consumption significantly by 1.4 ± 1.3 ml/min/kg when uterine blood flow was reduced to 30% at baseline.

Fig. 2 illustrates the relationship of fetal oxygen delivery to uterine blood flow reduction. In room air– and oxygen-treated fetuses, oxygen delivery was logarithmically related to uterine blood flow. Fetal oxygen delivery was significantly greater in fetuses treated with oxygen. The increase in fetal oxygen delivery by maternal oxygen administration was not related to the grade of uterine blood flow reduction, even when

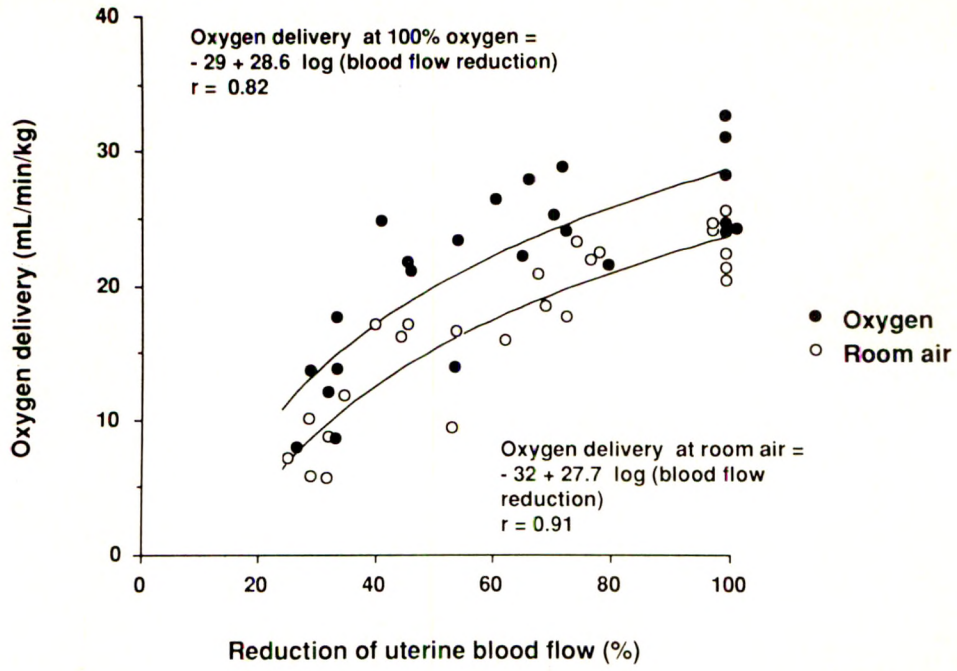

Fig. 2. Effect of maternal oxygen administration on fetal oxygen delivery during graded reductions of uterine blood flow.

uterine blood flow was reduced to 30% of baseline values.

Comment

The aim of the present study was to assess the effect of maternal oxygen administration on fetal blood gases, oxygen delivery, and oxygen consumption during graded reductions of uterine blood flow. The effect of maternal oxygen administration during reductions of uterine blood flow was also compared with that during reductions of umbilical blood flow of similar degree.

To reduce uterine blood flow, we used a snare placed around the common uterine artery. The effect of constricting the snare was monitored with a flow probe placed around the main uterine artery supplying the pregnant horn. Although the method is easy to use, certain limitations must be kept in mind. First, the uteroplacental circulation receives some blood supply from the ovarian arteries, which were not constricted by the snare, and second, although constriction of the snare should produce equal blood flow reduction in both uterine arteries, this may not always be true.[7] Because of these limitations, changes in uteroplacental blood flow may not have been accurately reflected by measurement of flow in one uterine artery.

Our results on the effect of reducing umbilical blood flow are in close agreement with previous studies.[8, 9] Umbilical venous oxygen content did not decrease during reduction of umbilical blood flow; thus fetal oxygen delivery was linearly related to umbilical blood flow. Fetal oxygen consumption was maintained with reduction of umbilical blood flow to about 50% of baseline values; further reductions were associated with a progressive fall in oxygen consumption.

The effect of maternal oxygen administration on fetal oxygenation during reduction of umbilical blood flow has been studied previously.[4] From these studies it was concluded that maternal oxygen administration increases oxygen delivery to the fetus during times of reduced umbilical perfusion. However, because umbilical venous oxygen content does not decrease and may actually increase during reduction of umbilical blood flow,[9] only a small amount of oxygen can be added by maternal oxygen administration. Under these conditions umbilical blood flow is the main determinant of fetal oxygen delivery; the beneficial effect of maternal oxygen administration diminishes with the severity of blood flow reduction. Thus maternal oxygen administration has only a modest effect on fetal oxygen delivery when umbilical blood flow falls below 50% of baseline values.

The effect of uterine blood flow reduction on fetal oxygenation has been studied extensively.[10-12] In agreement with these studies our results demonstrate that the oxygen supply to the pregnant uterus exceeds the minimum necessary to maintain fetal oxygen delivery. Thus fetal oxygen delivery started to decrease only when uterine blood flow fell below 60% of baseline values.

A previous study investigated the effect of maternal

oxygen administration on fetal oxygenation in chronically hypoxemic, growth-retarded fetal sheep.[5] In this study maternal arterial oxygen content and umbilical blood flow were in the physiologic range of values. Thus it may be speculated that the underlying cause for chronic hypoxemia in these fetuses was a severe reduction in uterine blood flow. Maternal oxygen administration increased fetal oxygen delivery by about 5.5 ml/min/kg.[5] In our present study maternal oxygen administration has been shown to have a significant effect on fetal oxygen delivery, even with a short-term reduction in uterine blood flow to 30% of baseline.

During reduction of uterine blood flow umbilical venous oxygen saturation decreases significantly. Thus a substantial amount of oxygen can be added to umbilical venous blood. For example, when uterine blood flow was reduced to 30% of baseline, maternal oxygen administration increased umbilical venous oxygen content from 3.8 to 5.4 ml/dl. Because umbilical blood flow did not change, maternal oxygen administration increased fetal oxygen delivery from 8.3 to 12.3 ml/min/kg, representing a 50% increase.

In summary, we have demonstrated that maternal oxygen administration has a significant effect on fetal oxygenation during short-term reductions of uterine or umbilical blood flow. However, the beneficial effect of maternal oxygen administration is far greater during reductions of uterine blood flow than during reductions of umbilical blood flow. If the response of the human fetus to maternal oxygen administration is similar to that of the sheep fetus, maternal oxygen administration may be beneficial to the fetus during labor, especially when the fetal heart rate pattern is suggestive of reduced uterine blood flow.

Convulsions in pregnancy in related gorillas

James G. Thornton, MD, and Joseph L. Onwude, MB
Leeds, England

Two related gorillas, the second the granddaughter of the first, had pregnancies complicated by convulsions and edema. They may have suffered from eclampsia, indicating that this is not an exclusively human disease and that in gorillas, as in humans, there is a familial factor. (Am J Obstet Gynecol 1992;167:240-1.)

Key words: Eclampsia, gorillas, pregnancy

It is generally considered that *Homo sapiens* is the only species affected by the pregnancy-specific diseases pre-eclampsia and eclampsia, although single cases of possible eclampsia[1] and preeclampsia have been reported in captive lowland gorillas. We wish to draw researchers' attention to another published case of probable eclampsia affecting the maternal grandmother in the case reported by Baird.[1]

Case report

The case in question was mentioned by George Schaller in his classic book, *The Mountain Gorilla,*[2] but there is no published reference to the fact that the gorillas were related. He reported that the first successful gorilla pregnancy in captivity at the Columbus Zoo, Columbus, Ohio, in 1956 was complicated by con-

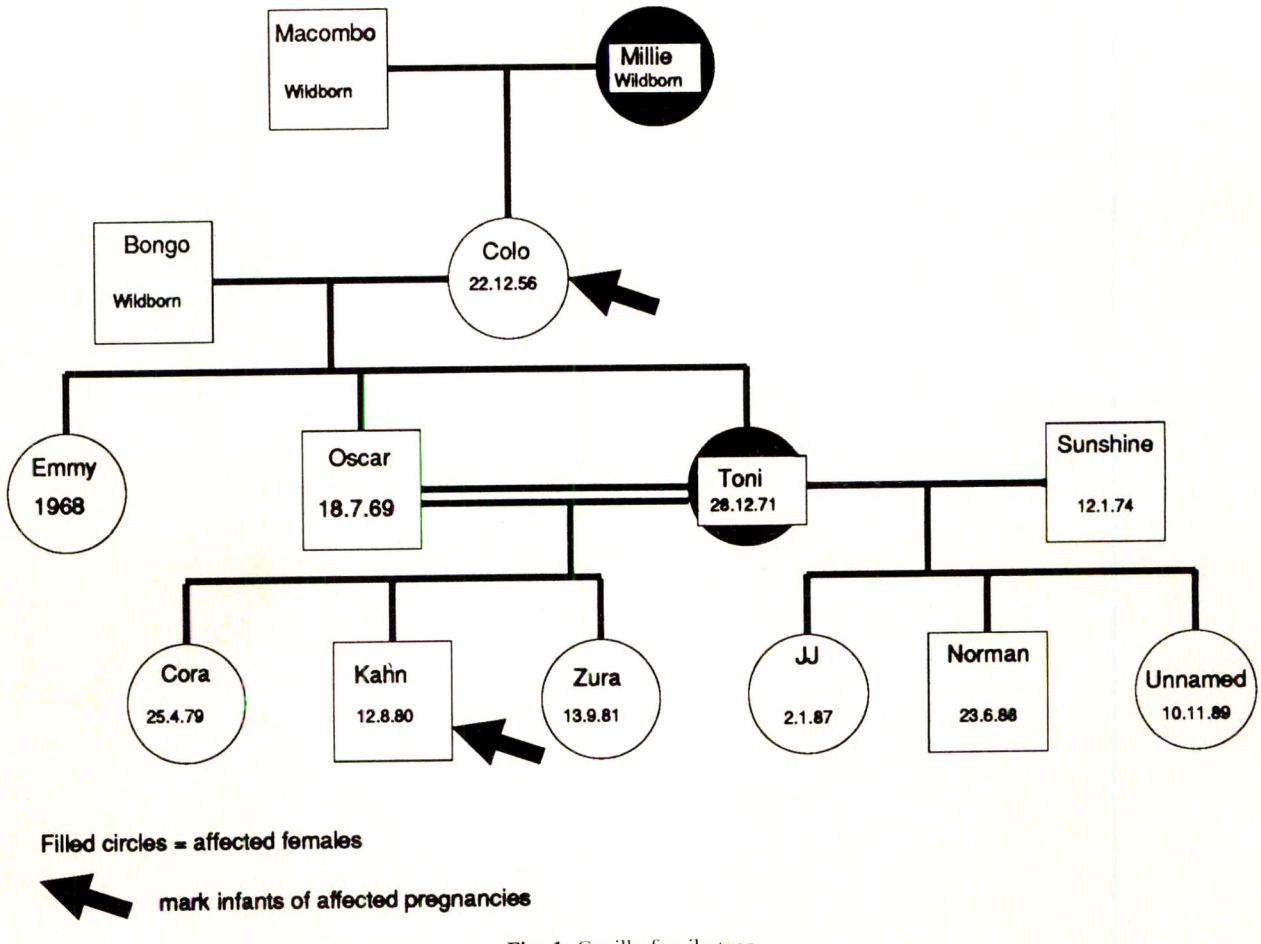

Fig. 1. Gorilla family tree.

vulsions and edema. The mother, Millie, delivered a female infant named Colo, which survived, but no further details were given. Colo had three offspring, a son and two daughters. One of the daughters, Toni, had three pregnancies by her brother Oscar. The first and third pregnancies were normal and resulted in the delivery of healthy daughters, but the second was complicated by convulsions and edema.[1] The blood pressure was not recorded, urine was not tested for protein, and the gestation was uncertain. The mother was treated with magnesium sulfate, and the pregnancy continued for 2 weeks after the convulsions. The male baby was alive at birth but died of salmonella sepsis at 18 days. The placenta was infarcted. Toni subsequently had three further pregnancies without complication and at the time of writing is pregnant again. The family tree is shown in Fig. 1. Both these cases are suggestive of eclampsia. Neither mother had convulsions before and after the affected pregnancies, and Millie went on to live another 20 years after the delivery of Colo, although she never had another pregnancy. There is no other disease with which they are likely to have been affected.

Comment

These two cases have prompted us to set up a data base of gorilla births in captivity. This is not yet complete, but there may have been another case of pre-eclampsia. That pregnancy was complicated by proteinuria (2+ to 3+) (specimen collected from the cage floor) and resulted in the stillbirth of a 2200 gm female fetus. There was evidence of abruptio placentae and infarction. This was the third of five pregnancies, paternity having changed after the fourth only. All the others resulted in live births. We have details of >200 gorilla births in captivity worldwide. A rate of two cases of eclampsia is similar to that in humans before the availability of widespread antenatal care, where rates of one to two per thousand pregnancies have been reported. We would be interested to hear of any other cases that may have gone unreported.

It would be surprising if preeclampsia were an exclusively human disease. Gorillas and chimpanzees are the primates most closely related to man, not only an atomically and behaviorally but also at the molecular level. In common with man both species have a hemochorial placenta and a comparable gestation period. Orangutans have a slightly shorter gestation, and although we can find no evidence of eclampsia occurring in an orangutan, one at the San Diego Zoo with a pregnancy complicated by proteinuria delivered a stillborn infant. The occurrence of eclampsia in related gorillas may support a genetic etiology. In humans some workers have demonstrated inheritance patterns compatible with mendelian inheritance, although our twin studies have recently provided conflicting data.[3]

Messenger ribonucleic acid for transforming growth factor-α, but not for epidermal growth factor, is expressed in fetal and neonatal mouse brain

John Yeh, MD,[a, b] Kenneth M. Rosen, PhD,[b] and Lydia Villa-Komaroff, PhD[b]

Boston, Massachusetts

OBJECTIVE: Little is known concerning the presence of transforming growth factor-α in fetal and neonatal tissues. Our objective was to analyze messenger ribonucleic acid expression for transforming growth factor-α and epidermal growth factor, the structural and biochemical analog of transforming growth factor-α in fetal and neonatal murine brain.

STUDY DESIGN: Messenger ribonucleic acid was prepared from whole brains of mice from these developmental stages: embryonic days 14, 15, and 17, postnatal days 0, 4, 10, and adult. Polymerase chain reaction was performed on the complementary deoxyribonucleic acid obtained from reverse transcription of messenger ribonucleic acid with transforming growth factor-α and epidermal growth factor primers. In addition, ribonuclease protection assay was used to identify transforming growth factor-α transcripts.

RESULTS: We found messenger ribonucleic acid encoding transforming growth factor-α in all stages of development used. Epidermal growth factor messenger ribonucleic acid was not found in any stage. Ribonuclease protection assay confirmed transforming growth factor-α transcripts in these tissues.

CONCLUSION: Transforming growth factor-α may play an autocrine or paracrine role in the differentiation or maintenance of murine fetal and neonatal brains. (Am J Obstet Gynecol 1992;167:242-5.)

Key words: Transforming growth factor-α, epidermal growth factor, brain development, growth factors

Transforming growth factor-α (TGF-α) is a 50-amino-acid peptide that causes a reversible transformation of phenotype in normal rat kidney cells.[1] It is a biochemical and structural homolog to epidermal growth factor (EGF) in that it has 30% to 40% amino acid identity and similar three-dimensional characteristics. Both growth factors act through the same 170 kd tyrosine kinase receptor, the EGF receptor, for signal transduction. The two growth factors have been implicated as autocrine or paracrine regulators of cellular function.

In situ hybridization analysis has revealed the presence of transforming growth factor-α messenger ribonucleic acid (mRNA) in adult mouse brain.[2] In situ hybridizations performed with whole fetal mice show TGF-α mRNA in the fetal otic vesicle and oral cavity, among other places, but no TGF-α mRNA was found after embryonic day 10.[3] Kudlow et al.[4] demonstrated that fetal rat hypothalamus and brain stem contained TGF-α mRNA but did not specify the developmental stage of the fetus studied.

Reverse transcription of mRNA into complementary deoxyribonucleic acid (cDNA) and then amplification of the cDNA by polymerase chain reaction has allowed the analysis of small quantities of mRNA. This method has been used to demonstrate that mRNA encoding TGF-α, but not EGF, is expressed in preimplantation mouse embryos.[5] We used this method and ribonuclease protection assay to study the developmental expression of TGF-α and EGF mRNA in fetal and neonatal murine brain. The presence of TGF-α mRNA would suggest a possible autocrine or paracrine role for this growth factor in brain development.

Material and methods

mRNA preparation. C57BL/6j mice were obtained from the breeding colony of the Children's Hospital Mental Retardation Research Center. The care and use of the animals were approved by the Children's Hospital animal care committee. Whole brains were isolated from the following developmental stages: embryonic

days 14, 15, and 17, postnatal days 0, 4, and 10, and a 60-day-old adult. RNA was isolated with the guanidine isothiocyanate method, followed by centrifugation through cesium chloride.[6, 7]

Reverse transcription. The mRNA from the murine brains was used as template for the synthesis of cDNA by the following method[5]: Two micrograms of oligodeoxythymidylic acid (12 to 18) (Pharmacia, Piscataway, N.J.) were used as primer for each reverse transcription reaction. Five hundred nanograms of RNA and oligodeoxythymidylic acid in a final volume of 20 μl was heated to 68° C for 2 minutes and then cooled to 25° C for 2 minutes. 5× BRL reverse transcription buffer (BRL, Gaithersburg, Md.), 2 μl RNAsin (Promega, Madison, Wis.), 16 μl 2.5 mmol/L deoxynucleotides, and 400 U Moloney murine leukemia virus reverse transcriptase (BRL) were added to the mRNA and oligodeoxythymidylic acid mixture in a final volume of 50 μl. This mixture was incubated at 42° C for 45 minutes. An additional 400 U Moloney murine leukemia virus reverse transcriptase was added, and the mixture was incubated at 42° C for a further 45 minutes. The incubation was terminated by heating to 68° C for 10 minutes and then stored at −20° C until used for polymerase chain reaction.

Polymerase chain reaction. TGF-α primers used were 5′ACCTGCAGGTTTTTGGTGCAG3′ and 5′GCAGACGAGGGCACGGCACCA3′.[5] The two TGF-α primers encompass a 239 bp nucleic acid region encoding bases 58 to 78 (5′-oligonucleotide) and bases 297 to 277 (3′-oligonucleotide), respectively, and with DNA sequence having a unique restriction endonuclease site for *Sph* I such that fragments of 159 and 80 bp are generated after cleavage. EGF primers used were from the mouse cDNA sequence and were 5′AATAGTTATCCAGGATGCCCA3′ (bases 3238 to 3259) and 5′TCGTAGGTCTCGAGTCTGACATCG3′ (bases 3381 to 3357).[8] The primers encompass the sequence encoding the first 48-amino-acid residues of the mature EGF peptide.

Polymerase chain reaction DNA amplification used 10 μl of the reverse transcribed cDNA.[5] A Perkin-Elmer/Cetus GeneAmp (Perkin-Elmer/Cetus, Norwalk, Conn.) kit was used according to manufacturer's instructions. Thirty cycles of the following thermocycling conditions were used: 94° C for 20 seconds, 55° C for 20 seconds, and 72° C for 30 seconds. mRNA from whole adult mouse ovary was used as positive control for TGF-α and adult male mouse salivary mRNA was a positive control for EGF for reverse transcription polymerase chain reaction. Yeast transfer RNA was used as negative control.

Analysis of polymerase chain reaction products. The amplified DNA fragments were analyzed without further purification by electrophoresis on 3% NuSieve and 1% SeaKem (FMC, Rockland, Me.) agarose gels. Before digestion with the restriction endonuclease *Sph* I, the polymerase chain reaction–amplified DNA fragments were chloroform extracted, ethanol precipitated, and resuspended in sterile water.

Ribonuclease protection assay. A TGF-α 239 bp polymerase chain reaction fragment was cloned into a Bluescript phagemid vector by the method of Marchuk et al.[9] This TGF-α clone was sequenced to confirm its identity and orientation. After that, in vitro transcription of TGF-α was performed (SP6/T7 Transcription Kit, Boehringer/Mannheim, Indianapolis), with α-^{32}phosphorus cytidine triphosphate (Amersham, Arlington Heights, Ill.) as the label, and the radiolabeled TGF-α RNA probe was purified with a 5% acrylamide gel. This purified TGF-α probe was then hybridized overnight at 45° C to 10 μg of murine brain RNA (RPA II Kit, Ambion, Austin, Tex.). The hybridized RNA was digested with ribonuclease A and T1 for 30 minutes at 37° C, then was subjected to electrophoresis in a 5% acrylamide gel. After that, the gel was exposed to Kodak XAR-5 film (Eastman Kodak Co., Rochester, N.Y.) at −70° C with an intensifying screen (Dupont Cronex Lightning Plus, Dupont Instruments, Wilmington, Del.) for 2 days. The positive control used was adult rodent ovary, which is known to contain TGF-α mRNA. The negative control was yeast RNA.

Northern blotting. RNA was fractionated on 2.2 mol/L formaldehyde and 1.2% agarose surface tension gel and transferred to a charged nylon membrane (Nytran, Schleicher, and Schuell, Keene, N.H.). The blots were hybridized in 50% formamide, 5× saline solution–sodium citrate buffer at 48° C overnight. A 925 bp fragment from the TGF-α probe phTGF1-10-925 (gift of G.I. Bell) was labeled (specific activity of 1×10^9 disintegrations/min/μg) with a random hexanucleotide priming kit (Boehringer-Mannheim, Indianapolis) and α-^{32}P deoxycytidine triphosphate (Amersham). After hybridization and washing, the filters were exposed to Kodak XAR-5 film at −70° C with an intensifying screen.

Results

With reverse transcription and then polymerase chain reaction, amplification products specific for TGF-α were detected in the brains at the following stages of development: embryonic days 14, 15, and 17, postnatal days 0, 4, and 10, and adult brain (Fig. 1). Restriction endonuclease digestion by *Sph* I of the polymerase chain reaction–amplified DNA revealed appropriate hydrolysis of the 239 bp TGF-α sequences into fragments of 159 and 80 bp (Fig. 1). With the cDNA from the same reverse transcription reaction, polymerase chain reaction amplification was performed with primers for EGF. No polymerase chain reaction–amplified

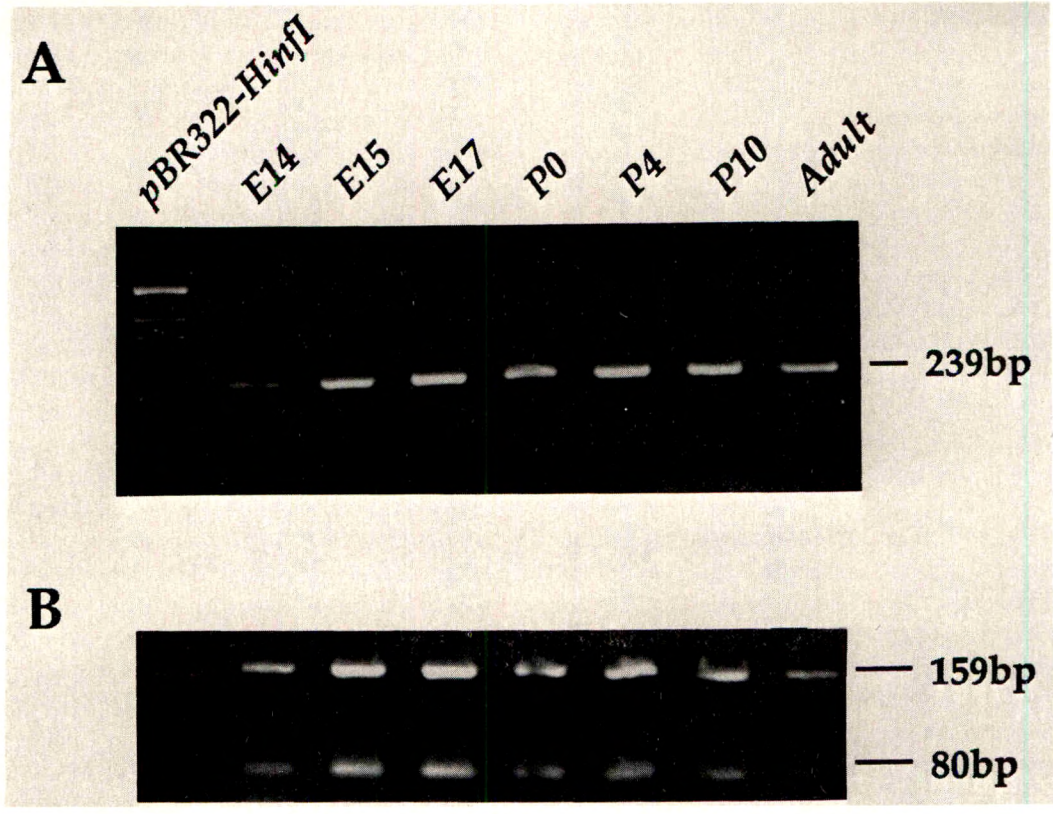

Fig. 1. A, Reverse transcription followed by polymerase chain reaction with primers for TGF-α of murine fetal (embryonic days *E14, E15,* and *E17*) and neonatal (postnatal days *P0, P4,* and *P10*) brain mRNA results in 239 bp DNA in all developmental stages studied. **B,** Digestion of the reverse transcribed polymerase chain reaction 239 bp DNA fragments with *Sph* 1 results in the predicted fragments of 159 and 80 bp, thereby confirming that polymerase chain reaction–amplified fragments encode TGF-α.

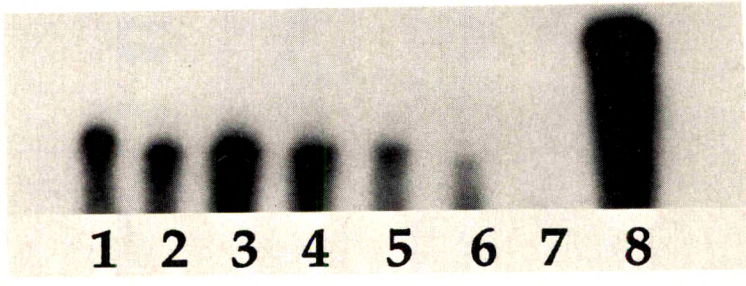

Fig. 2. Ribonuclease protection assay with 10 μg to total RNA from whole mouse brain hybridized with 239 bp TGF-α RNA probe. *Lanes 1 to 5* represent the following developmental stages: embryonic days 15 and 17 and postnatal days 0, 4, and 10. *Lane 6*, adult rodent ovary. *Lane 7*, Yeast negative control, *Lane 8*, Undigested radiolabeled TGF-α RNA probe.

DNA encoding EGF was observed in the brain developmental series. Mouse salivary gland mRNA, which is a positive control for EGF, resulted in the expected polymerase chain reaction amplification product.

Ribonuclease protection assay was used as a second method to confirm the expression of TGF-α in fetal and neonatal brain (Fig. 2). Ten micrograms of total RNA from embryonic days 15 and 17 and postnatal days 0, 4, and 10 murine brain was used for analysis and all developmental stages showed the presence of TGF-α transcripts. Northern analysis with up to 20 μg RNA was used as another method to confirm the presence of TGF-α and revealed faint positive signals at the expected 4.5 kb TGF-α mRNA location.

Comment

We conclude that fetal and neonatal expression of TGF-α, but not EGF, mRNA occurs in both the devel-

oping and mature mouse brain. Ribonuclease protection analysis also shows that TGF-α expression occurs in fetal and neonatal murine brain.

Rappolee et al.[5] detected mRNA for TGF-α, but not EGF, in preimplantation murine embryos with reverse transcription followed by polymerase chain reaction amplification of cDNA. Paria and Dey[10] found that addition of TGF-α or EGF to the culture medium of mouse blastocytes improved embryo development. They also showed that EGF receptors are present in eight-cell embryos. These data suggest that TGF-α or EGF may have an important role in the development of preimplantation and periimplantation mouse embryos.

Previous investigators have reported the presence of TGF-α in fetal rodent brains but have not reported expression of TGF-α in a developmental series. Brown et al.[11] found evidence for TGF-α by radioimmunoassay in late gestational fetal rat brains (embryonic day 20), with peak levels observed in late gestation. Ojeda et al.[12] reported that mouse embryonic day 18 fetal hypothalamus had TGF-α mRNA, by Northern analysis, but not EGF mRNA. They also reported that higher levels of TGF-α mRNA was observed on embryonic day 18 than postnatally. Kudlow et al.[4] showed that fetal rat hypothalamus and brain stem contained TGF-α mRNA but did not specify the developmental stage of the fetus studied. We used reverse transcription followed by polymerase chain reaction, a much more sensitive method of detection of mRNA encoding for TGF-α, to study the developmental expression of TGF-α and found that TGF-α mRNA was expressed in all stages studied, starting from embryonic day 14. Our evidence confirms that TGF-α mRNA is expressed in fetal mouse brain.

Cell culture and in vivo studies indicate that TGF-α or EGF may have a physiologic function in brain tissues. Cultures of fetal rat telencephalon with EGF cause a stimulation of lectin production, which in turn may be related to neuronal aggregation.[13] TGF-α and EGF increased gonadotropin-releasing hormone release from juvenile rodent female median eminances in a dose-related fashion.[12] The mRNA for both TGF-α and its receptor, the EGF receptor, are present in the bovine pituitary.[14] In vivo, Polk et al.[15] infused EGF in fetal sheep and found resultant increased corticotropin levels, suggesting that EGF or TGF-α may have pituitary functions. Thus TGF-α and its receptor may have physiologic roles in the regulation of brain and pituitary function. The most likely reason for our finding that TGF-α, but not EGF, mRNA is present in the fetal and neonatal tissues is that TGF-α is the physiologic factor that acts as the autocrine or paracrine ligand for the EGF receptor in the mouse brain. Furthermore, our data that TGF-α mRNA is expressed both in fetal and in neonatal brains suggest that TGF-α may be important both in utero and post partum.

Cardiac electromechanical dissociation in the hypoxic fetal sheep may have clinical implications

Reuven M. Lewinsky, MD, Lawrence W. Oppenheimer, MB, Robert J. Morrow, MD, S. Lee Adamson, PhD, Dan Farine, MD, and J.W. Knox Ritchie, MD

Toronto, Ontario, Canada

OBJECTIVES: Our purpose was to determine the sequence of fetal cardiac electrical and mechanical events associated with acute hypoxic acidemia and to correlate those events with terminal fetal heart rate patterns preceding fetal death.

STUDY DESIGN: Eight acutely catheterized fetal sheep were rendered hypoxic by placental embolization with microspheres until fetal death occurred. The fetal electrocardiogram, Doppler cardiogram, left ventricular and aortic pressures, and fetal heart rate were continuously recorded.

RESULTS: All eight fetuses showed a terminal bradycardia consisting of two phases: an initial phase of falling ventricular pressures, culminating in mechanical asystole, and a subsequent phase after asystole during which the electrocardiographic signal persisted for an average duration of 15.2 ± 8.7 minutes (range 3.1 to 32.4) and triggered a Hewlett-Packard 8040A monitor to show a heart rate pattern.

CONCLUSIONS: The phenomenon of cardiac electromechanical dissociation may be occurring during similar terminal bradycardias that are observed in human labor and explains the delivery of a fresh stillbirth in spite of the recording of an electrocardiographic signal from a scalp electrode. (Am J Obstet Gynecol 1992;167:246-9.)

Key words: Fetal death, fetal electrocardiogram, electromechanical dissociation, fetal monitoring, fetal sheep

Electromechanial dissociation is the persistence of electrocardiographic complexes in the absence of effective cardiac output. In adults it is usually due to a significant reduction in preload, as in exsanguinating hemorrhage or pericardial tamponade, or to a marked increase in afterload, such as in massive pulmonary embolism. Electromechanical dissociation may also reflect severe dysfunction of the cardiac pump.[1] Myocardial ischemia has been implicated in the development of electromechanical dissociation, and it is the most frequent cause of unsuccessful resuscitation in critically ill adults, accounting for up to 68% of sudden death after myocardial infarction.[2]

Although many obstetricians will have had the experience of delivering a fresh stillbirth after a sustained bradycardia, to our knowledge the cardiac electromechanical events underlying such terminal fetal heart rate (FHR) patterns have not been described. We now report the observation of electromechanical dissociation in hypoxemic and acidemic fetal sheep and discuss the clinical implications of this finding for electronic monitoring of the human fetus in labor.

Material and methods

Surgical procedure. Surgery was performed on eight pregnant ewes, each with a singleton gestation between 132 and 134 days. Anesthesia was induced with thiopental sodium infused intravenously and was maintained by positive pressure ventilation with isoflurane, 1.25% to 2%, and oxygen. The ewes were mildly hyperventilated (tidal volume 700 ml, respiratory rate 20 breaths/min) to prevent carbon dioxide accumulation. The fetal head, forelimbs, and chest were withdrawn through a uterine incision. Catheter-tip pressure transducers (2F, Millar, Houston) were introduced into the left ventricle and the aorta just above the aortic valve through a carotid artery (locations confirmed at necropsy). Three electrocardiogram (ECG) electrodes were sutured to the fetal chest. The fetus was replaced and the uterine incision was closed. The hind part of the fetus was then withdrawn through a separate uterine incision, and a fluid-filled catheter was introduced into the aorta through a femoral artery and used to obtain blood samples and inject microspheres for placental embolization. The hind part of the fetus was then replaced, and the second uterine incision was closed. The catheters and ECG leads were exteriorized through the abdominal incision of the ewe, which was

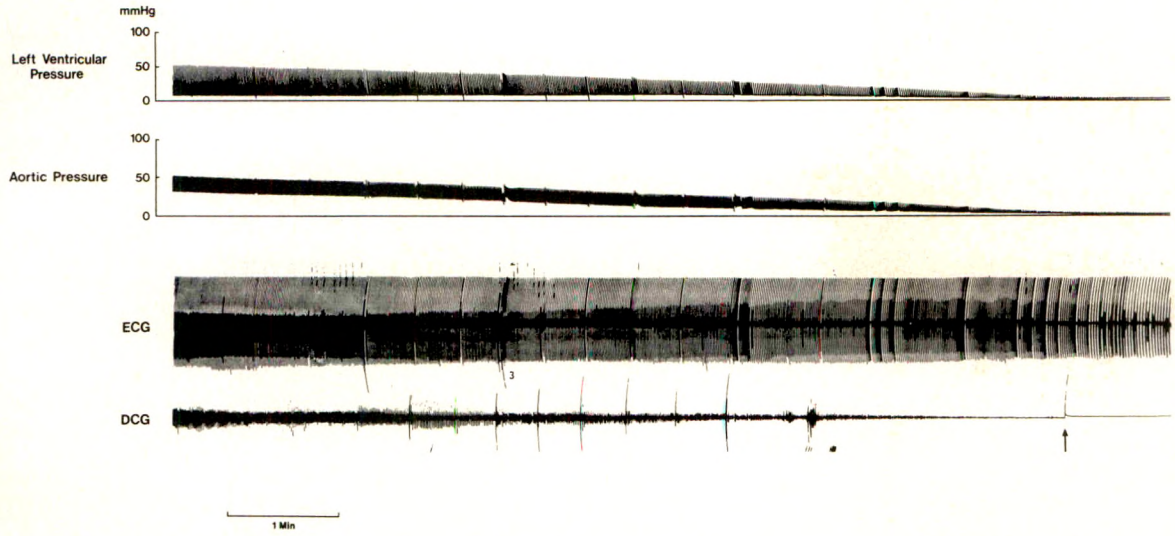

Fig. 1. Cardiac electrical and mechanical waveforms at onset of electromechanical dissociation. *DCG*, Doppler cardiogram. Note that ECG signal continues beyond point of mechanical asystole, which is indicated by *arrow*.

held closed with clamps. A vascular catheter was placed in the femoral artery of the ewe to monitor maternal blood pressure and blood gases.

Experimental procedure. The ECG leads were connected to an FHR monitor (Hewlett Packard 8040A, Hewlett Packard Co., Palo Alto, Calif.), which also supplied a Doppler signal when the transducer was placed on the maternal abdomen and directed toward the fetal heart. Fetal left ventricular pressure, aortic pressure, ECG, Doppler cardiogram, mean arterial pressure, and heart rate were monitored continuously on a polygraph (Grass Instruments, Quincy, Mass.). Fetal arterial blood samples, 0.5 ml per sample to a total not exceeding 5 ml, were obtained at intervals throughout the experiments and were immediately analyzed for blood gas tensions and pH with a blood gas analyzer (model 170, Corning Medical, Medfield, Mass.). Fetal blood gas tensions were temperature corrected to 39° C.

Fetal hypoxemia was induced by embolizing the placenta with injections of 5×10^5 50 μm polyethylene microspheres (3M, St. Paul, Minn.),[3] repeated every 15 minutes until fetal death occurred.

The study was approved by the hospital animal care committee following the guidelines of the Canadian Council for Animal Care.

Results

In all eight fetuses electromechanical dissociation was demonstrated by the persistence of cardiac electrical activity after mechanical asystole. The maternal arterial blood gas tensions remained relatively constant throughout the experiments with a pH of 7.47 ± 0.09 (mean ± 1 SD), P_{CO_2} 32.5 ± 4.0 mm Hg, and P_{O_2} 143.4 ± 17.6 mm Hg. FHR before embolization of the placenta was 141 ± 22 beats/min. There were no significant changes in the FHR before the onset of terminal bradycardia with the exception of one fetus that showed a sinusoidal pattern that lasted for 7 minutes. The mean number of microsphere boluses required to cause fetal death was six (range 5 to 8). Left ventricular systolic pressures were maintained at relatively stable levels of 54.0 ± 8.7 mm Hg, until 15.5 ± 10.4 minutes before the onset of electromechanical dissociation, when they started to decline simultaneously with the onset of a terminal bradycardia. Fetal arterial pH decreased from an initial value of 7.33 ± 0.07 at the start of the experiment to 7.01 ± 0.06 at the onset of terminal bradycardia. Mechanical asystole occurred at a fetal pH of 6.90 ± 0.11 and was demonstrated by the cessation of ventricular and aortic pressure waveforms, at which time the Doppler signal also ceased (Fig. 1). Fetal arterial P_{O_2} and P_{CO_2} at the onset of bradycardia were 11.6 and 62.4 mm Hg, respectively. At the time of onset of electromechanical dissociation, their values were 8.9 and 71.6 mm Hg, respectively. The duration of electromechanical dissociation was 15.2 ± 8.7 minutes (range 3.1 to 32.4), during which time regular supraventricular ECG complexes persisted with a mean rate at the onset of electromechanical dissociation of 91.3 ± 6.5 beats/min. This electrical activity was sufficient to trigger the HP 8040A FHR monitor to show an FHR pattern that gradually declined to a rate of between 40 and 50 beats/min (Fig. 2). In five cases the episode of electromechanical dissociation ended with electrical asystole and in three cases with ventricular fibrillation. The possibility that the mother was the source of the ECG signal was excluded by a comparison of the fetal and maternal heart rates.

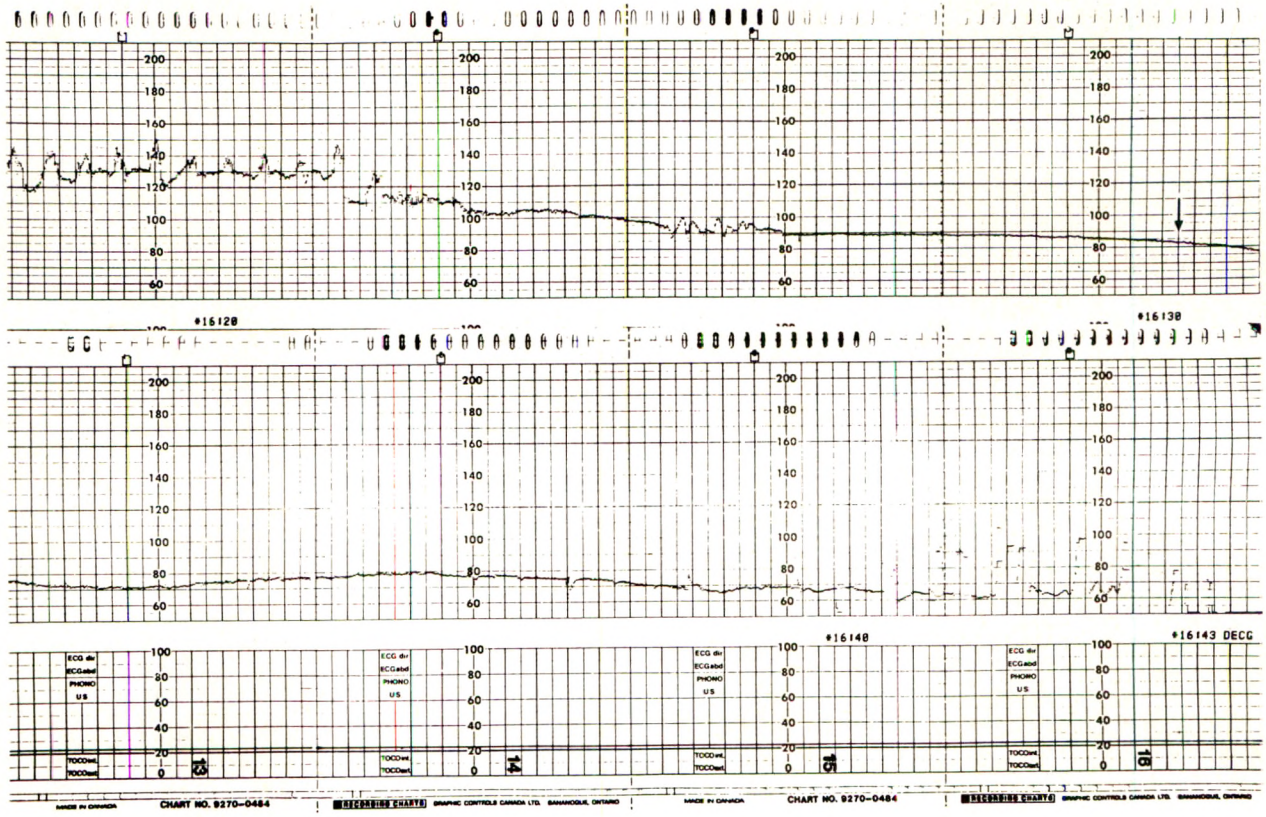

Fig. 2. Heart rate tracing showing a terminal bradycardia, from same fetal sheep as in Fig. 1. Heart rates <60 beats/min, although detected by the HP 8040A monitor, are not displayed on trace. *Arrow*, Mechanical asystole (fetal death) and onset of electromechanical dissociation. Upper and lower segments of trace are continuous (paper speed 3 cm/min).

Comment

In this experimental model of fetal asphyxia, a bradycardia culminating in electromechanical dissociation invariably occurred as a terminal event. We have previously shown that embolization of the fetal placenta in sheep results in a gradually deepening hypoxic acidemia[3] that closely resembles the blood gas changes observed with acute uteroplacental insufficiency and have thus elected to use this model in the present study. Although human fetal hypoxic acidemia is often slowly progressive, it may be accelerated by labor or other acute insults, resulting in a rapid deterioration of fetal blood gases as created by our experimental model. In other studies fetal hypoxemia with or without acidemia was created by interventions such as the induction of maternal hypoxemia, occlusion of the uterine or umbilical circulations, or by the direct infusion of acid into the fetal circulation. Clinically, maternal hypoxemia is very uncommon as a cause for fetal asphyxia. Furthermore, fetal asphyxia is a gradually progressive condition, whereas acidemia is paralleled by tissue acidosis. The intravascular administration of acid is not accompanied by carbon dioxide accumulation, and the degree of tissue acidosis generated by this intervention, especially myocardial tissue acidosis affecting contractility, might not accurately reflect clinical asphyxia.

The gradual decline in heart rate and the duration of the observed period of electromechanical dissociation is in keeping with observations from other species. Experimental electromechanical dissociation in adult dogs followed ventricular fibrillation induced by electrical current and persisted for >20 minutes,[2] during which time the initial rhythms were sinus or junctional tachycardias with a ventricular rate >100 beats/min. As electromechanical dissociation continued, the heart rate slowed, and 18 of 29 dogs developed complete atrioventricular block. Attempts to restore effective mechanical systole by various pharmacologic means were all unsuccessful. Similarly, during human adult electromechanical dissociation[2] the ECG demonstrated a gradually declining heart rate and in none of 36 patients was resuscitation successful. The pathophysiology of electromechanical dissociation is unknown, but the failure of myocardial contractility suggests a depletion of high-energy phosphate bonds.[2]

The hypothesis that electromechanical dissociation

also occurs in human fetal death is supported by published examples of terminal FHR tracings. Cetrulo and Schifrin[4] report four cases ending in fresh stillbirth where there was a profound and sustained terminal bradycardia recorded by a scalp electrode. Similarly, Kates and Schifrin,[5] Cibils,[6] and Perkins[7] report agonal FHR patterns culminating in bradycardia and fetal death. The duration of profound bradycardia before delivery of the dead fetuses in these published examples is similar to the observed time course of bradycardia in our fetal sheep. Fetal cardiac electrical asystole lasting for a few seconds was described by Kates and Schifrin[5] and carried with it a grave prognosis when it was associated with underlying fetal asphyxia. This is different from the long-lasting mechanical asystole with persistence of cardiac electrical activity observed in our study. On the basis of our experimental findings, we suggest that terminal bradycardias in human fetuses consist of two phases. During the initial phase before the occurrence of mechanical asystole, heart sounds are still audible in spite of falling ventricular pressures. In the second phase, electromechanical dissociation occurs, and the abdominal Doppler signal is lost while the ECG signal continues to trigger the FHR monitor. It is therefore not surprising that, in spite of the persistence of an ECG signal, the examples cited resulted in the delivery of dead infants who could not be resuscitated.

The only noninvasive test that could unmask electromechanical dissociation would be the observation of cardiac standstill on real-time ultrasonography. Ultrasonography is also important in excluding the possibility of the recording of a maternal ECG relayed through a dead fetus.[8, 9] It is important, however, to differentiate between the absence of fetal cardiac activity as a terminal event complicating severe asphyxia, which is likely to result in poor outcome, from asystole complicating an acute insult such as abruptio placentae or umbilical cord prolapse, which may have a more favorable outcome if emergency measures are taken in time.

In conclusion, we have documented the cardiac electromechanical events associated with terminal fetal bradycardia and have demonstrated electromechanical dissociation as a terminal event in the hypoxic fetal sheep. Furthermore, we suggest its occurrence may be an underlying factor in human intrapartum stillbirth.

We thank Charlene Small, Animal Care Technician, and Joyce Telford, RN, for their skilled laboratory assistance.

Despite all the research accumulated over the years regarding endometriosis, the cause, pathophysiology, natural course, and other aspects of this disease remain enigmatic. In particular, of the variety of clinical problems that affect patients who have endometriosis, the most perplexing problem for all gynecologists is the treatment of infertility associated with endometriosis. Although a close link between endometriosis and infertility has long been recognized, a direct cause-and-effect relationship between endometriosis and infertility has not yet been proved. Thus far many plausible mechanisms for endometriosis-associated infertility have been postulated. However, no single mechanism can explain the cause for infertility in every case. This may reflect the complexity of the pathophysiology of endometriosis, the multifactorial mechanisms involved in endometriosis-associated infertility, or both. Indeed, the clinical link between endometriosis and infertility does not always exist. For instance, some women who have severe endometriosis may also have normal reproductive performance. In contrast, we know of many patients who cannot conceive despite long-standing treatment for infertility. Many gynecologists may be inclined to use medical or surgical methods to treat infertile women who have endometriosis, without being certain of the efficacy of these treatments when all routine treatments for infertility have failed. However, it has not yet been established whether the treatment of endometriosis per se benefits patients who have impaired reproductive performance. The answer to this question must wait for the elucidation of the mechanisms involved in endometriosis-associated infertility.

With this in mind, we held a conference on the "Pathophysiology of infertility associated with endometriosis" in Hakone, Japan, on September 6, 1991. At the conference we attempted to address this issue from various standpoints and placed special emphasis on the immunologic aspects of the pathogenesis of endometriosis-associated infertility. To this end we called for a comprehensive and fundamental review of the involvement of immunology in reproduction.

As a whole these proceedings not only emphasize the complexity of the problem, but they raise some new concepts for the understanding of endometriosis-associated infertility.

We are grateful to Professor Masahiko Mizuno, Chairman of the Department of Obstetrics and Gynecology, University of Tokyo, for his advice and constant encouragement. We also thank all the contributors for their participation in the Second Hakone Conference on Endometriosis, and we gratefully acknowledge the educational grants from Tokyo Tanabe Co., Ltd., which made the conference and the publication of these proceedings possible.

The fetus as an allograft: Immunobiologic role of human trophoblasts for fetal survival

Fumitaka Saji, MD, DMSci, Noboru Matsuzaki, MD, DMSci, Chihiro Azuma, MD, DMSci, Masayasu Koyama, MD, DMSci, Kazutomo Ohashi, MD, DMSci, and Osamu Tanizawa, MD, DMSci

OBJECTIVE: The hypothesis of this study is that trophoblasts contribute to the survival of the mammalian fetal allograft.

STUDY DESIGN: Immunologic and molecular biologic studies were performed with human trophoblasts or trophoblastic tumor cells to investigate the expression of class I human leukocyte antigens, the susceptibility to natural killer and lymphokine-activated cells, the ontogeny of Fc γ-receptors, and the production of immunosuppressive factors.

RESULTS: Heterogeneous expression of class I human leukocyte antigens on trophoblasts was regulated at transcriptional level. Trophoblasts showed low susceptibility to natural killer and lymphokine-activated cells. Trophoblasts expressed natural killer cell–type Fc γ-receptor III, which mediates phagocytosis. The trophoblast-derived immunosuppressive factor was very similar to transforming growth factor–β.

CONCLUSION: The trophoblasts, which ultimately form the fetoplacental interface, constitute a major immune barrier for the survival of the allogeneic conceptus. (Am J Obstet Gynecol 1992;167:251-6.)

Key words: Trophoblast, major histocompatibility complex, lymphokine-activated killer cell, Fc γ-receptor, immunosuppressive factor

Histocompatibility differences between a mother and her offspring in mammalian species create a paradox because the semiallogeneic fetus is not rejected by a competent maternal immune system during pregnancy. Several mechanisms that might be involved in the survival of the allogeneic conceptus have been suggested[1-7] (Table I). However, some of these hypotheses remain controversial and may represent only secondary or backup systems that contribute to the survival of the fetoplacental allograft. Among these mechanisms, recent studies on the immunology of pregnancy in humans and rodents have focused on the possible role of the placental trophoblast as an important immune barrier at the fetomaternal interface. In this article we review some immunologic functions of the trophoblast itself and various trophoblast-derived factors on the basis of data obtained in our laboratory. These findings can provide information for the analysis of the pathogenesis of endometriosis from the immunologic viewpoint, because available evidence indicates that endometriosis begins with the extrauterine implantation of endometrial cells or endometrial fragments that are transported through fallopian tubes or vascular channels.

Heterogeneous expression of the human leukocyte antigen class I gene in human trophoblasts

The chorionic villi are enveloped by two layers of trophoblasts: the inner cytotrophoblasts and the outer syncytiotrophoblasts. Some extravillous cytotrophoblast cells migrate into the decidua and the myometrium. Thus a heterogeneous population of trophoblasts comes into close contact with various types of maternal tissue, including maternal blood and uterine elements, during pregnancy. Therefore the failure of trophoblast cells to demonstrate human leukocyte antigen (HLA) molecules may be one of the mechanisms that protects the semiallogeneic embryo from immunologic rejection by the mother.

Although HLA class I antigens are usually not detected on syncytiotrophoblasts or villous cytotrophoblasts, some extravillous cytotrophoblasts do express them.[3] However, the expression of these antigens by extravillous trophoblasts may be quantitatively different from the pattern of expression by other tissues. We used cultured trophoblastic tumor cells (SCH, JEG, BeWo, GCH1, NUC1, and HCCM5) as a model to investigate why trophoblasts do not demonstrate HLA antigens.

Various choriocarcinoma cell lines and two controls (RPMI 1788 and K562) were analyzed by cellular binding radioimmunoassay with use of monoclonal antibodies specific to HLA heavy chains and β_2-microglobulin. As shown in Table II, choriocarcinoma cells vary

Table I. Escape mechanisms of fetus/trophoblast from maternal immunity

1. Suppression of immune response by maternal lymphocytes
2. Poor immunogenicity of the trophoblast
3. Production of antiidiotypic antibodies
4. Production of blocking antibodies
5. Adsorption of antibodies by Fc receptors in the placenta
6. Blockade of afferent lymphatics by the decidua
7. Local immunoregulation caused by the products produced by the trophoblast and decidua
8. Reduced susceptibility of the trophoblast to immune lysis
9. Physiologic barrier of placenta to the passage of maternal and fetal cells.

widely in HLA class I surface antigens density.[8] SCH expresses approximately half the amount of HLA class I antigens compared with the B-lymphoblastoid cell line RPMI 1788. The expression of HLA class I antigens was weak on JEG, NUC1, and HCCM5, and no detectable levels of the antigens were observed on BeWo or GCH1 cells or on K562 cells that were used as the negative control. On the other hand, all the choriocarcinoma cells expressed a large amount of β_2-microglobulin on the cell surface. We analyzed the heterogeneity of HLA class I antigens expression in choriocarcinoma cell lines at the transcriptional level by Northern blot hybridization with use of phosphorus 32–labeled complementary deoxyribonucleic acid (DNA) probes specific for the HLA class I heavy chain and β_2-microglobulin. The levels of messenger ribonucleic acid (RNA) for the HLA class I heavy chain correlated well with the amounts of surface HLA class I antigens in all cell lines except BeWo. We detected a definite hybridizing band on the BeWo lane in spite of the absence of surface HLA class I antigens expression. Moreover, a band of truncated messenger RNA was observed in the BeWo lane which suggests an abnormality of class I heavy chain messenger RNA in BeWo. A recent study revealed that HLA-G antigen was expressed in first-trimester villous trophoblasts and that it was greatly reduced in third-trimester cytotrophoblasts. Among choriocarcinoma cell lines HLA-G antigen was expressed in JEG3 and BeWo but not in Jar.[9, 10] These findings indicate that the unique HLA class I antigens might be expressed in trophoblasts and choriocarcinomas.

The transcription of eukaryotic genes is usually regulated by the combination of *cis*-acting control elements and *trans*-acting cellular factors. Binding of nuclear proteins to regulatory elements can promote, enhance, or repress gene transcription. To study the differences in the control of major histocompatibility complex class I antigens expression among choriocarcinoma cell lines, we identified the human class I regulator elements located on the promoter region by their binding to nuclear proteins of the trophoblastic tumor cell lines.[11] By comparison of the murine and human major histocompatibility complex class I promoter region, we detected a human class I regulator element of 30 base pairs that was located 185 base pairs upstream of the HLA class I gene. This region contains core sequences that are identical to the murine class I regulator element described by Ozato et al.[12] A gel mobility shift assay was then performed to investigate the effect of nuclear factors binding to this regulator element. With use of nuclear extracts from SCH, JEG, HCCM5, and NUC1 cells that have HLA class I messenger RNA, we demonstrated that the human class I regulator element forms complexes on the polyacrylamide gel during electrophoresis. In the case of GCH1 or K562 cells no prominent DNA-protein complex was detected with use of this element. These results suggest that class I regulator element–nuclear protein interactions may be required for the transcription of HLA class I antigens on villous trophoblasts could be caused by the absence of this nuclear protein.

Impaired susceptibility of trophoblasts against major histocompatibility complex nonrestricted killer cells

The unique expression of major histocompatibility antigens on human trophoblast cells should allow the fetoplacental unit to escape recognition by the maternal immune system. Furthermore, the susceptibility of trophoblasts to class I–specific cytotoxic T lymphocytes is unique. Semiallogeneic and fully allogeneic trophoblast cells are resistant to allospecific T cell–mediated lysis.[13] The possibility exists that the placenta protects the fetus from maternal immune rejection through the resistance of trophoblast cells to major histocompatibility complex nonrestricted killer cells such as natural killer cells and lymphokine-activated killer cells. We have de-

*A 4-hour chromium-releasing assay was performed at an E/T ratio of 20.

scribed an in vitro experiment indicating that the susceptibility of cultured trophoblastic tumor cell lines to natural killer and lymphokine-activated killer cells is impaired.[14]

A standard 4-hour chromium 51–releasing assay was used to measure the killing activity of natural killer or lymphokine-activated killer cells against target cells. Lymphokine-activated killer cells were generated by in vitro incubation of peripheral blood lymphocytes in a complete medium that contained recombinant interleukin-2. We then determined the antitumor effect of lymphokine-activated killer cells against several gynecologic tumor cell lines. The cell lines used were HeLa (cervical adenocarcinoma), Ishikawa and Ono (endometrial adenocarcinoma), and GCH1, GCH2, BeWo, and HCCM5 (choriocarcinoma). The three cell lines derived from uterine cancer, HeLa, Ishikawa, and Ono, were killed by either natural killer cells or lymphokine-activated killer cells. On the other hand, lymphokine-activated killer activity against gestational choriocarcinoma cell lines was definitely low. Moreover, natural killer activity against the choriocarcinoma cell lines was not detected at all. These results suggest that the sensitivity of choriocarcinoma to natural killer and lymphokine-activated killer cells is much lower than that of other gynecologic tumors. This was confirmed by a more extended experiment that used a wide panel of culture tumor cell lines as a target of lymphokine-activated killer activity (Table III). Among the 21 cell lines tested, the five choriocarcinoma cell lines, GCH1, GCH2, BeWo, HCCM5, and SCH, showed low levels of cytotoxic effect, and specific lysis did not exceed 20% except for HCCM5. On the other hand, the remaining 16 tumor cell lines, which included uterine, renal, colon, lung, and leukemia cells, showed substantial levels of lysis that exceeded 40%. It was concluded that choriocarcinoma cell lines are less sensitive to lymphokine-activated killer cells than the other cell lines tested in this experiment.

The impaired sensitivity of trophoblastic tumor cell lines to lymphokine-activated killer cells was confirmed by a cold inhibition experiment against lymphokine-activated killer activity. Various numbers of cells were added to a given number of chromium 51–labeled lymphokine-activated killer–sensitive Daudi cells and the lymphokine-activated killer activity was determined. Daudi and K562 cells competitively inhibited lymphokine-activated killer activity. However, the GCH1 choriocarcinoma cell line was less inhibitory. No significant inhibition was observed with the same number of inhibition cells as target cells, and only slight inhibition was seen with a fourfold excess of inhibitory cells.

We examined the effect of the trinitrophenol modification of target cells on the extent of lymphokine-activated killer cell–mediated lysis. A choriocarcinoma cell line, GCH1, was modified with trinitrophenyl and used as the target of recombinant interleukin-2–activated effector cells. As control experiments, trinitrophenol modified or unmodified autologous phytohemagglutinin blasts were simultaneously examined for their sensitivity to lymphokine-activated killer cells. As expected, autologous phytohemagglutinin blasts could be lysed substantially by lymphokine-activated killer cells, and this specific lysis was significantly enhanced

Table IV. Messenger RNA expression and localization of three classes of Fc γ receptors in human placenta

Fc γ receptor	*Messenger RNA expression*				*Localization*
	5W	*9W*	*23W*	*38W*	
Fc γ RI	−	+	+ +	+ +	Hofbauer cell
Fc γ RIIa	−	+	+ +	+ +	Endothelial cell
Fc γ RIIb	−	−	+ +	+ +	
Fc γ RIII	−	+	+ +	+ +	Trophoblast cell

by trinitrophenol modification of the target phytohemagglutinin blasts. On the other hand, trinitrophenol modification did not affect specific lysis of the choriocarcinoma cell line. Little lysis by lymphokine-activated killer cells was observed for either trinitrophenol-modified GCH1 cells or unmodified GCH1 cells. These results indicate that stearic hindrance of the lymphokine-activated killer target molecules expressed on trophoblast cells is unlikely. The impaired susceptibility of trophoblast cells to major histocompatibility complex nonrestricted killing, as demonstrated by these studies, should contribute to the survival of the semiallogeneic fetus.

Ontogeny and localization of Fc γ-receptors on the fetomaternal interface

Fc γ-receptors on the fetomaternal interface may act as multifunctional molecules, which may serve not only to transmit immunoglobulin G (IgG) but also to adsorb cytotoxic antibodies or to clear immune complexes.[5] Increasing evidence has recently indicated a previously unrecognized molecular and functional heterogeneity of the Fc γ-receptor. Three distinct classes of this receptor (Fc γ RI, Fc γ RII, and Fc γ RIII) have been defined on human myeloid cells by their reactivity with specific monoclonal antibodies.[15, 16] Fc γ RI (CD64) is a 70-kd glycoprotein found on monocytes and macrophages that binds human monometric IgG with a high affinity. Fc γ RII (CDw32) is a 40-kd glycoprotein receptor and is expressed on neutrophils, eosinophils, platelets, B cells, and monocytes. Fc γ-receptor RIII (CD16) has a different molecular structure and its own distinctive pattern of cellular distribution. It appears on macrophages, eosinophils, neutrophils, natural killer cells, killer cells, and some T cells. Fc γ RII and RIII are low affinity receptors for IgG and the demonstration of these Fc γ-receptors requires the presentation of ligands as a complex, either as a soluble IgG complex or as IgG-coated particles. Complementary DNA clones of these three classes of Fc γ-receptors have been isolated by several investigators since 1988 and are now available for the study of these receptors at the transcriptional level.

We used human placenta from different gestational weeks to demonstrate the expression of Fc γ-receptors at the fetomaternal interface. Four previously described complementary DNA clones, p135 (Fc γ RI), FcR2003 (Fc γ RIIa), FcR201 (Fc γ RIIb), and pCD16 (Fc γ RIII), were probed to demonstrate differential messenger RNA expression of Fc γ-receptors in human placental tissue at 5, 9, 23, and 38 gestational weeks (Table IV). The p135 probe hybridized the 1.7 kb messenger RNA of Fc γ RI in placenta from gestational weeks 9, 23, and 38; the pCD16 probe hybridized the 2.0 kb messenger RNA of Fc γ RIII in placenta from the same weeks as those used in the hybridization with p135. The transcriptional level of both receptors in the placenta was consistent through the first, second, and third trimesters of pregnancy. In contrast to Fc γ RI and RIII, two different transcripts, 2.4 kb and 1.6 kb of Fc γ RIIa, were detected in placenta from gestational weeks 9, 23, and 38. On the other hand, a 1.6 kb Fc γ RIIb transcript was recognized at gestational weeks 23 and 38 but not at gestational weeks 5 and 9 with the FcR201 probe, which indicates that the placenta expresses abundant Fc γ RII, especially Fc γ RIIb, in the placenta from the second and third trimester.[17]

We further investigated immunohistochemically the localization of the three Fc γ-receptors in placental tissue with specific monoclonal antibodies raised against them (Table IV). Monoclonal antibody 32.2 against Fc γ RI stained placental macrophages that have large nuclei and are known as Hofbauer cells, whereas positive staining of monoclonal antibody 2E1 for Fc γ RII was observed on the endothelial cells of small vessels on the fetal side. When we used monoclonal antibody Leu11b for Fc γ RIII, the outer layer containing syncytiotrophoblasts and cytotrophoblasts was stained. These results indicate that the Fc γ-receptors examined were localized at different sites within the placenta.[18]

Sequence analysis of the complementary DNA clones encoding placental messenger RNA from the Fc γ RIII receptor revealed that this fragment is a membrane-spanning molecule that has a 21 amino acid insertion and is located at the c terminus of Fc γ RIII on polymorphonuclear cells, resembling that on the natural killer cells.[19] Natural killer cell–type Fc γ RIII on placental trophoblasts might mediate phagocytosis. We

propose that these Fc γ-receptors located at different sites of the fetomaternal interface may act as multifunctional molecules that participate in the transmission of IgG and the clearance of immune complexes.

Trophoblast-derived immunosuppressive factor

A number of laboratories have demonstrated that trophoblast cells isolated from the placenta inhibit lymphocyte functions in vitro. This has led to the hypothesis that local immunoinhibition by a factor secreted by the trophoblast and operating only at the fetomaternal interface prevents maternal antifetal responses.

We have found a lymphocytostatic soluble factor secreted from cultured human trophoblasts.[20] Trophoblast cells prepared by collagenase digestion followed by differential centrifugation were cultured for a short time, and the culture supernatant was examined for its effect on in vitro lymphocyte functions. The supernatant suppressed the reaction of peripheral blood lymphocytes to mitogens and alloantigens. In addition, the supernatant reduced natural killer cell activity against K562 target cells. Moreover, the generation of cytotoxic T lymphocytes was markedly depressed.

Because we could not obtain large amounts of the immunosuppressive factor from human placenta, which is very unstable, we could not further explore the mechanisms of its immunosuppressive effect. However, while investigating the culture supernatants of choriocarcinoma cell lines, we found that these trophoblastic tumor cells produced the same suppressive factor produced by normal trophoblast cells.[21] The site of action of this factor in the T-cell signal transduction pathway was investigated with use of phorbol ester and a calcium ionophore (A23187), reagents that strongly stimulate the interleukin-2–mediated T-cell response, and we could demonstrate that this factor completely suppresses the human T-cell response activated by phorbol ester and A23187.[21-23] It failed to inhibit CD25 expression and interleukin-2 production by T-cell blasts in the T-cell activation phase, but it completely blocked the recombinant interleukin-2–induced proliferation of T-cell blasts in the T-cell blast proliferation phase. This factor acted on the cytoplasmic signal transduction pathways without interfering with the interleukin-2 molecules themselves or their interaction with interleukin-2 receptor. These findings suggest that the choriocarcinoma-derived factor only suppresses the proliferative function of immunocompetent cells and does not inhibit either activation or differentiation events.

At present, the choriocarcinoma-derived immunosuppressive factor has been neither purified nor identified as a single molecule. However, the comparison of this factor with several immunosuppressive agents indicates that it might be associated with the transforming growth factor–β (Table V). Transforming growth factor-β is a product of neoplastic and hematopoietic cells that is a functional regulator of the immune response. Transforming growth factor–β blocks the ability of interleukin-1 to stimulate lymphocyte proliferation. Besides, transforming growth factor–β_1 and its homologue, transforming growth factor–β_2, suppress interleukin-1-dependent murine thymocyte proliferation. Transforming growth factor–β also inhibits human peripheral blood T-lymphocyte mitogenesis. Inhibition of cell division appears to occur after activation of the lymphocytes, because neither the gene expression nor the translation of the interleukin-2 receptor is suppressed.[24] Furthermore, transforming growth factor–β does not block the synthesis of interleukin-2. These findings are very similar to the data we obtained on the mode of action of the choriocarcinoma-derived factor. We also found a significant level of latent transforming growth factor–β activity in defined trophoblast culture medium, as assayed by the inhibition of DNA synthesis in mink lung epithelial cells.[25]

Table V. Association of the choriocarcinoma-derived factor with immunosuppressive agents

Immunosuppressive agent	*Association with choriocarcinoma-derived factor*
α-Fetoprotein	No
Carcinomembryonic antigen	No
Human chorionic gonadotropin	Unlikely
Progesterone	Unlikely
Interferon-β	Unlikely
Ganglioside	No
Transforming growth factor–β	Probable

Comment

Within the placenta the fetal boundary consists entirely of trophoblastic material that is either exposed directly to maternal blood or in intimate apposition to endometrial cells. A central issue regarding the survival of the fetal allograft during pregnancy is therefore whether the trophoblast expresses those antigens coded for by the paternally inherited genes of the fetus. The unique regulation of HLA class I antigen expression by the interaction of the regulatory element with the nuclear proteins could be the important key to solve this question. The second role of the trophoblast for fetal survival against maternal immune attack is the low susceptibility of the trophoblast to either major histocompatibility complex restricted or nonrestricted immune cytolysis. In addition to their resistance to cell-mediated cytolysis, the trophoblast can adsorb cytotoxic antibodies or immune complexes by various subtypes of Fc γ-receptors expressed at different sites in the

placenta. Furthermore, soluble immunosuppressive molecules derived from the trophoblast could modulate immune reactivity in the periplacental environment. Thus the immunoregulatory mechanisms mentioned above appear to operate in harmony to regulate the maternal immune system and support fetal survival and growth during pregnancy.

Similar to the fetoplacental allograft, endometriosis is considered to be associated with altered immune function. Changes in both cell-mediated and humoral immunity in women who have endometriosis have been observed by several investigators.[26, 27] The presence of antibodies against endometrial tissue antigens in serum and peritoneal fluid from women with endometriosis could be caused by enhanced local immune reactivity.[28] Furthermore, the levels of antiendometrial antibodies in endometriosis were lowered by treatment with danazol or gonadotropin-releasing hormone agonists.[29, 30] These observations may lead to a reconsideration of the diagnostic and therapeutic approaches in endometriosis.

Suppression of natural killer cell activity by sera from patients with endometriosis

Hideharu Kanzaki, MD, Huei-Sheng Wang, MD, Masatoshi Kariya, MD, and Takahide Mori, MD

Kyoto, Japan

OBJECTIVE: We determined the effect of sera from patients who have endometriosis on natural killer cell activity.

STUDY DESIGN: The natural killer cell activity of lymphocytes from healthy volunteers was examined after incubation with sera from patients who had endometriosis or from controls, with K562 cells used as targets.

RESULTS: Lymphocytes treated with sera from patients who had endometriosis expressed significantly lower levels of cytotoxicity compared with lymphocytes treated with control sera. This suppression of cytotoxicity was dose dependent, and the degree of suppression was proportional to the incubation time of the effector cells with the sera. Decreased cytotoxicity after serum treatment was also observed with sera from patients who had been treated with danazol.

CONCLUSIONS: These findings show that humoral factors that can inhibit natural killer cell activity in vitro are present in the peripheral blood of patients who have endometriosis; moreover, they suggest that the suppressed natural killer cell activity may allow the development of endometrial cells at ectopic sites. (AM J OBSTET GYNECOL 1992;167:257-61.)

Key words: Endometriosis, natural killer cell activity, suppression, serum factors

Endometriosis is a well-tolerated autotransplantable disease that primarily affects women who are in their reproductive years. Retrograde spillage of menstrual blood into the peritoneal cavity occurs in most women who have patent fallopian tubes and is considered the leading cause of endometriosis.[1, 2] However, it is not known why endometriosis occurs in only a small percentage of susceptible women. Therefore it is possible that mechanisms that prevent the ectopic development of endometrial cells operate in resistant women.

Natural killer cells belong to a subpopulation of lymphocytes that represent the first line of defense against the initiation and spread of tumors in vivo.[3] Defective natural killer cell activity has been shown to predispose subjects to an enhanced growth of transplanted tumors.[4, 5] Diminished natural killer cell activity has also been found in tumor-bearing animals[6] and in humans who have malignant disease, especially in those who have widely disseminated tumors.[7] Therefore it is of great interest to know whether endometriosis is associated with certain aspects of natural killer cell activity believed to be important in the restriction of tumor growth in vivo. In this study we investigated the effect of sera obtained from fertile control subjects and from patients who had endometriosis on natural killer cell activity in vitro by a cytotoxicity assay. Natural killer–sensitive K562 cells were used as the target.

Material and methods

Serum samples. Serum samples were obtained from 10 healthy men and 10 fertile women who did not have endometriosis (control groups) and from 34 patients who had endometriosis (experimental group). Of the experimental group 9 patients were untreated, 12 were undergoing therapy with danazol (Bonzol, Tokyo Tanabe Co., Ltd., Tokyo, Japan), and 13 had completed treatment (9 patients received danazol therapy and 4 patients received danazol therapy followed by surgery). Blood samples in the group that had been treated were taken at least 2 months after the completion of treatment. The mean age of patients who had endometriosis before, during, and after danazol therapy was 30 years, 33 years, and 33 years, respectively. The mean age of the male and female control subjects was 31 years and 28 years, respectively. Serum samples were heat inactivated at 56° C for 30 minutes and stored at −20° C until use. Endometriosis was diagnosed by laparoscopic or laparotomic examination. None of the women included in this study had a malignant disease or had received any other hormone therapy, except for danazol, for at least 2 months before the serum collections.

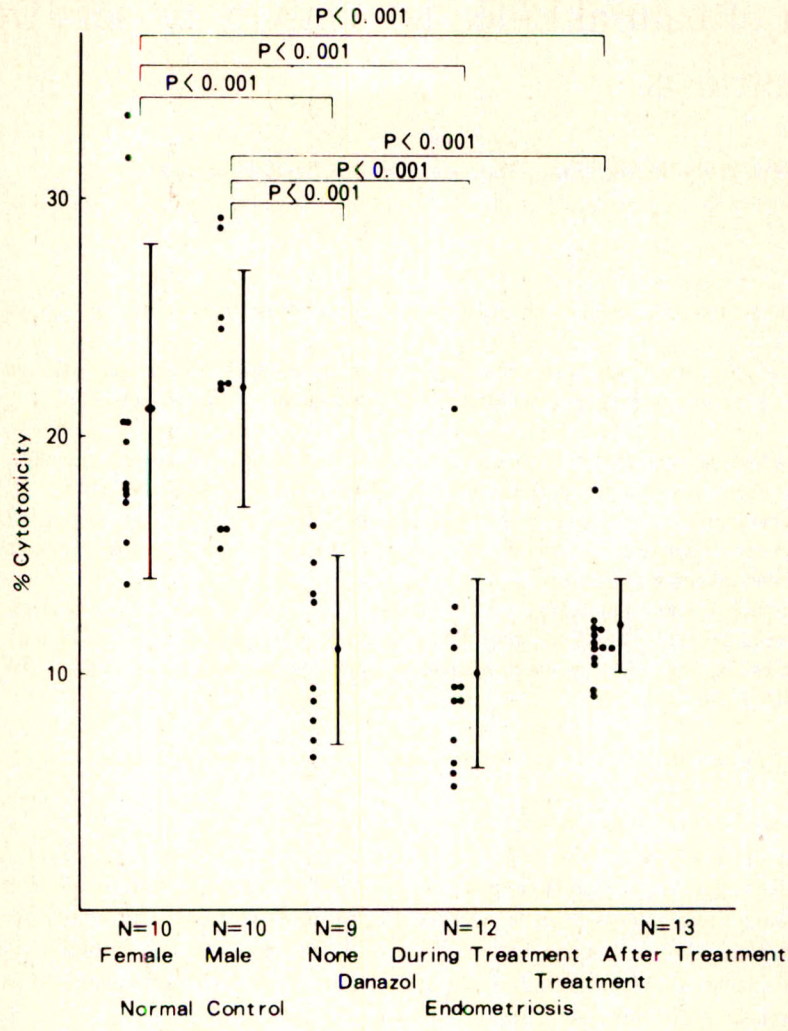

Fig. 1. Effects of peripheral blood sera on natural killer cell activity in vitro. Percent cytotoxicity after incubation with sera from 34 patients (9 before therapy, 12 during therapy with danazol, and 13 after therapy with danazol, surgery, or both) was significantly lower than after incubation with sera from male and female control subjects (n = 10 each).

Effector cells. Lymphocytes from two healthy men and two healthy women volunteers were separated by centrifugation on Ficoll-Hypaque gradients. The lymphocytes were suspended in RPMI-1640 medium (Gibco Laboratories, Grand Island, N.Y.) supplemented with 100 IU/ml of penicillin G and 100 μg/ml of streptomycin sulfate. The 600 μl aliquots of lymphocyte suspensions that contained 1.5 × 10^6 cells each were placed in round-bottomed tubes (12 × 75 mm, Falcon 2063, Becton Dickinson Labware, Lincoln Park, N.J.) and incubated with serum samples (40% vol/vol; total volume: 1 ml) previously sterilized through millipore (0.45 μm pore Millex HA filter unit; Millipore Co., Tokyo, Japan). After incubation at 37° C in a humidified atmosphere of 5% CO_2 and 95% in air for 18 hours the lymphocytes were washed three times and resuspended in RPMI-1640 medium supplemented with 100 IU/ml of penicillin G, 100 μg/ml of streptomycin sulfate, and 10% heat-inactivated fetal calf serum (Gibco) (complete medium). These serum-treated lymphocytes were usually more than 95% viable as assessed by the trypan blue dye exclusion test and were used as the effector cells.

Target cells. Human K562 myeloid leukemia cells were used as the target cells. They were labeled with 100 μCi $Na_2{}^{51}CrO_4$ (specific activity: 100 to 350 μCi/μg chromium; Radiochemical Center, Amersham, Buckinghamshire, England) and incubated at 37° C for 2 hours. The K562 cells were then washed three times, suspended in complete medium, and further incubated at 37° C for 1 hour. Finally, the cells were washed again and resuspended in complete medium to a concentration of 5 × 10^4 cells/ml.

Chromium 51–release cytotoxicity assay (natural

killer assay). The 100 μl of chromium 51–labeled cell suspension (5×10^3 cells) and 100 μl of effector cell suspension were mixed together in 96-well round-bottomed microtiter plates (Corning Glass Works, Corning, N.Y.) in triplicate to yield various effector to target cell ratios (40:1, 20:1, and 10:1). The plates were incubated at 37° C in a humidified atmosphere of 5% CO_2 and 95% in air for 4 hours. The supernatants were then harvested, and the radioactivity was measured in an autogamma scintillation counter (model ARC-301B, Aloka, Tokyo, Japan). The mean percent cytotoxicity for each assay and the mean percent suppression in comparison with controls were calculated by the following formulas:

Percent cytotoxicity =
[(test cpm − spontaneous cpm)/(maximum cpm − spontaneous cpm)] × 100

Percent suppression = [(% cytotoxicity in controls − % cytotoxicity in patient sera-treated cells)/% cytotoxicity in controls] × 100

The spontaneous release was measured in wells that contained only labeled K562 cells. The maximum release was measured in wells that contained 100 μl of labeled K562 cells suspension and 100 μl of 3% Triton-X100 (Sigma Diagnostics, St. Louis, Mo.). The spontaneous chromium 51 release was 3% to 12% of the total isotope count, and the maximum release varied from 80% to 90%.

Statistical analysis. The results were expressed as mean values ± SD, and the statistical significance was examined by the unpaired Student *t* test.

Results

The control lymphocytes from two men and two women who were treated for 18 hours with sera from patients who had endometriosis showed significantly decreased natural killer cell activity at all effector to target cell ratios. Fig. 1 shows a representative result of the cytotoxicity assay performed at a 40 to 1 effector to target ratio with lymphocytes from a healthy male donor. Peripheral sera from the 34 patients who had endometriosis showed significantly higher inhibition of natural killer cell activity than those from the women and men in the control groups. No difference was found in natural killer suppressive activity of sera among those obtained before ($n = 9$), during ($n = 12$), and after ($n = 13$) treatment with danazol (400 mg/day for 4 months). No correlation was found between the level of suppression and the severity of endometriosis (data not shown); moreover, the inhibition of natural killer cell activity depended on the concentration of serum in the reaction mixture (Fig. 2).

Experiments on the kinetics of the serum treatment revealed that the cytotoxicity of lymphocytes treated with serum from patients who had endometriosis was

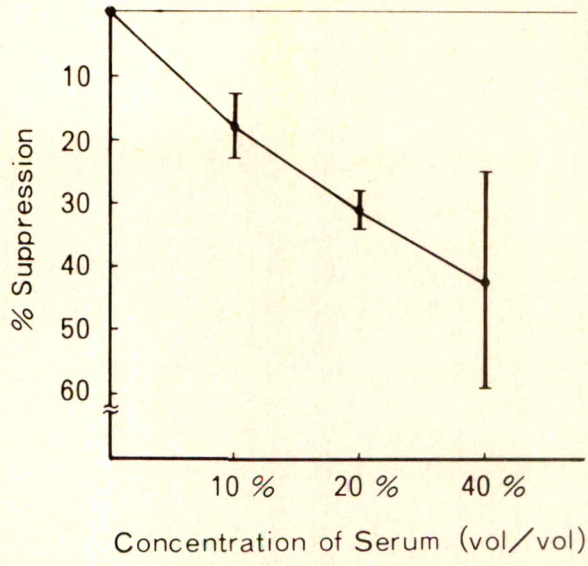

Fig. 2. Percent suppression of natural killer cell activity after an 18-hour incubation period with serum at various concentrations from a patient who had endometriosis.

significantly lower than that of lymphocytes treated with normal serum at every time point tested, except at 2 hours (Fig. 3). The percent inhibition increased when the serum treatment was prolonged from 2 hours to 27 hours. However, more than 27 hours were necessary to significantly decrease natural killer cell activity when control sera were used.

Comment

Several studies have suggested that endometriosis is accompanied by impaired immunity. In rhesus monkeys with spontaneous endometriosis cellular immune responses were reportedly depressed;[8] in humans, T-lymphocyte–mediated cytotoxicity to autologous endometrial cells was significantly reduced,[9] and lymphocytes stimulated by autologous endometrial antigens were also at a lower level in women who had endometriosis.[9]

Natural killer cells are considered the first line mechanisms of innate defense by which the host can prevent foreign cells from entering the body, surviving, or implanting themselves within the body. Natural killer cells can also control the development of neoplastic tumor cells. At present the role of natural killer cells in the occurrence or development of endometriosis is not fully understood, but it is reasonable to speculate that decreased natural killer activity may be associated with the onset or progression of this disease.

Oosterlynck et al.[10] recently reported that peripheral lymphocytes from women who had endometriosis had decreased natural killer activity against K562 cells and decreased cytotoxicity against both autologous and heterologous endometrial cells.[10] Our study demonstrated

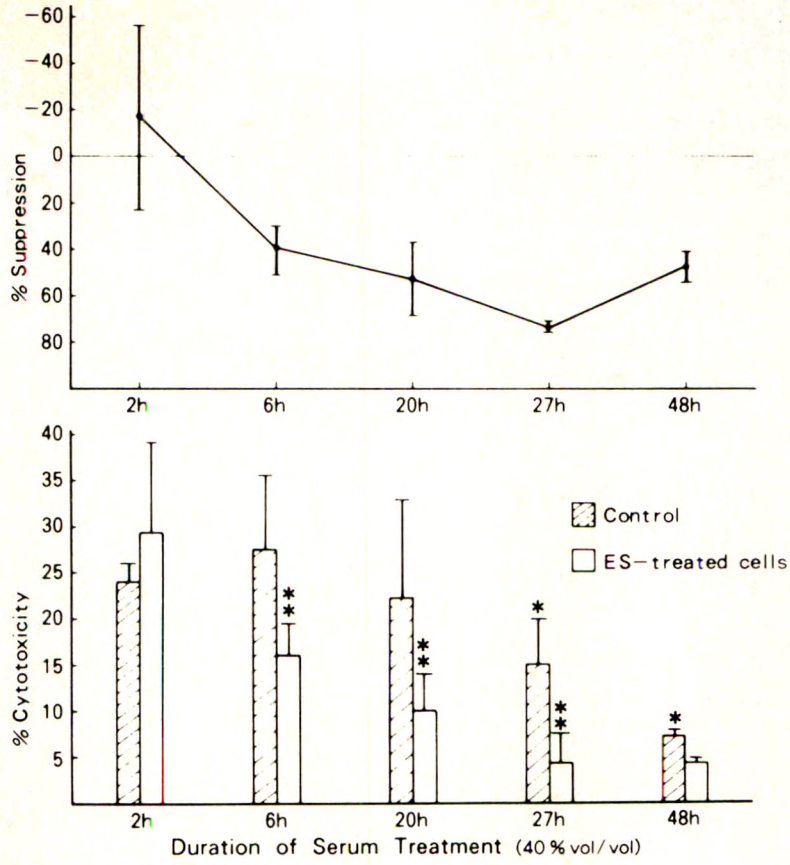

Fig. 3. Effect of the duration of serum treatment on natural killer cell activity. $*p < 0.01$ versus 2 hours. $**p < 0.01$ versus each control.

that serum obtained from patients who have endometriosis can inhibit natural killer cell activity in vitro. The spontaneous cytolytic activity of serum-treated lymphocytes against K562 cells was almost twofold greater with the use of sera from male or female control subjects than with the use of sera from patients who had endometriosis.

The decrease of natural killer cell activity induced by serum from patients who had endometriosis was not caused by the cytotoxicity of the sera, because the viability of the effector cells at the end of the serum treatment was usually more than 95%. Our previous studies demonstrated that the nondecidualized human endometrium releases some soluble factors that are capable of blocking lymphocyte proliferation in vitro[11, 12]; therefore it might be possible that the inhibition of natural killer cell activity was also mediated by soluble suppressive factors produced or released from the endometrial tissues.

In this study no difference was found in the percent suppression induced by sera obtained from patients before, during, and after treatment with danazol. In addition, no correlation was observed between the severity of the disease and the level of suppression. Therefore the serum factors that suppress natural killer cell activity probably do not derive directly from the ectopic endometrial cells themselves. To clarify the role of natural killer cells in the pathogenesis and prognosis of endometriosis it is necessary to know whether the serum natural killer cell suppression factors are present before the onset of the disease or are induced secondarily after the establishment of endometriosis.

Significance of peritoneal macrophages on fertility in mice

Naohiko Umesaki, MD, PhD, Satoshi Uda, MD, Masami Kawabata, MD, PhD, and Sachio Ogita, MD, PhD

Osaka, Japan

OBJECTIVE: To elucidate the role of peritoneal macrophages in infertility, we investigated how the presence of peritoneal macrophages would affect fecundity in mice. Moreover, we also studied the effects of interleukin-1 on embryonic development.

STUDY DESIGN: Mice were administered OK-432 intraperitoneally to induce macrophage infiltration of the peritoneal cavity; ovulation was then induced and animals were mated. On day 13 of gestation, fetuses were counted. After injection of OK-432 or interleukin-1, the mice were mated. Three days later, embryos were collected and the stage of embryo development was determined.

RESULTS: In mice given OK-432 ($n = 33$), four (12%) became pregnant and the mean litter number was 6.0 ± 3.6, whereas in the control group 23 of 30 mice (77%; $p < 0.01$) became pregnant and the litter number was 14.1 ± 5.3 ($p < 0.01$). OK-432 and interleukin-1 administered intraperitoneally significantly suppressed embryo development ($p < 0.01$).

CONCLUSION: Increased numbers of peritoneal macrophages negatively affect fecundity, probably by suppressing embryonic development. (Am J Obstet Gynecol 1992;167:261-4.)

Key words: Peritoneal macrophages, infertility, embryonic development, endometriosis

There are many infertile patients among even those with mild endometriosis,[1, 2] a disease of unknown origin. It is unclear how fecundity is affected in patients with mild endometriosis; some authors have postulated that the increased number[3, 4] and activity[5] of peritoneal macrophages in patients with endometriosis may be related to their decreased fecundity.

To elucidate the cause of infertility in patients with endometriosis, we investigated how the presence of peritoneal macrophages would affect embryonic development in mice. Moreover, we also studied the effects of interleukin-1, a humoral factor produced by peritoneal macrophages, on the embryonic development.

Material and methods

Animals. ICR mice, 10 weeks old, were obtained from Clea Japan, Inc. (Tokyo, Japan).

Induction of macrophage infiltration into the peritoneal cavity. To cause macrophage infiltration into the peritoneal cavity we used OK-432 (Picibanil, Chugai Pharmaceutical Co., Tokyo, Japan) as the chemotactic factor. This is a lyophilized preparation of the penicillin-treated Su-strain of the *Streptococcus pyogenes* group A111.[6] OK-432 at a dose of 0.1 klinische Einheit was injected intraperitoneally. One klinische Einheit corresponded to 0.1 mg of the dried *Streptococci*. In a preliminary study the abdominal cavity was opened 3 days

Table I. Effect of OK432 intraperitoneal administration on animal fecundity

Group	*No.*	*Pregnancy rate*	*Litter No. (mean ± SD)*
OK-432	33	12% (4) *	6.00 ± 3.56 †
Control	30	77% (23) *	14.1 ± 5.26 †

*$p < 0.01$ (χ^2 test).
†$p < 0.01$ (Student t test).

Table II. Effect of prednisolone after OK-432 intraperitoneal administration on animal fecundity

Group	*No.*	*Pregnancy rate*	*Litter No. (mean ± SD)*
OK-432	33	12% (4) *	6.0 ± 3.6 †
OK-432 and prednisolone	21	43% (9) *	16.1 ± 8.7 †

*$p < 0.01$ (χ^2 test).
†$p < 0.05$ (Student t test).

later; 10 ml of physiologic saline solution was pipetted into the abdominal cavity and then aspirated. After centrifugation of the aspirate, the number of macrophages was counted. Macrophages were identified by a staining for α-naphthyl butyrate esterase.[7, 8]

Effect of OK-432 on ovulation rate. The effect of OK-432 on the ovulation rate was studied in another preliminary study in which the number of corpora lutea was counted. OK-432 was injected on day 1. Pregnant mare serum gonadotropin, 5 IU (Teikoku Zouki Co., Tokyo, Japan), was injected intraperitoneally on day 5, and human chorionic gonadotropin (hCG) (Mochida Pharmaceutical Co., Ltd., Tokyo, Japan) was injected on day 7 to induce ovulation. On the next day, both ovaries were removed, and the number of corpora lutea was counted.

Evaluation of fecundity. Fecundity of the mice was evaluated on the basis of the pregnancy rate and the number of fetuses. Ovulation was induced as previously described. Seven hours after the hCG injection, the animals were mated. The presence of a vaginal plug was then checked on the following morning, and if found, this was considered day 0 of gestation. On day 13 of gestation, the abdominal cavity was opened, and the fetuses, if any, were counted.

Study of the effects of OK-432 on fecundity. OK-432, pregnant mare serum gonadotropin, and hCG were injected as previously described. The day of the OK-432 injection was designed as day 1. Seven hours after the hCG injection, the animals were mated. On day 13 of gestation, the abdominal cavity was opened, and the fetuses, if any, were counted.

Study of the effects of prednisolone on fecundity after OK-432 administration. OK-432, pregnant mare serum gonadotropin, and hCG were injected, and the animals were treated as previously described. Prednisolone, 1 mg, was administered intraperitoneally on days 3, 4, and 6.

Study of the effects of OK-432 and interleukin-1 on embryonic development. After injection of OK-432, pregnant mare serum gonadotropin, and hCG, the animals were mated. In case of interleukin-1, recombinant human interleukin-1β (Otsuka Pharmaceutical Co., Ltd., Tokushima, Japan), at a dose of 100 pg (1 μg/12.1 Japan reference unit), was administered intraperitoneally 5 hours after administration of hCG. Recombinant interleukin-1 was prepared in *Escherichia coli* and purified according to the method of Hirai et al.[9] The endotoxin level after purification was less than 100 pg/mg of protein. Ninety-six hours after hCG injection, the abdominal cavity was opened, and both uterine horns were extirpated. The uterine cavum was flushed with 0.2 ml of physiologic saline solution. Cleavage of embryo in flushed saline solution was examined under a contrast phase microscope. The results were expressed as the total number of blastocysts and morula divided by the total number of embryos.

Statistical analysis. The significance of the differences between two groups was evaluated by the Student t test or χ^2 test. When the results from the three groups were compared they were analyzed by Dunnett's multiple comparison test.

Results

After OK-432 administration, 95% of the leukocytes infiltrating the peritoneal cavity were macrophages. The mean number of macrophages after OK-432 administration to 20 mice [$(55.2 \pm 23.5) \times 10^5$] was significantly higher ($p < 0.01$) than in the 10 control mice injected with saline solution only [$(8.1 \pm 6.3) \times 10^5$]. The number of corpora lutea was not significantly different in the OK-432 group ($n = 3$; 24.3 ± 5.0 per mouse) and control group ($n = 3$; 24.5 ± 5.0 per mouse).

In the 33 mice given OK-432, the pregnancy rate was 12%, and the mean litter number was 6.0 ± 3.6 (± SD), that is, lower than in the (77% and 14.1 ± 5.3, respectively) 30 control mice; the difference was significant ($p < 0.01$) for the pregnancy rate and the litter number (Table I).

The pregnancy rate increased ($p < 0.01$) and the litter number was larger ($p < 0.05$) in mice given OK-432 and prednisolone than in those mice given OK-432 alone (Table II).

Regarding the effects of the intraperitoneal administration of OK-432 and interleukin-1 on embryonic development, the number of embryos that had reached the blastocyst or morula stages in the OK-432 group

Table III. Effect of OK-432 and interleukin-1 on embryo development

Group	No.	$\frac{\text{Blastocyst and morula}}{\text{All zygotes}} \times 100\ (\%)$		
OK-432	15	28.9 ± 22.9†		
Interleukin-1	15	39.3 ± 12.7	$p < 0.01$*	$p < 0.01$*
Control	15	65.3 ± 18.6

†Data are expressed as mean ± SD.

($n = 15$) was 28.9 ± 22.9 and 39.3 ± 12.7 in the interleukin-1 group ($n = 15$); both were markedly lower ($p < 0.01$) than the number of blastocysts and morula in the control group (65.3 ± 18.5; $n = 15$) (Table III).

Comment

This study was undertaken to evaluate the effects of peritoneal macrophages on fertility with use of a mice model. OK-432 is used as a biologic response modifier and is also known as an activator of macrophages and natural killer cells[10]; we used it here to cause macrophage infiltration of the peritoneal cavity.

For the identification of macrophages, α-naphthyl butyrate esterase staining was used. With the technologic advances, a new technique that uses monoclonal antibodies has been developed for the identification of macrophages. However, it has been reported that with nonspecific esterase staining, such as the α-naphthyl butyrate esterase staining used in this study, the results obtained are the same as those obtained with monoclonal antibody.[11] In this study 95% of peritoneal leukocytes were macrophages; however, small numbers of lymphocytes and natural killer cells were included. We first studied the effects of OK-432 on ovulation, because prostaglandins secreted from macrophages are known to affect ovulation.[12] According to our observation, however, the number of corpora lutea was not different in mice given OK-432 or physiologic saline only after ovulation induced by pregnant mare serum gonadotropin and hCG, which suggests that these treatments do not interfere with ovulation.

The mice given OK-432 had decreased fecundity, which may suggest that the macrophages infiltrating the abdominal cavity interfere with fecundity. Prednisolone was then given to determine whether a decrease in the macrophage activity with the abdominal cavity would help restore fecundity; both the pregnancy rate and the number of fetuses increased. These results strongly suggested that the large number of macrophages observed in the peritoneal fluid of patients with endometriosis may contribute to infertility in these patients.

To evaluate the participation of macrophages on the decrease of fecundity, we studied their effects on embryonic development. Only a small number of fertilized eggs reached the stage of blastocyst or morula in the OK-432 group, which indicates that macrophages have an adverse effect on the growth of embryos.

On the basis of these results, we can say that the presence of macrophages in the abdominal cavity negatively affects fecundity and that their adverse effect on embryonic development is possibly one of the main etiologic factors involved in the decrease in fecundity.

In mice the ovary and uterus are connected; therefore neither the ovum, the sperm, or the embryo could have direct contact with the macrophages as it occurs in humans. It is then presumed that these adverse effects could have been caused by a humoral factor derived from macrophages.

Hence we examined the possible effects of interleukin-1, which is present at high concentrations in the peritoneal fluid of patients with endometriosis.[13, 14] The dose of recombinant interleukin-1β used here was 100 pg, because at this dose level we observed inhibition of fecundity in our previous study.[14] As a result, embryonic development was suppressed by recombinant interleukin-1β administration.

The adverse effects of peritoneal fluid of patients with endometriosis on embryonic development have been reported by Morcos et al.,[15] although their research was based on data obtained from in vitro fertilization. Similar reports were made by Fakih et al.[13] and Hill et al.[16] However, a recent study by Schneider et al.[17] showed that purified interleukin-1 had no effect on embryonic development.

Although our experiments were carried out in vivo, in view of the results reported by Schneider et al.,[17] we have to consider not the activity of interleukin-1 per se but also the possible participation of other cytokines such as prostaglandins and interleukin-6, which would increase after the administration of interleukin-1.

On the basis of the data presented here, it can be said that peritoneal macrophages have an adverse effect on fecundity and that they probably suppress embryonic development.

The restoration of fecundity after treatment with prednisolone suggested that prednisolone or any other immunosuppressive agent might be beneficial in the treatment of infertility associated with endometriosis, especially in those patients who do not respond to da-

nazol or gonadotropin-releasing hormone agonists alone, because prednisolone does not interfere with ovulation. Furthermore, it is presumed that this experimental model may be useful in the research of the mechanisms involved in infertility associated with endometriosis.

Comparison of cytokine levels and embryo toxicity in peritoneal fluid in infertile women with untreated or treated endometriosis

Yuji Taketani, MD, PhD, Tong-Ming Kuo, MD, PhD, and Masahiko Mizuno, MD, PhD
Tokyo, Japan

OBJECTIVE: Our aim was to examine the relationship between the levels of cytokines in peritoneal fluid and its embryo toxicity.
STUDY DESIGN: The levels of interleukin-1 and tumor necrosis factor were measured in peritoneal fluid from infertile women who did not have endometriosis (n = 21), who had untreated endometriosis (n = 19), and who had undergone medical treatment for endometriosis (n = 10). Embryo toxicity was investigated in mouse two-cell embryos cocultured with the oviducts in culture media that contained various concentrations of peritoneal fluid.
RESULTS: The levels of cytokines were significantly higher in the peritoneal fluid from women who had untreated endometriosis than in women who did not have endometriosis, but they were extremely low in women who had undergone medical treatment with either danazol or buserelin. The peritoneal fluid from women who had untreated endometriosis adversely affected the cleavage of mouse two-cell embryos. After medical treatment the embryo toxicity of the peritoneal fluid was almost undetectable.
CONCLUSION: These results offer some theoretic bases in support of medical treatment to improve reproductive performance in infertile women who have endometriosis. (Am J Obstet Gynecol 1992;167: 265-70.)

Key words: Endometriosis, peritoneal fluid, cytokines, embryo toxicity, medical treatment

Endometriosis is strongly associated with infertility. Reproductive performance is impaired even in women who have minimal and mild endometriosis and who are found to have no apparent anatomic derangement that might hinder early reproductive events, such as ovum pick up or its transport.[1, 2] Thus far diverse plausible mechanisms have been postulated to explain the lessened fecundity associated with endometriosis, including luteinized unruptured follicle,[3] anovulation,[4] luteal phase defect,[5] and impaired glycogen synthesis in the endometrium,[6] among others.

Several reports have recently pointed to the chronic inflammatory changes in the peritoneal cavity of women who have endometriosis, which are manifested by an increased volume of peritoneal fluid[7] and an increased number of peritoneal macrophages and their activities.[8, 9] Furthermore, it has been reported that macrophages from patients who have endometriosis release significantly higher tumor necrosis factor activity than those from fertile women who do not have endometriosis[10]; in addition, elevated levels of interleukin-1[11] and tumor necrosis factor[10, 12, 13] have been demonstrated in the peritoneal fluid of patients who have endometriosis. Because peritoneal fluid is supposed to go into the oviductal cavity, it may influence the early reproductive processes by modulating the microenvironment that surrounds the embryos. In this regard we have demonstrated that the peritoneal fluid from women who have endometriosis inhibits the cleavage of mouse early embryos by acting on the oviducts; thus it is possible that factors in the peritoneal fluid from these women are involved in the pathogenesis of infertility associated with endometriosis.[14] More specifically, we have suggested that elevated interleukin-1[14] and tumor necrosis factor[13] in the peritoneal fluid may be responsible for the embryo toxicity of the peritoneal fluid from women who have endometriosis.

These observations prompted us to investigate whether medical treatment of endometriosis reduces the levels of cytokines in peritoneal fluid and its effect on embryonic development. In this study we offer evidence that medical treatment of endometriosis decreases the cytokine levels and concurrently eliminates the embryo toxicity of the peritoneal fluid from women who have endometriosis.

Material and methods

Patients. The subjects in this study were 50 infertile women who had normal ovulatory cycles. Peritoneal fluid was collected during laparoscopy or laparotomy either for an evaluation of infertility or for treatment of infertility by means of tubal microsurgery. Twenty-

Table I. Clinical profile of the women studied

	Nonendometriosis	*Untreated endometriosis*	*Treated endometriosis*
No. of cases	21	19	10
Age (mean ± standard error of mean)	32.5 ± 5.1	30.8 ± 3.8	31.9 ± 4.0
Duration of infertility	5.2 ± 3.0	4.6 ± 2.5	4.9 ± 2.7

Table II. Volume of peritoneal fluid

	Peritoneal fluid (ml)
Nonendometriosis	10.6 ± 8.5*
Untreated endometriosis	19.6 ± 9.0
Treated endometriosis	6.0 ± 4.1**

Values are mean ± standard error of the mean.
*$p < 0.05$ versus untreated endometriosis.
**$p < 0.01$ versus untreated endometriosis.

nine women had endometriosis. Of these, 19 (revised American Fertility Society stage I/II = 10; stage III = 3; and stage IV = 6) had not undergone any treatment for endometriosis, and 10 (stage I/II = 2; stage III = 4; and stage IV = 4) had received medical treatment for 4 to 6 months (4 with danazol [Bonzol, Tokyo Tanabe Co., Ltd., Tokyo, Japan], 400 mg/day, and 6 with intranasal buserelin [Suprecur, Hoechst Japan Ltd., Tokyo, Japan], 900 μg/day). The remaining 21 women had no evidence of endometriosis.

Collection of peritoneal fluid. Peritoneal fluid samples were obtained from each woman in the late proliferative phase by aspirating the fluid in the anterior uterovesical space and cul-de-sac. Peritoneal fluid samples from women who had endometriosis that had been treated were obtained 3 months after the termination of treatment. The fluid was centrifuged at 600*g* for 15 minutes, and the resultant cell-free supernatant was stored at −80° C until use.

Measurement of cytokines. The concentration of interleukin-1β in peritoneal fluid was measured with enzyme-linked immunosorbent assay kits (Otsuka Pharmaceutical Co., Ltd., Tokyo, Japan). The lowest measurable concentration was 2 pg/ml. The intraassay coefficient of variation was 4%, whereas the interassay coefficient of variation was 8.2%. The concentration of tumor necrosis factor−α was measured with enzyme-linked immunosorbent assay kits (Otsuka). The lowest measurable concentration was 4 pg/ml. The intraassay and interassay coefficients of variation were 3.1% and 12.0%, respectively.

Effect of peritoneal fluid on embryonic development. In a previous report[14] we have shown that the peritoneal fluid from women who have endometriosis inhibits the cleavage of mouse two-cell embryos cocultured with the oviducts. Therefore it was suggested that the peritoneal fluid from women who have endometriosis may primarily act on the oviducts and stimulate the release of certain humoral factors that in turn adversely affect embryonic development. In this study we used the same in vitro system to assess the embryo toxicity of the peritoneal fluid. Briefly, 8-week-old ICR mice were injected with 5 IU of pregnant mare serum (Teikoku Hormone Manufacturing Co., Ltd., Tokyo, Japan) intraperitoneally to induce superovulation, followed by an intraperitoneal injection of 5 IU of human chorionic gonadotropin (Teikoku) 48 hours later. Mating was confirmed by the presence of the copulatory plug. The oviducts were taken 48 hours after the human chorionic gonadotropin injection to obtain two-cell embryos. The embryos were cultured for 24 hours at 37° C under the condition of 95% air and 5% CO_2 in modified Biggers-Whitten-Whittingham medium in the presence of a piece of oviductal tissue (approximately 5 mm in length). The oviductal tissue was taken from nonpregnant 8-week-old Crj:CD-1 mice. The presence of the oviductal tissue did not affect the pH or the osmotic pressure of the culture media. Usually 10 embryos were cultured in a plastic organ culture dish (Becton Dickinson Labware, Lincoln Park, N.J.) that contained 1.5 ml of the medium. The maximum concentration of peritoneal fluid from women who did not have endometriosis at which no adverse effect was observed on embryonic development in vitro was 5%. Therefore this concentration was used throughout the experiments. From 10 to 30 embryos were used to assess the effect of each sample. The degree of development of cultured embryos was determined by microscopic observation.

Statistics. Data regarding cytokines were expressed as the mean ± standard error of the mean and analyzed by the Student *t* test. The Mann-Whitney U test was used for the analysis of embryonic development. A possibility of 0.05 was considered significant.

Results

Table I summarizes the clinical profiles of the women who participated in this study. Their mean age and the duration of infertility were essentially the same among the three groups (nonendometriosis, untreated endometriosis, and endometriosis after medical treatment).

Table II compares the volume of aspirated peritoneal fluid. The volume of peritoneal fluid in the untreated

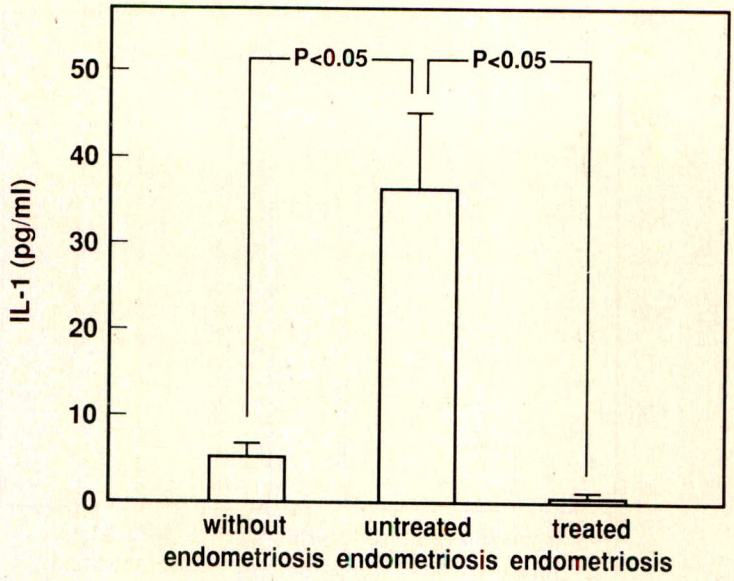

Fig. 1. Concentration of interleukin-1 in peritoneal fluid from women who did not have endometriosis, who had untreated endometriosis, and who had treated endometriosis. Each value represents the mean ± standard error of the mean.

endometriosis group was about twofold the volume found in the nonendometriosis group. However, the volume of peritoneal fluid was markedly lower in women who had undergone medical treatment; it was less than one third of the volume found in the untreated endometriosis group.

Interkeukin-1 levels in the peritoneal fluid from women who had untreated endometriosis were significantly higher than interleukin-1 levels in the nonendometriosis group. Notably, the interleukin-1 levels in women who had been treated for endometriosis were almost below detectability in all cases except one (Fig. 1). The same phenomenon was observed in the case of tumor necrosis factor (Fig. 2). The tumor necrosis factor levels in the peritoneal fluid from women who had untreated endometriosis were about fivefold the levels detected in the endometriosis group. The tumor necrosis factor levels were extremely low in the treated endometriosis group.

Fig. 3 illustrates the distribution of embryos according to their embryonal stage after they were cultured for 24 hours in medium that contained peritoneal fluid from women in each study group. Among the embryos cultured with peritoneal fluid from women who did not have endometriosis, 5- to 8-cell and 16-cell or more advanced stages accounted for 50% and 30% of the cultured embryos, respectively. In contrast, the percentage of 5- to 8-cell and 16-cell or more advanced stages were 33% and 13%, respectively, when 2-cell embryos were incubated with the peritoneal fluid from women who had untreated endometriosis. The analysis of the overall distribution between the two groups demonstrated that the embryonal development of embryos incubated with peritoneal fluid from women who had untreated endometriosis was significantly delayed ($p < 0.001$). It is noteworthy that the rate of degenerated embryos was significantly higher ($p < 0.001$) when embryos were incubated with the peritoneal fluid from women who had untreated endometriosis (25%) than that found when embryos were incubated with the peritoneal fluid from women who did not have endometriosis (8%). The peritoneal fluid from women who had treated endometriosis showed markedly reduced embryo toxicity compared with the peritoneal fluid from women who had untreated endometriosis; however, the rate of degenerated embryos was still higher (20%) compared with the rate found when embryos were incubated in the presence of the peritoneal fluid from women who did not have endometriosis ($p < 0.001$). Hence, regarding the overall distribution of the embryonal stages, a significant difference was found between the peritoneal fluid from women who did not have endometriosis and the peritoneal fluid from women who had treated endometriosis ($p < 0.01$).

We then examined the effect of each peritoneal fluid sample on embryonal development (Table III). Because the lowest percentage of embryos that developed into five-cell or more advanced stages was about 70% when two-cell embryos were incubated without peritoneal fluid, we regarded peritoneal fluid samples that produced over 70% embryos of five-cell or more advanced as nonembryo toxic. According to this definition 3 of 11 (18%) peritoneal fluid samples from women who

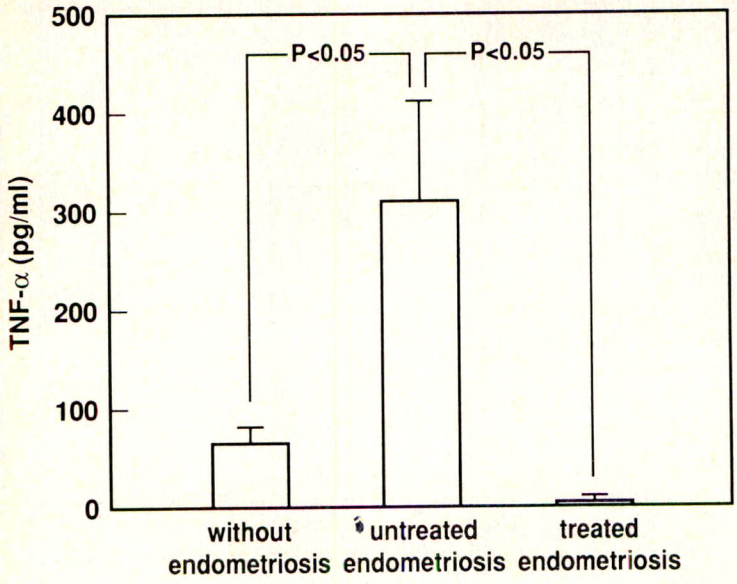

Fig. 2. Concentration of tumor necrosis factor in peritoneal fluid from women who did not have endometriosis, who had untreated endometriosis, and who had treated endometriosis. Each value represents the mean ± standard error of the mean.

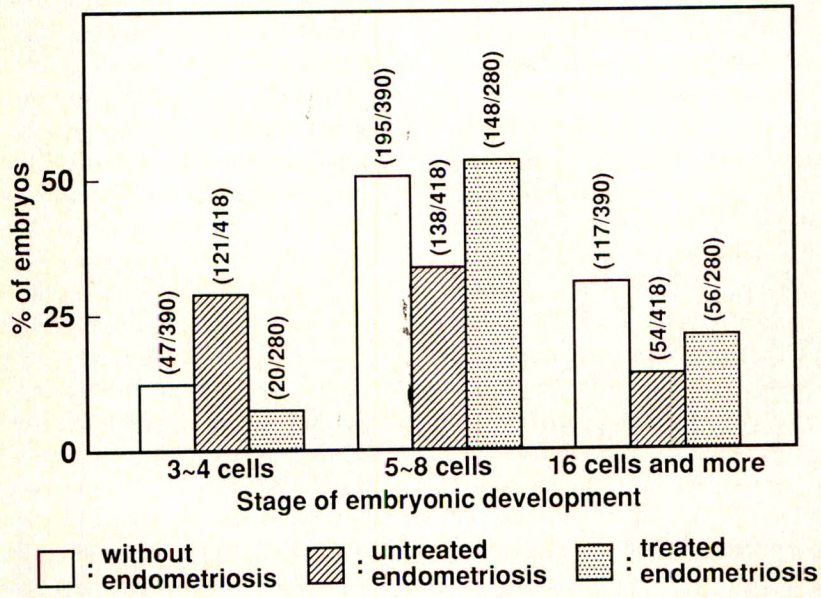

Fig. 3. Number of embryos at different stages of embryonic development after 24-hour incubation of mouse two-cell embryos with peritoneal fluid. Denominators correspond to the number of embryos examined and numerators correspond to the number of embryos at each stage of embryonic development. The remaining embryos were degenerated.

did not have endometriosis were embryo toxic, whereas 15 of 19 (79%) peritoneal fluid samples from women who had untreated endometriosis were embryo toxic; thus the incidence of embryo toxic peritoneal fluid was significantly different in these two groups ($p < 0.05$). However, only 20% of the peritoneal fluid samples in the treated endometriosis group were embryo toxic; that is, almost no difference was found in the occurrence of peritoneal fluid with embryo toxicity between the nonendometriosis group and the treated endometriosis group.

Comment

The main finding of this study is that the cytokine levels were markedly low in the peritoneal fluid from women who had undergone medical treatment for en-

dometriosis. The peritoneal fluid of these women also showed much less embryo toxicity compared with the peritoneal fluid from women who had untreated endometriosis. These results offer a theoretic background in favor of medical treatment for endometriosis-associated infertility.

A considerable body of evidence suggesting that intraperitoneal chronic inflammatory changes are presumptive etiologic factors for endometriosis-associated infertility has been accumulated. For instance, peritoneal fluid from patients who have endometriosis and increased levels of tumor necrosis factor reduces sperm motility.[15] In addition, peritoneal fluid from women who have endometriosis has been shown to exert a deleterious effect on sperm-oocyte interaction in mice.[16] Furthermore, Morcos et al.[17] reported that peritoneal fluid from women who have endometriosis inhibits the cleavage of mouse embryos. However, Awadalla et al.[18] failed to duplicate this finding. We were also unable to demonstrate a direct toxic effect of peritoneal fluid on embryonic development.[14] These conflicting results may be partly caused by the different species of mice or culture media that were used. Because peritoneal fluid is in direct contact with the oviductal cavity, we wondered whether peritoneal fluid could hinder embryonic development by altering the intraoviductal microenvironment that surrounds embryos at an early stage. Thus we cocultured the embryos with the oviducts in the presence of peritoneal fluid from infertile women who had endometriosis and were able to demonstrate the inhibition of embryonic development by the peritoneal fluid.[14] In this study we have confirmed our previous findings with use of the same experimental system. It is especially interesting to note that the embryo toxicity of peritoneal fluid was hardly detected after medical treatment. However, some of the peritoneal fluid samples still showed some degree of embryo toxicity after the treatment.

Cytokines, such as interleukin-1 or tumor necrosis factor, are usually found in high amounts in the peritoneal fluid from women who have endometriosis.[10-13] In our previous study[14] interleukin-1, like peritoneal fluid, inhibited embryonic development in the presence of the oviducts. Interestingly, indomethacin, which is an inhibitor of prostaglandin synthesis, effectively abolished the inhibitory effect of interleukin-1 and the peritoneal fluid on embryonic development. These findings suggested that interleukin-1, at increased concentrations, could contribute to the embryo toxicity of the peritoneal fluid from women who have endometriosis. The same was true for tumor necrosis factor.[13] Moreover, we showed that prostaglandin E_2 directly inhibits embryonic development in the absence of the oviducts.[14] Accordingly, prostaglandin E_2, which is released from the oviductal tissues through stimulation with peritoneal fluid,[14] appears to be one of the mediators in the pathogenesis of endometriosis-associated infertility. Notably, in this study we have demonstrated that the decrease in embryo toxicity of the peritoneal fluid from women who have treated endometriosis was accompanied by decreased cytokine levels. This finding provides strong support for the aforementioned suggestion that increased levels of cytokines in the peritoneal fluid may be involved in the pathogenesis of endometriosis-associated infertility.

Table III. Incidence of embryo toxic peritoneal fluid among women in the three groups studied

	No. of women with embryo toxic peritoneal fluid	*(%)*
Nonendometriosis	2/11*	18
Untreated endometriosis	15/19	79
Treated endometriosis	2/10*	20

Mouse two-cell embryos were incubated for 24 hours with 10% of each peritoneal fluid sample. Peritoneal fluid samples that could not produce 70% of embryos of five cells or more were regarded as embryo toxic.

*$p < 0.05$ versus untreated endometriosis.

The question remains as to whether the inflammatory changes in the peritoneal cavity are a consequence of the presence of endometriotic tissues. In this study cytokine levels were markedly lower in the peritoneal fluid from women who had treated endometriosis. This finding appears to support the viewpoint that the presence of endometriotic tissues evokes inflammatory changes in the peritoneum. The possibility remains that the drugs used in this study directly modulate the cytokine production in a manner unrelated to their clinical efficacy. Indeed, danazol has been shown to have immunosuppressive effects in vitro.[19] Moreover, danazol, but not buserelin, suppresses autoantibodies in women who have endometriosis.[20] Thus it cannot be ruled out that danazol may directly modulate the production of cytokines by macrophages. However, both danazol and buserelin were associated with low cytokine levels. In addition, it has been reported that treatment of endometriosis with medroxyprogesterone reduces intraperitoneal inflammatory changes, which is exemplified by a reduced peritoneal fluid volume and lower leukocyte counts in the peritoneal fluid of those patients.[21] Therefore it appears that the reduced cytokine levels observed in the peritoneal fluid from women who have treated endometriosis are presumably caused by a reduction of endometriotic tissues but not by the direct effect of the drug used.

The data obtained in this study provide some insight into the causal relationship between endometriosis and infertility. Regarding the embryo toxicity of the peritoneal fluid, results from this study suggest that the presence of endometriosis adversely affects fecundity.

However, as yet the beneficial effect of medical treatment in improving fecundity in women who have endometriosis has not been proved. A likely explanation for this is that divergent mechanisms may be involved in endometriosis-associated infertility and medical treatment cannot eliminate every possible etiologic factor of infertility. Alternatively, our results showed that degenerated embryos were still found more frequently among embryos incubated with peritoneal fluid from women who had treated endometriosis compared with those incubated with peritoneal fluid from women who did not have endometriosis. It thus appears feasible that unidentified factors involved in the degeneration of embryos may remain in the peritoneal fluid from women who have treated endometriosis. We are currently investigating the presence of such factors.

Luteinized unruptured follicle in the early stages of endometriosis as a cause of unexplained infertility

Yasuyuki Mio, MD, PhD, Toshiko Toda, MD, PhD, Tasuku Harada, MD, PhD, and Naoki Terakawa, MD, PhD

Yonago, Japan

OBJECTIVE: We attempted to clarify the relationship between luteinized unruptured follicle, which occurs in the early stages of endometriosis, and unexplained infertility.

STUDY DESIGN: Seventy patients who had unexplained infertility were reviewed.

RESULTS: Laparoscopic examination showed that 47 patients (67%) had endometriosis; of these, 40 (85%) had minimal or mild disease. The incidence of luteinized unruptured follicle was higher ($p < 0.05$) in patients who had endometriosis (35%/patient and 25%/cycle) compared with patients who did not have endometriosis (11%/patient and 7%/cycle). Degenerated oocyte cumuli were collected in 6 (43%) of 14 luteinized unruptured follicles diagnosed by transvaginal ultrasound.

CONCLUSIONS: These results show that luteinized unruptured follicle is common in patients who have mild or minimal endometriosis and that it may be one of the causes of endometriosis-associated infertility. Transvaginal ultrasound-guided follicular puncture of luteinized unruptured follicle during the mid luteal phase may be useful in establishing a definitive diagnosis of luteinized unruptured follicle. (AM J OBSTET GYNECOL 1992;167:271-3.)

Key words: Luteinized unruptured follicle, endometriosis, unexplained infertility, ultrasonography

Endometriosis is an enigmatic disease that is frequently associated with infertility. In the advanced stages of the disease infertility is easy to explain because of the presence of adhesions, ovarian endometrioma, or both, but a direct cause-and-effect relationship in the early stages of endometriosis is not fully understood. Among the mechanisms that might be involved in endometriosis-associated infertility is the luteinized unruptured follicle.[1] Originally described by Jewelewicz,[2] the luteinized unruptured follicle may be one of the causes of infertility in women who have endometriosis,[3-6] although its significance is still controversial.[7-9] In our fertility clinic minimal or mild endometriosis was demonstrated on laparoscopy in more than 50% of patients who had unexplained infertility. Moreover, luteinized unruptured follicle was frequently found by ultrasonic examination in patients who had unexplained infertility.

This study was undertaken to elucidate whether luteinized unruptured follicle is associated with endometriosis in the early stages of the disease and to investigate its potential role in endometriosis-associated infertility. We discuss the results in relation to the relevant published reports available.

Material and methods

Between May 1989 and April 1991, 146 patients who desired to have a child underwent diagnostic laparoscopic examination and a tubal dye test in our clinic. Seventy of these 146 patients had received a diagnosis of unexplained infertility before laparoscopic examination, because their test results from the routine laboratory workup for couples with infertility were normal. This routine laboratory workup included follicular monitoring by ultrasonography. From these 70 patients a study group of 47 patients who had endometriosis was selected. Of the remaining patients who had normal findings, 28 had husbands with a low semen analysis; these patients constituted the control group in this report.

Documentation of endometriosis. We performed all laparoscopies with use of the double-puncture technique, with the patients under general anesthesia, on day 7 to day 10 of the menstrual cycle. The stage of endometriosis was determined according to the weighted point system of the Revised American Fertility Society Classification of Endometriosis.[10] Unipolar electrocautery was performed when minimal or mild endometriosis was observed. When we believed that electrocautery would not be effective, no attempt was made to excise or cauterize the endometriotic lesion. In such cases medical therapy with danazol (Bonzol, Tokyo Tanabe Co., Ltd., Tokyo, Japan) or gonadotropin-releasing hormone analog (buserelin; Suprecur, Hoechst Japan, Tokyo, Japan) was chosen for further treatment.

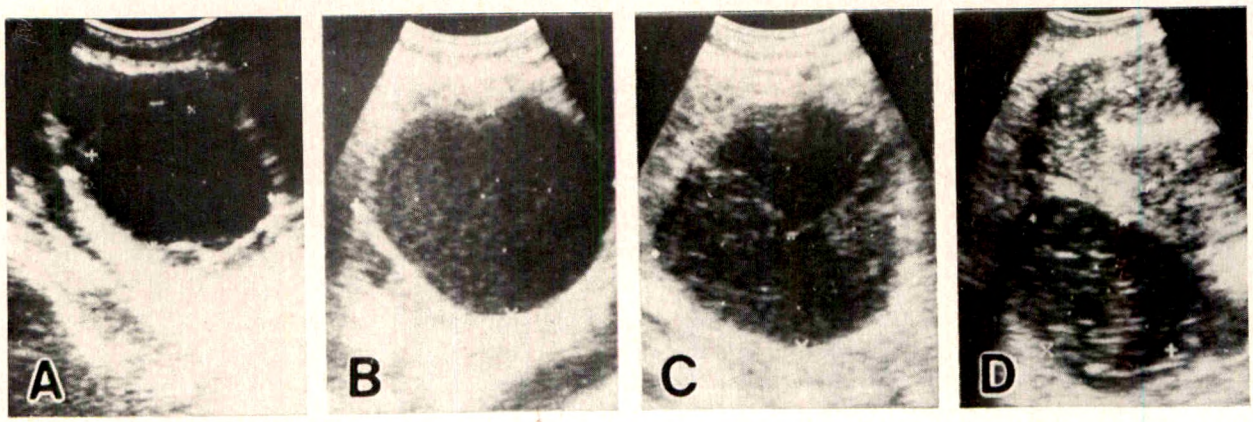

Fig. 1. Representative patterns of a luteinized unruptured follicle seen by transvaginal ultrasonography. **A,** Mature follicle (21-27 mm) on day 14 of menstrual cycle. **B,** Luteinized unruptured follicle (29-39 mm) on day 16 of the cycle. **C,** Enlarged luteinized unruptured follicle (36-37 mm) with intrafollicular echogenicity on day 18 of the cycle. **D,** Reduced size of luteinized unruptured follicle (30-36 mm) with increasing intrafollicular echogenicity on day 22 of the cycle.

Table I. Incidence of luteinized unruptured follicle

	% incidence of LUF (n)	
	In patients	*In cycles*
Endometriosis group	35 (11/31)*	25 (20/81)*
Control group	11 (3/28)	7 (3/44)

LUF, Luteinized unruptured follicle.
*$p < 0.05$ vs control.

Ultrasonographic documentation of LUF. Follicular development was monitored by transvaginal ultrasonography (SSD-650 and SSD-630; Aloka, Tokyo, Japan), daily or every other day, from day 8 of the menstrual cycle until 3 days after human chorionic gonadotropin administration. A diagnosis of luteinized unruptured follicle was established when the following signs were present: (1) a rise in basal body temperature; (2) ultrasonically persistent and enlarged follicles after human chorionic gonadotropin administration, without the collapse of the large follicle and free fluid in the pouch of Douglas (Fig. 1); (3) >5 ng/ml of serum progesterone during the mid luteal phase; and (4) a degenerated oocyte mass in the contents of persistent follicles.

Eighty-one cycles of 31 patients who had endometriosis were used to retrospectively investigate the occurrence of luteinized unruptured follicle during the year before laparoscopic examination. Forty-four cycles of 28 control patients who did not have endometriosis and whose husbands showed subnormal semen analysis were also analyzed for luteinized unruptured follicle. In luteinized unruptured follicle cycles follicular development and ovulation had been monitored by serial transvaginal ultrasonography. The concentration of serum progesterone during the mid luteal phase had been measured in most of the cycles. Furthermore, after the patients' informed consent was obtained, transvaginal, ultrasound-guided follicular aspiration of 14 follicles was performed as previously described[11] 3 to 5 days after human chorionic gonadotropin administration in 10 patients whose developed follicles did not rupture.

Results

Of 70 patients who were diagnosed with unexplained infertility, 47 (67%) had endometriosis; 40 (85%) of these had minimal ($n = 22$) or mild ($n = 18$) endometriosis. The remaining seven patients had moderate ($n = 5$) or severe ($n = 2$) endometriosis. Among the 23 women who did not have endometriosis, 2 had inflammatory adhesions of the pelvis and 21 had normal pelvic findings.

The incidence of luteinized unruptured follicle was 35% (11/31) among the patients and included 25% (20/81) of the cycles. In contrast, the incidence of this phenomenon in the control group was 11% (3/28) among the patients and included 7% (3/44) of the cycles monitored. The incidence of luteinized unruptured follicle among patients and the cycles monitored was significantly ($p < 0.05$) higher in the endometriosis group than in the control group (Table I).

Degenerated or postmature oocyte cumuli were observed in 6 (43%) of 14 luteinized unruptured follicles; the contents included yellowish-brown solids and a hazy and viscous fluid.

Comment

In this study we found that most of the patients who were diagnosed with unexplained infertility before laparoscopic examination had minimal or mild endome-

triosis. Moreover, the incidence of luteinized unruptured follicle was significantly higher in patients who had endometriosis than in those who did not have it.

Brosens et al.[3] postulated that luteinized unruptured follicle might be a cause of infertility in women who have endometriosis. Likewise, Donnez and Thomas[5] found that the incidence of luteinized unruptured follicle cycles was significantly higher in patients who had endometriosis (26% vs 9% in the control). Toda[6] recently reported that the incidence of luteinized unruptured follicle diagnosed by transvaginal ultrasonography was 13.5% per cycle monitored (n = 384) in patients who had infertility. A particularly higher incidence of luteinized unruptured follicle (range, 37.5% to 21.4%) was observed in patients who had polycystic ovarian syndrome, tubal infertility, and endometriosis when compared with the incidence in the case of male infertility and ovulatory disorder (range, 6.8% to 6.3%). The results in this study are comparable with the data reported in those articles. However, other investigators have reported very little association, if any, between luteinized unruptured follicle and endometriosis.[7-9]

When we consider these conflicting data, at least two aspects should be taken into account. One refers to the accuracy of the diagnosis of luteinized unruptured follicle by ultrasonography. Liukkonen et al.[12] reported that the diagnosis of the luteinized unruptured follicle syndrome by ultrasound examination seems to be fairly accurate according to the laparoscopic confirmation of the findings. However, Petsos et al.[13] emphasized that serial ultrasound scans alone cannot be used to detect ovulation. In this study transvaginal, ultrasound-guided follicular aspiration[11] of the luteinized unruptured follicle diagnosed by ultrasound examination was performed to examine the follicular contents during the mid luteal phase. Forty-three percent (6/14) of the luteinized unruptured follicles contained degenerated oocyte masses in the mid luteal phase. The results demonstrate that this technique may be useful to establish a definitive diagnosis of luteinized unruptured follicle and to elucidate the mechanisms involved in this phenomenon.

We must also consider how minimal or early endometriosis interferes with the process of ovulation and fertilization. It is theorized that prostaglandins,[14] proteolytic enzymes,[15] and cellular components such as macrophages and lymphocytes[16] in the peritoneal fluid of patients who have minimal or mild endometriosis may individually or jointly affect the ovulation. In addition, it is known that the peritoneal fluid itself is toxic to the growth and development of embryos in the early stages of embryogenesis.[1,16] Therefore minimal or mild endometriosis may be associated with infertility. However, the relationship between luteinized unruptured follicle and endometriosis-associated infertility remains to be elucidated.

Luteal function in infertile patients with endometriosis

Koji Kusuhara, MD
Tokyo, Japan

OBJECTIVE: Our purpose was to determine whether infertile patients who have endometriosis show luteal phase defects.
STUDY DESIGN: The luteal function in 24 infertile patients who had endometriosis was compared with the luteal function in 20 patients who had unexplained infertility and did not have endometriosis (control). In both groups serum luteinizing hormone, follicle-stimulating hormone, progesterone, and estradiol were assayed every day throughout the menstrual cycle. Endometrial biopsy specimens were obtained from eight patients of the endometriosis group for histologic dating of the endometrium.
RESULTS: No significant differences in progesterone levels were observed between these two groups during the mid and late luteal phase. Seven of the eight patients who underwent histologic dating showed a luteal phase pattern, whereas only one patient was out of phase.
CONCLUSION: Infertile patients who have endometriosis do not always have luteal phase defects. (Am J Obstet Gynecol 1992;167:274-7.)

Key words: Endometriosis, luteal function, infertility

The real cause of infertility in patients who have endometriosis has not yet been clarified. Functional or anatomic abnormalities of reproductive organs within the pelvic cavity that are induced by extended endometriosis are considered to be a direct cause of infertility; however, the presence of organ abnormalities alone does not explain the cause of infertility in patients who have mild and moderate endometriosis. There must be other factors associated with endometriosis that cause infertility in these patients. One of the possible causes is ovarian dysfunction. Luteal phase defects in particular have been suggested as a plausible explanation. Williams et al.[1] reported that the progesterone level is low in patients who have endometriosis. Conversely, Radwanska and Dmowski[2] reported that endometriosis is not complicated by luteal phase defects. Thus no conclusions have been reached regarding the presence or absence of luteal phase defects in infertile patients who have endometriosis.

Consequently, in the current study I compared the progesterone levels of infertile patients who had endometriosis and patients who had unexplained infertility without endometriosis to clarify whether infertile patients with endometriosis have luteal phase defects.

Material and methods

The subjects were 20 patients who had unexplained infertility in whom the absence of endometriosis was confirmed by laparoscopic examination (control group) and 24 infertile patients who had laparoscopically confirmed endometriosis (endometriosis group). No significant differences in age and the duration of infertility existed between these groups (Table I).

Endometrial biopsy specimens were obtained from eight patients of the endometriosis group 7 days after the luteinizing hormone (LH) surge and were histologically examined. Dating was conducted according to the criteria proposed by Noyes et al.[3]

Blood samples were taken every day throughout the menstrual cycle from each of the patients ($n = 44$), and serum was stored until assayed to determine the concentrations of LH, follicle-stimulating hormone, estradiol, and progesterone in the course of time.

A kit for radioimmunoassay from Daiichi Radio Isotope Inc. (Tokyo, Japan) was used to measure serum LH, follicle-stimulating hormone, estradiol, and progesterone. The coefficient value was satisfactory; it was 5% to 9% or less in the intraassay and 8% to 14% in the interassay. Statistical significance was analyzed by the Student t test.

Results

Fig. 1 demonstrates the results of the comparison of gonadotropins levels between the control group (*shadow*, mean values ± SD) and the group of patients who had endometriosis (*open circle*, mean values ± SD). The date of the LH surge was designated as day 0. The value of the LH surge in the control group was 91.2 ± 50.0 IU/ml. Similarly, the value of the LH surge in the endometriosis group was 105.5 ± 55.5 IU/ml, which revealed no significant differences between these two groups.

Moreover, comparison of the basal LH levels in the follicular and luteal phases in the control and endometriosis groups revealed no significant differences.

Follicle-stimulating hormone levels were also com-

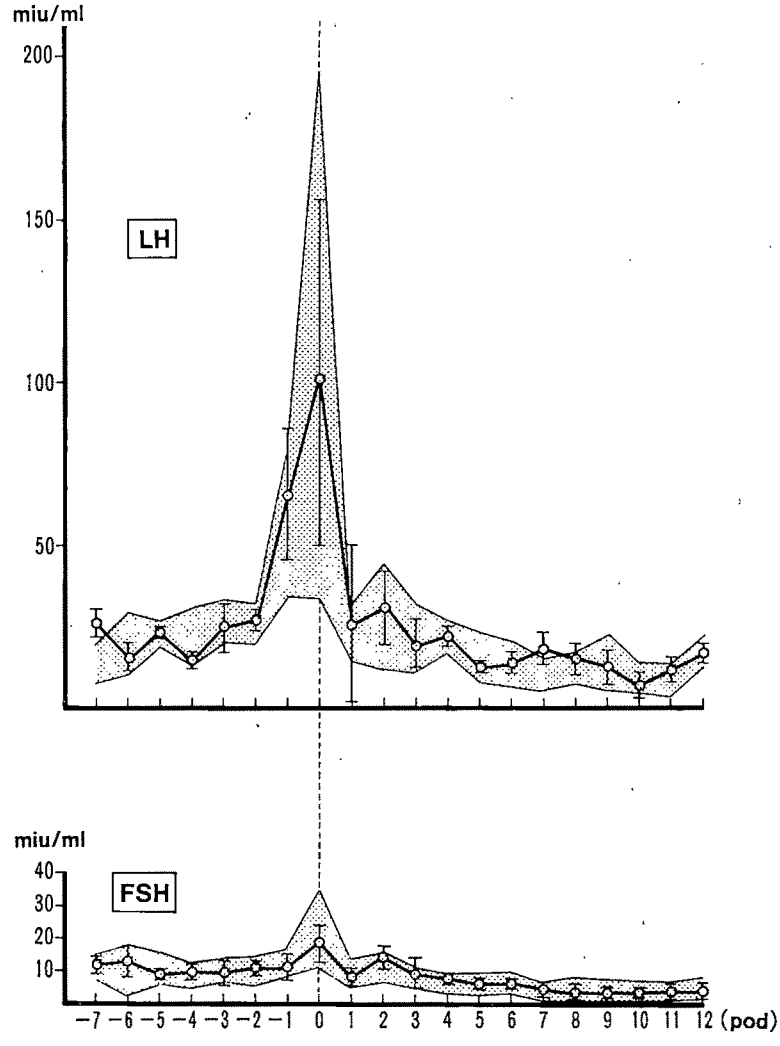

Fig. 1. Serum LH and follicle-stimulating hormone concentrations in control (*shaded background, n* = 20) and endometriosis (*open circle, n* = 24) groups. Data are expressed as mean values ± SD.

pared between the control and endometriosis groups (Fig. 1). No significant differences were observed between the two groups regarding the basal follicle-stimulating hormone levels in the follicular or luteal phase.

Progesterone and estradiol levels in both groups were compared to investigate the luteal function in the endometriosis group. Fig. 2 shows the changes in the levels of progesterone and estradiol in the control and endometriosis groups. The progesterone level in the control group rose immediately after ovulation, reached the peak value of 16.3 ± 4.7 ng/ml on day +6, and then declined. On the other hand, in the endometriosis group the level was slightly low on days +1 and +2, but it reached the peak value of 14.1 ± 5.5 ng/ml on day +7. The peak value was not significantly different from the peak value in the control group. No significant differences from the control group were observed even during the subsequent late luteal phase.

Table I. Characteristics of the study population

	Endometriosis group (n = 24)	*Control group (n = 20)*
Age (yr)	30.7 ± 4.3	31.5 ± 5.3
Duration of infertility (yr)	4.3 ± 3.2	3.7 ± 2.5
Endometriosis stage*	Minimal 2 cases Mild 10 cases Moderate 6 cases Severe 6 cases	—

Data are expressed as mean values ± SD.
*Revised American Fertility Society Classification.

Regarding estradiol levels, the preovulatory surge in the control group occurred on day −1 (237.6 ± 78.9 pg/ml) and the mid luteal surge occurred on day +7 (176.7 ± 60.8 pg/ml). In contrast, although estradiol

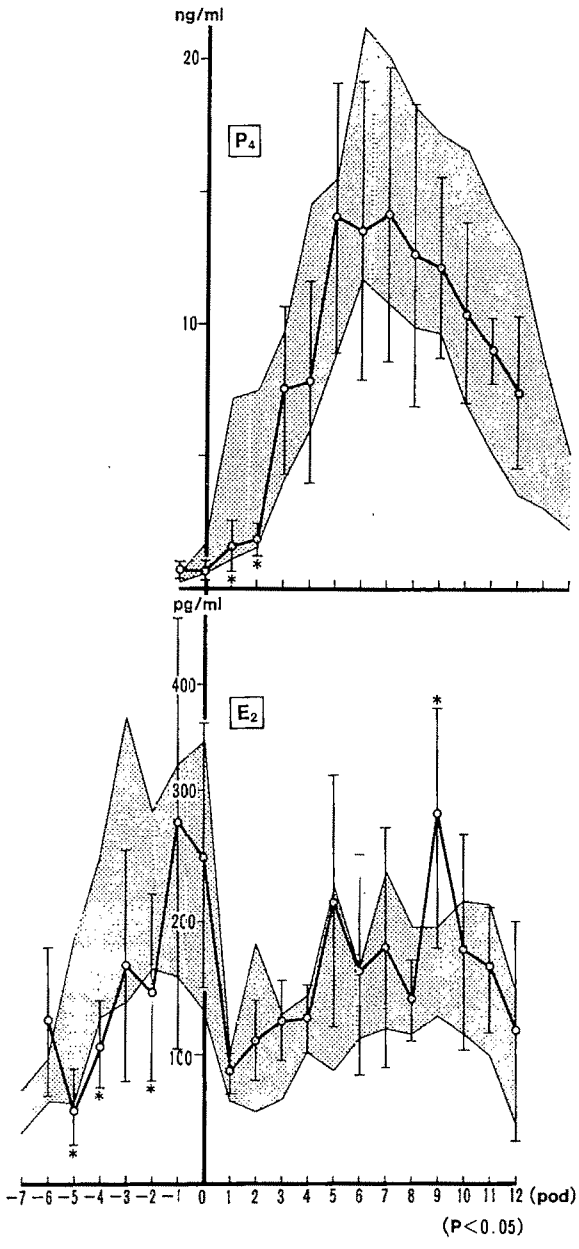

Fig. 2. Serum progesterone and estradiol concentrations measured during luteal phase in control (*shaded background, n* = 20) and endometriosis (*open circle, n* = 24) groups. Data are expressed as mean values ± SD.

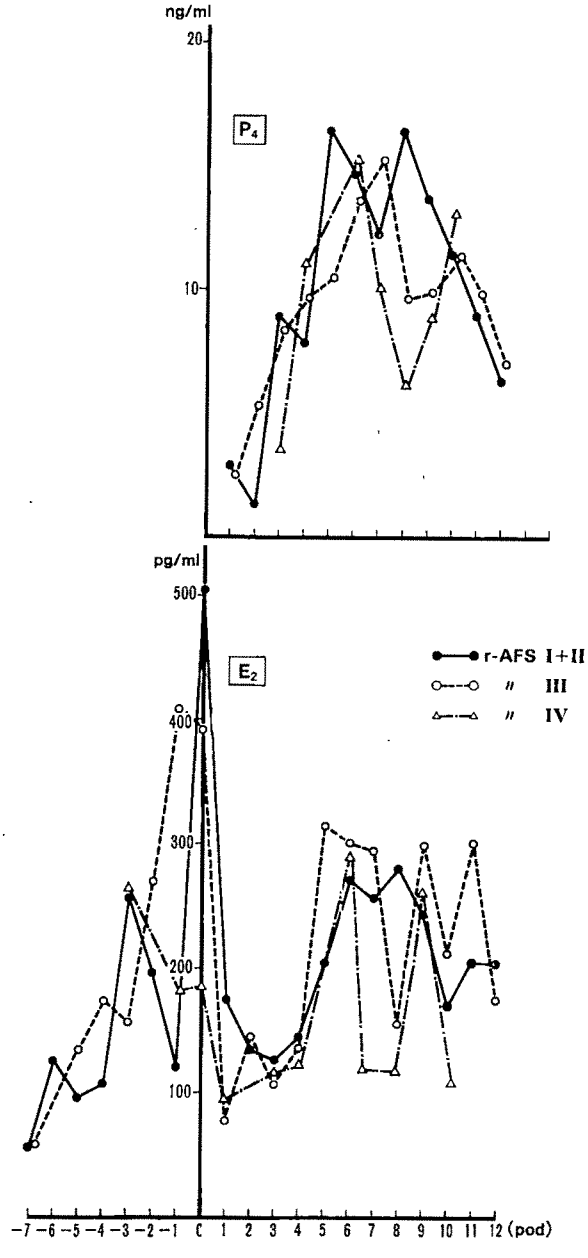

Fig. 3. Mean value of progesterone and estradiol in patients who had endometriosis classified according to stage of disease. Stage I + II (*closed circle, n* = 12), stage III (*open circle, n* = 6), and stage IV (*open triangle, n* = 6). Data are expressed as mean values.

levels in the endometriosis group were slightly lower during the late follicular phase, no significant differences in the control group were observed. In the endometriosis group the estradiol levels reached the preovulatory peak of 277.8 ± 174.5 pg/ml on day −1, and the mid luteal surge of 215.7 ± 95.0 pg/ml occurred on day +5.

The endometriosis group was then divided into three groups according to the stage of the disease on the basis of the revised American Fertility Society Classification: the first group consisted of patients who had stage I and II disease, the second group consisted of patients who had stage III disease, and the third group consisted of those who had stage IV disease. The progesterone and estradiol levels in these three groups are shown in Fig. 3.

Although patients who had stage IV disease showed slightly lower progesterone and estradiol levels on day +8, no significant differences were observed regarding these two parameters when compared with those pa-

tients who had stage I, II, or III disease. A decline in progesterone levels along with the progression of endometriosis was not observed.

Finally, histologic dating of endometrial tissues performed in 8 of the 24 patients who had endometriosis demonstrated that 7 of the 8 patients showed a luteal phase pattern, whereas only 1 patient was out of phase.

Comment

It has been noted that endometriosis is accompanied by mild ovarian dysfunctions such as anovulation[4] and hyperprolactinemia,[5] but luteal phase defects are said to be one of the most typical ovarian dysfunctions in patients who have endometriosis-associated infertility.[6]

Methods for the evaluation of the luteal function include use of a basal body temperature chart and endometrial biopsies. In the current study progesterone levels in patients who had endometriosis-associated infertility were compared with those of patients who had unexplained infertility without endometriosis, because all of the conflicting results in the literature[1, 2, 6] were in relation to progesterone function.

Hargrove and Abraham[7] reported for the first time that because of the low progesterone levels in infertile patients who have endometriosis during the mid luteal phase, abnormal luteal function is often observed in these patients. Moreover, Williams et al.[1] continuously measured the progesterone levels throughout the luteal phase and also pointed out that luteal phase defects often occur in these patients because progesterone levels are significantly lower during the early and mid luteal phases.

On the other hand, numerous reports state that luteal phase defects do not occur so frequently in infertile patients who have endometriosis. Radwanska and Dmowski[2] compared the mid luteal serum levels of progesterone and the preovulatory serum levels of estradiol in clinically ovulatory women and infertile patients who had endometriosis, and they observed no significant differences between the nonendometriosis and endometriosis groups regarding the levels of progesterone and estradiol. In light of these findings Randwanska and Dmowski[2] concluded that luteal deficiency is not more likely to occur in patients who have endometriosis and that luteal deficiency is not the direct cause of endometriosis-associated infertility. Furthermore, Pittaway et al.[8] evaluated the luteal function in endometrial biopsies and reported that the incidence of luteal phase defects was 5.3% in the nonendometriosis group and 8.8% in the endometriosis group, which demonstrates that no significant difference exists between these groups.

In the current study progesterone levels during the luteal phase were measured in patients who did and did not have endometriosis. The results contradicted the previous results reported by Cheesman et al.[6]; that is, the progesterone levels of the patients evaluated in this study were slightly lower during the early luteal phase (days +1 and +2) but were completely normal during the mid and late luteal phases. Besides, no correlation existed between the stage of endometriosis and progesterone levels.

Moreover, histologic dating of the endometrium during the mid luteal phase revealed that the endometrium was abnormally retarded in only one of eight patients (12.5%).

In short, although progesterone levels were low in the endometriosis group during the early luteal phase (days +1 and +2), they returned to normal soon afterward. Consequently, it would be difficult to regard luteal phase defects as the main cause of endometriosis-associated infertility.

The impact of endometriosis on the reproductive outcome of infertile patients

Masato Inoue, MD, DMSci, Yoshimune Kobayashi, MD, DMSci, Ikuko Honda, MD, Hideo Awaji, MD, and Akikazu Fujii, MD, DMSci

Kanagawa, Japan

OBJECTIVE: We examined whether the presence and severity of endometriosis affect the reproductive outcome of infertile patients.

STUDY DESIGN: The conception rates of 2080 infertile women, 1263 who had endometriosis and 817 who did not have endometriosis, were analyzed retrospectively by means of the χ^2 test. Depending on the stage of the disease patients who had endometriosis-associated infertility underwent expectant management, danazol therapy, or minor or major conservative surgery. The patients who failed to conceive after these conventional treatments were enrolled in the in vitro fertilization–embryo transfer program.

RESULTS: The conception rates were virtually identical regardless of the presence or absence of endometriosis (30.7% vs 30.0%). The outcome of in vitro fertilization–embryo transfer was not affected either by the presence or the severity of the disease.

CONCLUSION: Endometriosis had no impact on the reproductive outcome of infertile patients in this series unless the anatomy of the pelvic organs was heavily distorted, which can occur in the advanced stages of the disease. (Am J Obstet Gynecol 1992;167:278-82.)

Key words: Endometriosis, infertility, electrocoagulation, danazol, in vitro fertilization–embryo transfer

Minimal and mild endometriosis is frequently found in infertile women,[1] and a definite decrement of fertility has been reported even in patients who have minimal endometriosis.[2] Many possible causes have been proposed to explain the relationship between endometriosis and infertility.[3, 4] More recently, after the advent of in vitro fertilization–embryo transfer (IVF-ET), it has been implied that endometriosis affects the quality of oocytes; therefore the fertilization rates are low.[5] However, the exact mechanism by which minimal endometriosis interferes with fertility is still unknown.[3, 4]

Various types of therapy have been devised to treat endometriosis-associated infertility; these include expectant management,[1, 6] medical treatment,[7, 8] conservative surgery,[2, 9] and operative laparoscopy.[10, 11] Nevertheless, no medical or surgical therapy has been shown to be truly efficacious.[12]

It has recently been reported that the fertility rate is normal in women who have minimal endometriosis,[13] which casts doubt on the relationship between endometriosis and infertility.

In this study we analyzed our data retrospectively to determine whether the presence and severity of endometriosis affect the reproductive outcome of infertile patients. The cause-and-effect relationship between endometriosis and infertility is also discussed.

Material and methods

By the end of December 1988, 2080 women had undergone diagnostic laparoscopic examination at our hospital as part of an infertility evaluation. Their mean age was 32.3 years, and the mean infertility period was 6.0 years. Of the entire study population 1263 (60.7%) patients had endometriosis.

Endometriosis was confirmed by direct laparoscopic visualization or biopsy of lesions. The severity of disease was determined according to the American Fertility Society revised classification. The laparoscopic procedures usually included ascites aspiration from the pouch of Douglas, chromopertubation, and cervical dilation and curettage.

Treatment of stage I and II endometriosis. At first most patients (n = 359) who had stage I and II disease underwent expectant management of infertility for 1 year after laparoscopy. During this period all other major infertility factors were corrected if found. Those who did not conceive then started therapy with danazol (600 mg/day for 6 months) or were treated by laparoscopic electrocoagulation.

The policy was later changed, and patients (n = 442) who had minimal or mild disease were treated exclusively by electrocoagulation at the time of the initial

laparoscopy. A monopolar cautery was applied to the endometriotic implants until the lesions and the surrounding tissues blanched. Adhesions were lysed sharply with a monopolar needle-point cautery.

After electrocoagulation the pelvis was irrigated with saline solution. No complications during or after the operation were noted among these patients.

Treatment of stage III and IV endometriosis. At initial laparoscopic examination, ovarian endometriomas were aspirated and irrigated with saline solution. Adhesions around the ovaries and tubes, when found, were lysed sharply with monopolar microelectrodes. They then underwent expectant management for infertility for 4 to 6 months. The patients who did not conceive were prescribed danazol (600 mg/day) for 6 months and were followed up for at least 1 year. Recurrent endometriomas were managed laparoscopically or were aspirated through the vagina under ultrasonographic control. Major conservative surgery ($n = 41$) was performed only when other infertility factors, such as myomas or hydrosalpinx, were found.

Treatment of patients who did not have endometriosis. These patients were treated individually according to the infertility factors: tubal factors were corrected laparoscopically or by microsurgery, myomas were enucleated when indicated, and patients who had a normal pelvis were subjected to empiric treatment, such as ovarian stimulation with or without intrauterine insemination.

In vitro fertilization and embryo transfer. A total of 309 patients who had endometriosis and 392 patients who did not have endometriosis and who did not conceive after conventional treatments (expectant management, danazol, and electrocoagulation) were enrolled in the IVF-ET program. Their mean age was 34.9 years and 33.3 years, respectively, and the mean duration of infertility was 8.8 years and 8.5 years, respectively.

Ovarian stimulation was accomplished with a combination of clomiphene citrate and human menopausal gonadotropin or human menopausal gonadotropin alone, with or without gonadotropin-releasing hormone agonists.

The response to treatment was monitored by ultrasound studies together with the measurement of serum estradiol. Ovulation was triggered by the administration of 10,000 IU of human chorionic gonadotropin when at least two follicles greater than 17 mm in diameter were present and the serum estradiol level was between 200 and 300 pg/ml per mature follicle. Follicular aspiration by laparoscopy or transvaginal ultrasound guidance was performed 36 hours after human chorionic gonadotropin injection.

Semen was obtained by masturbation, and motile spermatozoa were prepared by the standard swim-up procedure. Oocytes were inseminated (1×10^5 motile sperm/ml) 4 to 8 hours after collection, pronuclei were identified 16 to 20 hours later, and ET was performed 24 to 72 hours after insemination. The media used were Ham-F10 or human tubal fluid supplemented with 7.5% (insemination medium) and 15% (growth medium) heat-inactivated human cord serum.

All patients who underwent ET received supplemental progesterone throughout the luteal phase. Pregnancy was diagnosed when a highly-sensitive pregnancy test (Testpack, Dainabot Co., Ltd., Tokyo,

Table III. Conception rates after expectant management of endometriosis

Stage II	166	36	21.7

Japan), which was performed 14 to 16 days after ET was positive. Statistical analysis of the data was performed with the χ^2 test.

Results

The mean age and mean infertility period of patients who had endometriosis (32.5 years and 6.0 years) and who did not have endometriosis (31.9 years and 6.0 years) were not statistically different. Interestingly, these two parameters were also almost identical when the patients were compared according to the stage of endometriosis.

By the end of August 1991, 633 patients (30.4%) had conceived after conventional therapy that included intrauterine insemination. The presence of endometriosis did not affect the conception rate of infertile patients (Table I). The conception rate slightly declined as the stage of the disease progressed (Table II). However, a statistically significant difference was observed only between stage I and stage IV ($p < 0.005$). A considerable number of patients who had stage IV endometriosis had undergone major conservative surgery before coming to our hospital, and laparoscopic examination revealed that many of them had severely distorted pelvic organs. Therefore the difference between stage I and stage IV in terms of conception rate should be interpreted with caution. To address the cause-and-effect relationship between endometriosis and infertility, expectant management and laparoscopic electrocoagulation were compared in stage I and stage II disease. A total of 241 stage I patients and 118 stage II patients underwent expectant management for at least 1 year after laparoscopy. The conception rates were almost satisfactory (Table III). Ninety-eight patients who did not conceive after expectant management received therapy with danazol (600 mg/day for 6 months). However, the results were very disappointing. Of 44 patients who had stage I disease, only 3 (6.8%) became pregnant, and none of 54 stage II patients conceived.

Unexpectedly, electrocoagulation did not increase the pregnancy rate. The patients whose endometrial implants were treated by electrocoagulation showed somewhat lower pregnancy rates compared with patients who underwent expectant management (Table IV). The results of IVF-ET are given in Tables V and VI. The number of oocytes that were retrieved and fertilized and the number of embryos transferred were almost the same, regardless of the presence or absence of endometriosis. Moreover, the presence of endometriosis did not affect the conception rate of the IVF-ET program.

The patients who had endometriosis had a somewhat higher pregnancy rate per ET compared with those who did not have endometriosis. Furthermore, the severity of the disease did not affect the pregnancy rate either per patient or per ET.

Comment

A strong association exists between infertility and endometriosis. In this study we found endometriosis in 60.7% of the infertile patients. Koninckx et al.[14] have also recently reported a 68% incidence of endometriosis in patients who underwent laparoscopy for infertility. Interestingly, the mean age of our patients and their mean infertility period were almost identical, regardless of the presence or absence of endometriosis or the stage of the disease. The natural history of endometriosis is poorly understood. Mild endometriosis can progress if left untreated.[15,16] It is also true, however, that endometriotic implants can either regress spontaneously or not progress when left untreated.[16] The present data support the previous observation that endometriosis may not always progress from stage I to stage II and eventually to stage IV.[16]

Patients who have minimal disease and those who have severe disease may represent two different spectrums of this disease, and different mechanisms may be involved in infertility, as suggested by Mahmood and Templeton.[16]

Endometriosis has been implicated as a cause of infertility. Acosta et al.[2] reported a definite reduction in fertility even in patients who had mild endometriosis. Several hypotheses have been proposed to explain the relationship between endometriosis and infertility; these include altered prostaglandin secretion and metabolism, increased macrophage activity, ovarian dysfunction, and aberrant immune response.[3,4] In recent years, however, doubt has been cast on the causal relationship between endometriosis and infertility. Rodriguez-Escudero et al.[13] have demonstrated that in patients who have minimal endometriosis the fertility and

Total	309	476	131	147	42.4	30.9

monthly fecundity rates are normal on the basis of their experience with artificial insemination by means of donor semen.

Indeed, endometriosis is not infrequent in fertile women. Moen[17] reported a group of 108 women who underwent laparoscopic sterilization; endometriosis was found in 18% of these patients. Liu and Hitchcock[18] noted a high incidence of endometriosis (43%) in a group of 75 patients who sought laparoscopic sterilization. Furthermore, expectant management or no treatment, interestingly enough, yields pregnancy rates that are similar to the outcome of medical or surgical intervention.[12, 19] Thus endometriosis of minimal or mild degree may be an incidental finding and of no importance in the pathogenesis of infertility.

The results of this study also question the cause-and-effect relationship between endometriosis and infertility. The presence of endometriosis did not affect the crude pregnancy rates of infertile patients. Moreover, no significant difference in pregnancy rates was found between those who underwent expectant management and those who underwent laparoscopic electrocoagulation; when the patients who had stage I and stage II disease were compared, elimination of endometrial implants did not result in an improvement of fecundity. The presence of endometriosis may be a marker of some other acquired or developmental pathologic state that may be the cause of infertility and that remains after the endometriosis is eradicated, as suggested by Redwine.[20]

The severity of endometriosis did not affect the reproductive success rate of infertile patients. No significant difference was found between patients who had stage I, stage II, and stage III disease when the crude pregnancy rates were compared.

A statistically significant difference in conception frequency was noted only between stage I and stage IV. However, it should be remembered that a considerable number of patients in stage IV had received major conservative surgery before they were referred to our hospital, and many of them revealed heavily distorted pelvic organs at laparoscopy; therefore, conventional treatments were ineffective for the treatment of fertility.

The predominant feature of stage III and stage IV disease was the presence of ovarian endometriomas, which were resistant to treatment and visualized by vaginal ultrasound scans in most patients even after pregnancy was established.

The advent of IVF-ET has provided a unique opportunity to assess the potential effect of endometriosis on oocyte quality or the implantation process. Earlier studies have shown that endometriosis affects the pregnancy rate of IVF-ET programs.[5, 21-23]

Wardle et al.[5] have reported that mild or moderate endometriosis affects the fertilization rate by reducing the quality of oocytes compared with that of women who have tubal disease only. Others have shown that the fecundity rate per cycle in women who had stage I and stage II endometriosis was similar to that of the group with tubal factors, but it was significantly reduced in women who had stage IV disease.[21, 22] A reduced number of recovered oocytes and a decreased implantation rate per embryo transferred might be responsible for the reduced pregnancy rate in patients who have severe endometriosis after IVF-ET, which sug-

gests the presence of an implantation inhibitory factor in these patients.[23]

More recently, however, Garcia et al.[24] and Gerday et al.[25] have reported that severity of endometriosis does not impair the follicular recruitment parameters, the oocyte fertilizing ability, or the pregnancy rate. Our results support these recent observations. The presence of endometriosis did not affect the pregnancy rate after IVF-ET, and the severity of the disease did not affect the pregnancy rate either per patient or per embryo transfer.

It appears unlikely that endometriosis affects the quality of oocytes or impairs embryo implantation. The patients who had endometriosis and did not conceive after conventional therapy should be treated by IVF-ET irrespective of the stage of the disease.

In conclusion, the reproductive outcome of infertile patients was not significantly affected either by the presence of endometriosis or by the stage of the disease unless the pelvic organs were heavily distorted because of previous conservative surgery. Furthermore, neither the presence nor the severity of the disease affected the outcome of IVF-ET.

These results cast serious doubt on a cause-and-effect relationship between endometriosis and infertility. Endometriosis may be an incidental finding and of no importance in the pathogenesis of infertility except for the terminal stage, in which the anatomy of pelvic organs is heavily distorted.

Mechanisms involved in the pituitary desensitization induced by gonadotropin-releasing hormone agonists

Tsuguo Uemura, MD, PhD, Takashi Yanagisawa, MD, Kazuhiro Shirasu, MD, Akemi Matsuyama, MD, PhD, and Hiroshi Minaguchi, MD, PhD
Yokohama, Japan

OBJECTIVE: We investigated the mechanisms of desensitization induced by gonadotropin-releasing hormone agonist in the pituitary.
STUDY DESIGN: Effects of gonadotropin-releasing hormone agonist on the pituitary were studied in vitro and in vivo in the rat. In the clinical study serum luteinizing hormone was measured by radioimmunoassay with a polyclonal luteinizing hormone antibody (luteinizing hormone-radioimmunoassay) and by immunoradiometric assay with monoclonal luteinizing hormone antibodies (luteinizing hormone-immunoradiometric assay) during gonadotropin-releasing hormone agonist treatment.
RESULTS: In the in vitro study bead-attached pituitary cells that were desensitized with a continuous infusion of 10^{-7}mol/L gonadotropin-releasing hormone responded to 50 mmol/L K^+. In the in vivo study gonadotropin-releasing hormone binding sites and rat luteinizing hormone β–messenger ribonucleic acid in the pituitary decreased during gonadotropin-releasing hormone agonist treatment, but serum levels of rat luteinizing hormone did not decrease. In addition, a disparity between luteinizing hormone-radioimmunoassay and luteinizing hormone-immunoradiometric assay was demonstrated during gonadotropin-releasing hormone agonist treatment.
CONCLUSION: Pituitary desensitization in response to gonadotropin-releasing hormone agonist may not be wholly receptor mediated and a nonreceptor process may be involved. (Am J Obstet Gynecol 1992;167:283-91.)

Key words: Pituitary desensitization, gonadotropin-releasing hormone agonist, luteinizing hormone, luteinizing hormone β–messenger ribonucleic acid, gonadotropin-releasing hormone receptor

Gonadotropin-releasing hormone agonists (GnRHa) have proved useful for the treatment of endometriosis because GnRHa affect only specific organs and induce hypogonadotropic hypoestrogenism (desensitization), which renders the endometrial implant atrophic. However, the mechanisms involved in the desensitization of the pituitary are still poorly understood.

To investigate these mechanisms, we administered GnRH agonist to rats and humans for more than 4 weeks. We then measured the concentrations of serum rat luteinizing hormone (LH) and pituitary rat LH, the response of serum rat LH to GnRH, and GnRH-binding sites and gene expression of rat LH β in the pituitary in the rat. In humans who were undergoing GnRH agonist treatment, we investigated the concentration of serum LH determined by a polyclonal antibody and by monoclonal antibodies. We also examined rat pituitary cells in vitro.

Material and methods

Desensitization of pituitary cells in vitro. Pituitary cells obtained from Wistar male rats were dispersed in HEPES dissociating buffer (137 mmol/L sodium chloride, 5 mmol/L potassium chloride, 0.7 mmol/L disodium acid phosphate, and 25 mmol/L HEPES, pH 7.3) with the use of 0.4% of collagenase type II and 10 μg/ml deoxyribonuclease II (Sigma Chemical Co., St. Louis, Mo.). The final cell suspension (approximately 10^6 cells/ml) was cultured with swollen and autoclaved Cytodex beads (Pharmacia Biosystems, Piscataway, N.J.) at a concentration of 0.1 ml beads/ml of cell suspension as described by Smith and Vale.[1] The bead-attached cells were packed into mini-columns (0.6 × 10 cm, Bio-Rad Laboratories, Richmond, Calif.) and superfused at a constant flow rate (0.13 ml/min). The cells were first superfused with GnRH and then with the test substances; effluent fractions were collected at 6-minute intervals and stored at −20° C until assayed.

Study of rats in vivo

Animals and sample collection. Immature Sprague-Dawley female rats (21 days of age) were administered a sustained-release formulation of GnRH agonist (TAP-144-SR; D-Leu^6-[des-Gly^{10}-NH_2] GnRH-EA, Takeda

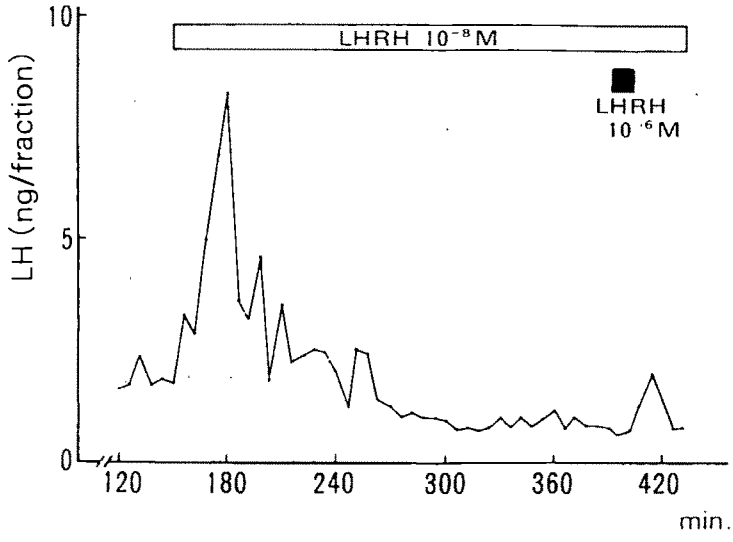

Fig. 1. Rat LH responses of bead-attached pituitary cells to 10^{-6} mol/L GnRH after continuous infusion of 10^{-8} mol/L GnRH.

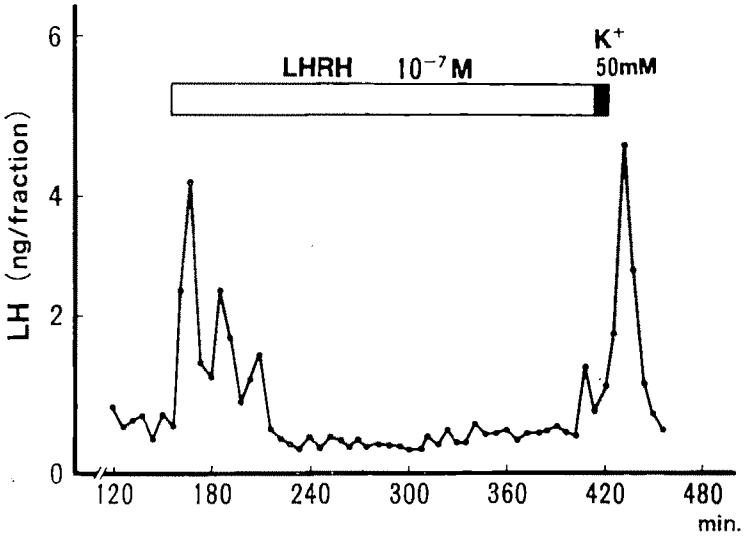

Fig. 2. Rat LH responses of bead-attached pituitary cells to 50 mmol/L K^+ after continuous infusion of 10^{-7} mol/L GnRH.

Chemical Industries, Ltd., Osaka, Japan) subcutaneously at a dose of 0.94 mg per rat every 4 weeks and were killed by decapitation at various time intervals after GnRH agonist injection. The pituitaries were harvested under sterile conditions and stored at −70° C until subsequent analysis. Trunk blood was collected and stored at −20° C until assayed.

To monitor the pituitary response to GnRH blood samples were obtained by heart puncture under light ether anesthesia before and 30 minutes after a subcutaneous injection of 1 μg of a native GnRH (Lutamin, Daiichi Medical Co., Ltd., Tokyo, Japan) on days 0, 7, 14, 21, and 28.

GnRH receptor assay. With use of a GnRH agonist (buserelin; [D-Ser (tBu^6) des-gly-NH_2^{10}] GnRH-ethlamide, Hoechst Japan Co., Ltd., Tokyo, Japan) as a ligand, the binding capacity of the rat pituitary was examined as described previously.[2]

Assay of rat LH β-messenger ribonucleic acid. The preparation of rat pituitary messenger ribonucleic acid (mRNA) for assay by dot blot hybridization was performed as described by Abbot et al.[3] Briefly, the pitui-

taries were homogenized in 200 μl of homogenization buffer and centrifuged at 15,000*g*. Proteins in the supernatant were denatured, extracted with phenol, and reextracted with chloroform. The RNA was precipitated overnight with ethanol and 3 mol/L sodium acetate at −70° C. The RNA was recovered by centrifugation at 15,000*g* for 30 minutes and dissolved in sterile distilled water.

A synthetic labeled oligodeoxynucleotide was produced as described by Gharib et al.[4] RNA samples of 5 μg each were applied to a gene hybridization membrane, which was baked at 80° C for 2 hours before prehybridization. The baked membrane was incubated at 65° C for 4 hours with 5 ml of prehybridization buffer before incubation with 50 to 100 ng of (phosphorus 32) complementary deoxyribonucleic acid for 3 hours at 60° C. After hybridization excess unbound (phosphorus 32) complementary deoxyribonucleic acid was removed by sequential washing with constant agitation in buffer. After washing, the membrane was dried, placed in contact with an X-ray film and autoradiographed for 16 to 24 hours at −70° C. The mRNA

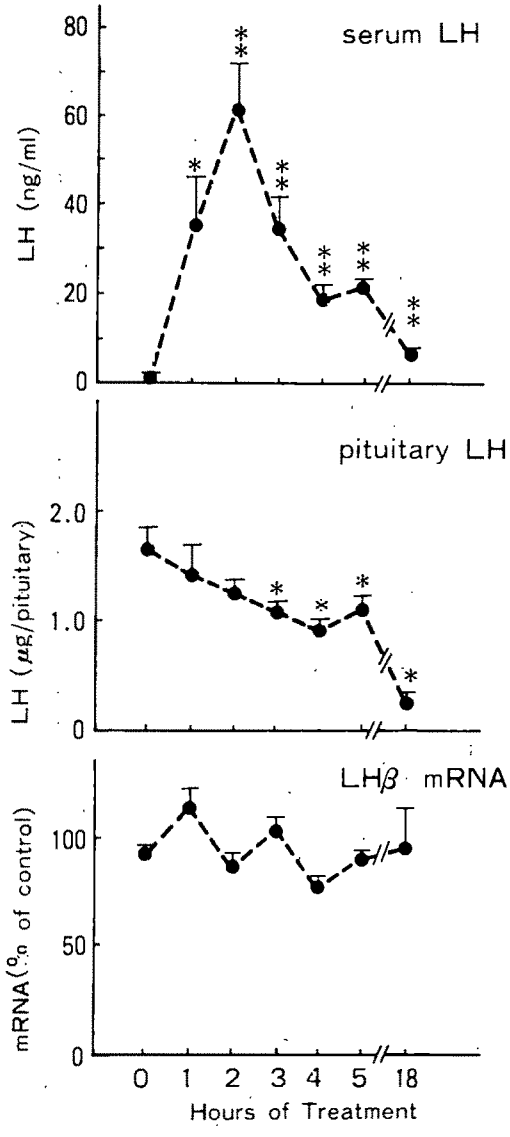

Fig. 5. Serum rat LH (mean ± SE, $n = 5$), pituitary rat LH content ($n = 5$) and rat LH β-mRNA ($n = 3$ to 4) from 0 to 18 hours after GnRH agonist treatment. Levels of rat LH β-mRNA are expressed as a percentage of the control. $*p < 0.05$, $**p < 0.01$ compared with the control value (hour 0).

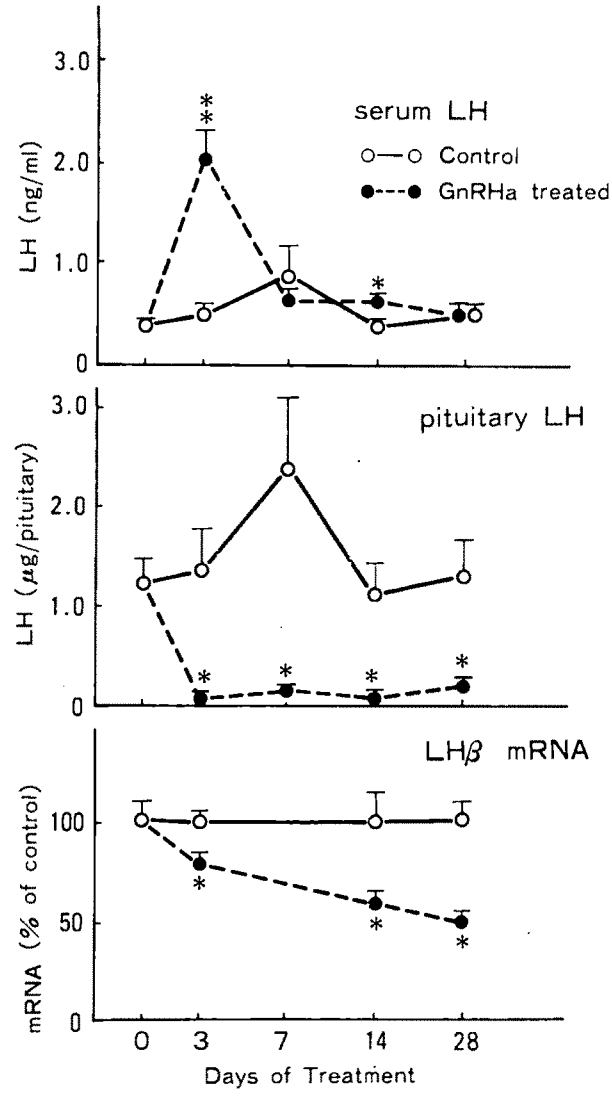

Fig. 6. Serum rat LH (mean ± SE, $n = 5$), pituitary rat LH content ($n = 5$), and rat LH β-mRNA ($n = 5$) from 0 to 28 hours after GnRH agonist treatment. The levels of rat LH β-mRNA are expressed as a percentage of the controls. $*p < 0.05$, $**p < 0.01$ compared with controls.

content of each dot was determined by densitometry of autoradiograms with a densitometer (Ultrascan XL, Pharmacia LKB Nuclear, Gaithersburg, M.D.).

Clinical study. A GnRH agonist (nafarelin; [D-Ala-3(2-naphtyl)^6] GnRH, Nippon Syntex KK, Tokyo, Japan) was administered intranasally at a dose of 400 μg/day for 3 weeks to eight patients who had polycystic ovarian disease and seven infertile patients. Another GnRH agonist (TAP-144-SR) was administered subcutaneously at a dose of 3.8 mg per 4 weeks for 24 weeks to 16 eumenorrheic patients who had endometriosis. Blood samples were obtained twice a week, either every week or every 2 weeks. Serum levels of LH were examined by radioimmunoassay (RIA) with a polyclonal antibody and by immunoradiometric assay (IRMA) with monoclonal antibodies.

Hormone assays and statistical analyses. Serum and pituitary homogenates were assayed for rat LH by a double-antibody RIA technique with rat hormone kits supplied by the National Pituitary Agency (NIDDK, USA), and rat LH concentrations were expressed in NIH-LH-SI. "Daiichi" LH-kit (Daiichi Isotope Inc., Tokyo, Japan) was used for RIA with a polyclonal LH antibody and World Health Organization second immunoreactive plasma–human menopausal gonadotropin as the standard preparation. A "Spac-S LH-kit"

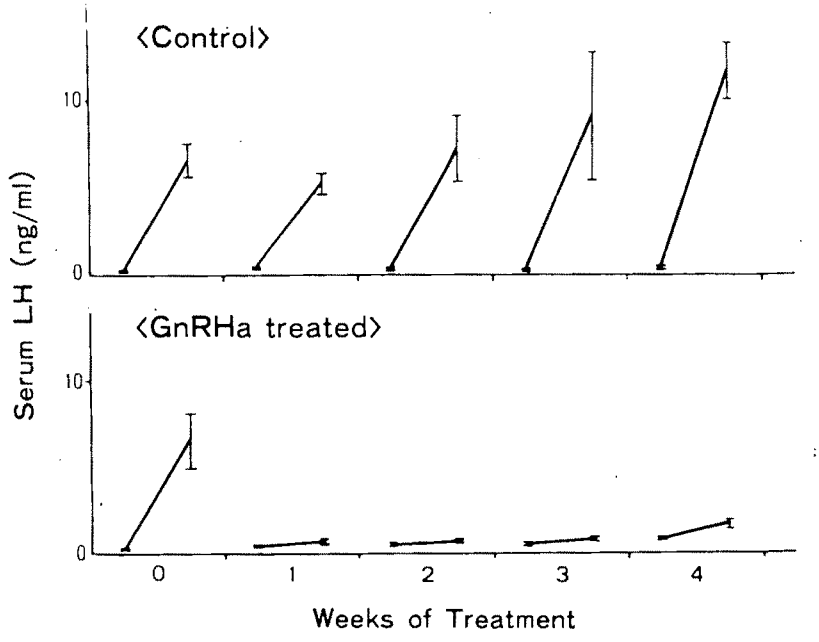

Fig. 7. Serum rat LH before and 30 minutes after native GnRH (1 μg/rat, subcutaneous) administration 0 to 4 weeks after GnRH agonist treatment in intact immature female rats *(upper panel)* and in GnRH agonist–treated immature female rats *(lower panel)* (mean ± SE, $n = 5$).

(Daiichi Isotope Inc.) was used for IRMA with monoclonal LH antibodies and World Health Organization first immunoreactive plasma–LH as the standard preparation. For follicle-stimulating hormone (FSH) determinations we used the FSH kit "Daiichi" for RIA with a polyclonal antibody, World Health Organization second immunoreactive plasma–human menopausal gonadotropin and "Spac-s FSH-kit" for IRMA with monoclonal antibodies, and World Health Organization second immunoreactive plasma–human pituitary gonadotropin. Data were subjected to a one-way analysis of variance followed by the Student t test.

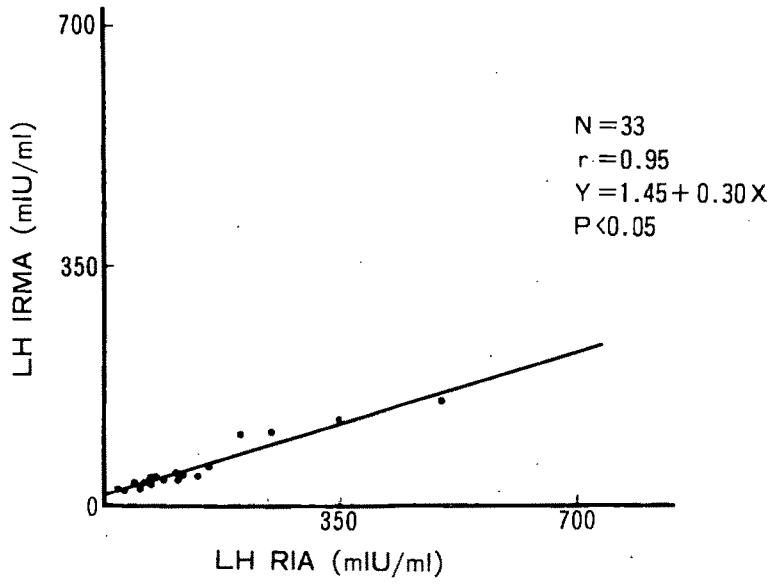

Fig. 9. Correlation between LH values determined by RIA (LH-RIA) and IRMA (LH-IRMA).

Results

Desensitization of pituitary cells in vitro. Pulsatile infusion of 10^{-9} mmol/L GnRH induced pulsatile secretion of rat LH, but continuous infusion of 10^{-8} mmol/L GnRH or 10^{-7} mmol/L GnRH induced a rapid and transit increase of rat LH; thereafter the levels of rat LH decreased to the pretreatment level within 3 to 4 hours (desensitization). The desensitization was also observed when the pulse amplitude of GnRH was more than 10^{-7} mol/L GnRH or when the pulse frequency was more than four times per hour. Even after this continuous infusion of 10^{-8} mol/L or 10^{-7} mol/L GnRH, the pituitary cells responded to 10^{-6} mol/L GnRH, 50 mmol/L K^+, and 3 mmol/L 8-bromo-cyclic adenosine monophosphate (Figs. 1 to 3).

Study in rats in vivo. During the treatment of GnRH agonist (0.94 mg/rat) the ovarian weight was 17.1 ± 1.7 mg per ovary (mean ± SE) on day 0 and 18.3 ± 0.8 mg on day 3. Thereafter the weights decreased significantly to 15.2 ± 0.9 mg (control, 22.9 ± 2.3; $p < 0.05$) on day 7 and 9.2 ± 1.7 mg (33.2 ± 5.8; $p < 0.01$) on day 28 (Fig. 4).

The serum concentration of rat LH increased after hour 1 of treatment ($p < 0.05$) and continued to rise until hour 2 ($p < 0.01$). Thereafter the levels decreased gradually but were higher than those measured in the intact control animals on day 3 ($p < 0.01$). On day 28 the concentrations had returned to the control levels. Serum rat FSH was also the same level as the control (Figs. 5 and 6).

Serum rat LH response to GnRH (1 μg) in GnRH agonist–treated rats decreased significantly ($p < 0.05$) on day 7 compared with the control group, and this blunted response remained unchanged up to week 4 after GnRH agonist administration (Fig. 7).

The pituitary rat LH content decreased gradually after GnRH agonist administration. Three hours after treatment the rat LH content was significantly lower than the basal level; it continued to drop slowly until day 3 and then remained unchanged up to day 28 (Figs. 5 and 6).

GnRH receptors in the pituitary markedly decreased to 17.3 ± 2.6 fmol/mg protein (mean ± SE) compared with the control group (123.2 ± 0.8; $p < 0.01$) on day 7 and remained at low levels (Fig. 8).

The rat LH β-mRNA concentrations in the GnRH agonist–treated group were not significantly different from those in the control group from 1 to 18 hours after GnRH agonist administration, but the mRNA concentrations in the GnRH agonist–treated animals from day 3 to day 28 ($p < 0.05$) were lower than those in the control group ($p < 0.05$) (Figs. 5 and 6).

Clinical study

GnRH agonist (nafarelin) administration to eight patients who had polycystic ovarian disease and seven infertile patients. LH values determined by IRMA (LH-IRMA; Y) and those determined by RIA (LH-RIA; X) correlated significantly ($r = 0.9472$; $p < 0.01$) except for LH values during nafarelin treatment ($Y = 1.45 + 0.3X$) (Fig. 9). Nafarelin decreased LH-IRMA significantly from day 7 to day 21 ($p < 0.01$), but it did not decrease LH-RIA. Therefore the ratio LH-RIA to LH-IRMA (LH-RIA/LH-IRMA) increased significantly from 8.4 ± 1.5 to 17.4 ± 2.3 ($p < 0.05$) at week 3 of nafarelin treatment (Fig. 10).

The mean value of serum estradiol decreased from

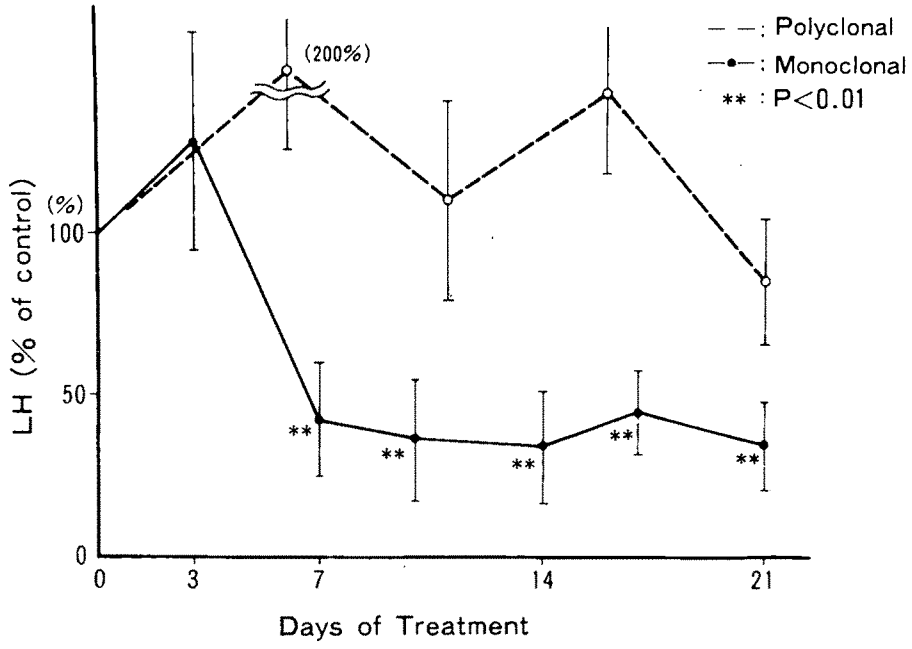

Fig. 10. Changes in LH-RIA, LH-IRMA, and estradiol in blood during treatment with GnRH agonist (nafarelin, 400 μg/day) for 3 weeks (mean ± SE, $n = 15$).

44.1 ± 5.9 pg/ml to 16.3 ± 2.9 pg/ml after treatment; this change was consistent with that of LH-IRMA but not with that of LH-RIA.

GnRH agonist (TAP-144-SR) treatment for patients who had endometriosis. The mean LH-RIA was 20.1 ± 2.6 mIU/ml ($n = 16$) before treatment and did not decrease significantly at week 2 (21.3 ± 1.9), week 4 (16.4 ± 0.6), week 16 (14.3 ± 2.1), or week 20 (15.8 ± 1.8) of treatment. On the other hand, LH-IRMA was 6.5 ± 1.3 mIU/ml before treatment and decreased dramatically from week 2 (3.3 ± 0.5; $p < 0.05$) to week 24 (0.5 ± 0.01; $p < 0.001$) of treatment.

FSH-IRMA also decreased more than FSH-RIA, and the estradiol levels reflected the changes of LH-IRMA and FSH-IRMA more than those of LH-RIA and FSH-RIA (Fig. 11).

Comment

Treatment with GnRH agonist (0.94/mg/rat/28 days) did not decrease serum concentrations of rat LH, but it inhibited rat LH responses to GnRH agonist starting on day 7 and decreased ovarian weights significantly from day 7 to day 28. Moreover, we have observed that these dosages of GnRH agonist delayed vaginal opening in immature female rats (unpublished data). These findings indicate that the dosage of GnRH agonist used in this study was large enough to induce pituitary desensitization within 7 days.

After treatment with GnRH agonist, the GnRH agonist binding sites decreased significantly compared with those of controls. In the in vitro study desensitized gonadotropes responded to potassium, a high dose of GnRH, and a cyclic adenosine monophosphate derivative, 8-bromo-cyclic adenosine monophosphate, which could clearly induce rat LH secretion in nontreated pituitary cells.[1] These results suggest that the content of pituitary rat LH was not exhausted and that desensitization was mainly caused by an alteration at the receptor level.

The mRNA of the rat LH β-subunit appears to be an important rate-limiting factor in the synthesis of mature gonadotropin; therefore the changes in rat LH β-mRNA were examined during the down-regulatory phase of GnRH agonist treatment. This study showed that reduced availability of rat LH β-mRNA was an important factor that contributed to the depletion of rat LH content in the pituitary from GnRH-desensitized rats, although rat LH β gene expression was not involved in the marked reduction in pituitary content during the early stage of GnRH agonist treatment.

In the clinical study different groups were given different types of agonists; therefore comparison between patient groups is not appropriate. The differences between continuous and subcutaneous administration versus intermittent intranasal administration are important, because continuous administration of GnRH agonist has been shown to result in greater inhibition of LH secretion than intermittent administration.[5] Moreover, the dosage of GnRH agonist (TAP-144-SR

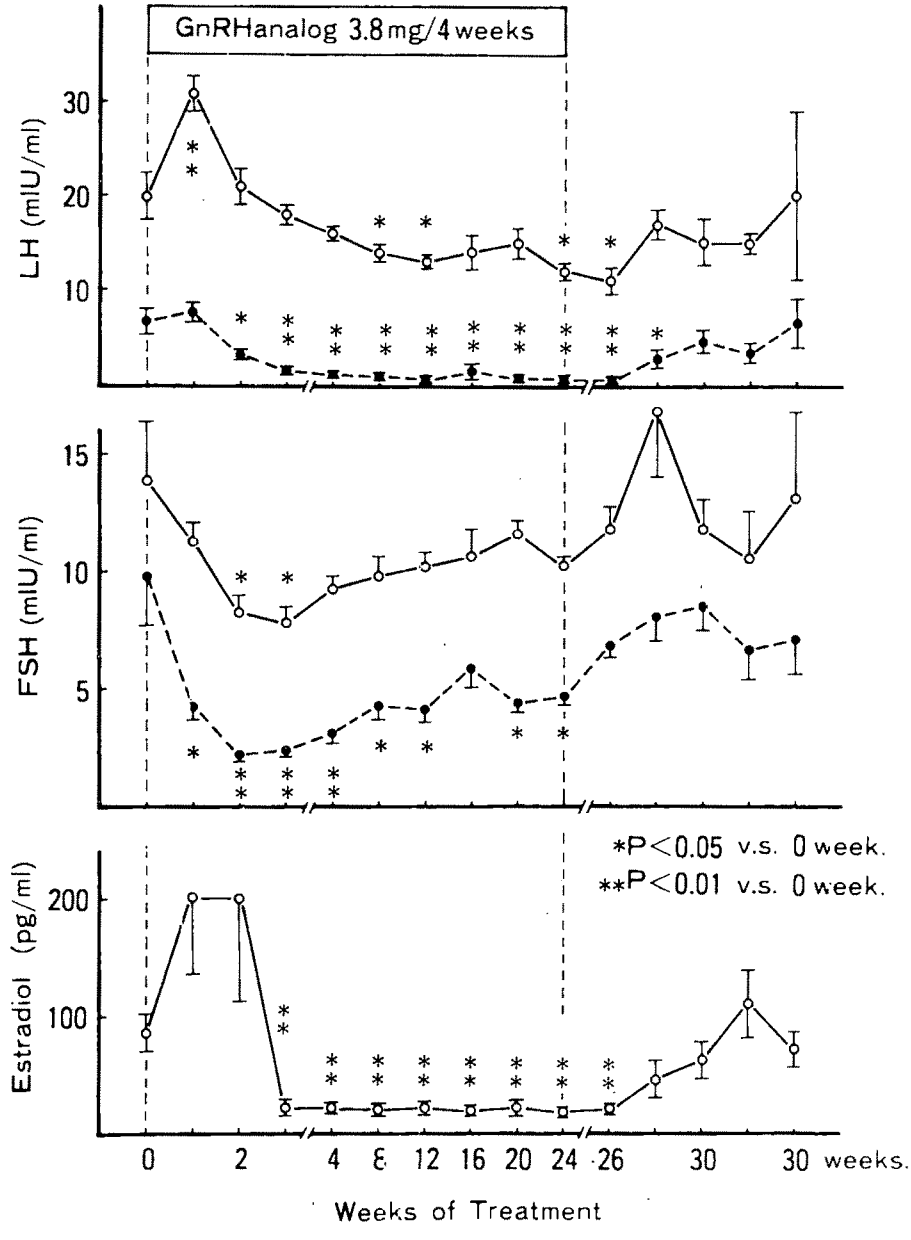

Fig. 11. Changes in LH-RIA, LH-IRMA, FSH-RIA, FSH-IRMA, and estradiol in blood during treatment with GnRH agonist (TAP-144-SR 3.8 mg/4 wk, subcutaneous) for 24 weeks (mean ± SE, $n = 16$).

3.8 mg/4 wk, subcutaneous) was larger than that of GnRH agonist (nafarelin 400 μg/day, intranasal), because the absorption rate of intranasal administration is about 1% to 10%.[6] Therefore TAP-144-SR suppressed LH-RIA and LH-IRMA more than nafarelin.

In this study a disparity between LH-RIA and LH-IRMA in the process of gonadotrope desensitization to GnRH was demonstrated; that is, the levels of LH-RIA did not change markedly, but LH-IRMA decreased dramatically during treatment with GnRH agonist. The changes in LH-IRMA were consistent with those of serum estradiol. The mechanisms involved in this disparity after GnRH agonist treatment are uncertain, but increases of immunoreactive molecules such as α-subunit and LH fragments might be related. These findings are consistent with the data presented in previous reports, that is, that unchanged immunoreactivity of serum LH after GnRH agonist treatment is partially caused by the cross-reactivity of free α in the LH-RIA[7] and that common α-subunit gene expression is sustained in the presence of a pharmacologic concentration of GnRH agonist.[8]

In the desensitized pituitary FSH-IRMA was also significantly suppressed from week 1 to week 24 and correlated well with estradiol levels; however, FSH-RIA suppression was significant only at weeks 2 and 3. It

was reported that rat FSH β-mRNA levels were markedly reduced when gonadotropes were desensitized by GnRH agonist and that the effects of GnRH agonist on FSH β-nRNA levels were paralleled by its effects on LH β-mRNA levels.[9] These data also suggested increases of immunoreactive molecules such as α-subunit and FSH fragments.

These data suggested involvement of a postreceptor mechanism or non-GnRH receptor–mediated mechanisms, in addition to a receptor mechanism in desensitization, although chemical characterization should be investigated to elucidate the molecular heterogeneity observed during GnRH agonist treatment.

We gratefully acknowledge receipt of the rat LH kits from the National Hormone and Pituitary Program, NIDDK. GnRH analogs TAP-144-SR, buserelin, and nafarelin were kindly provided by Takeda Chemical Industries, Ltd., Hoechst Japan Co., Ltd., and Nippon Syntex KK.

LETTERS TO THE EDITORS

Myocardial necrosis in a newborn after long-term maternal subcutaneous terbutaline for suppression of premature labor

To the Editors: We read with interest the report by Fletcher et al. (Fletcher SE, Fyfe DA, Case CL, Wiles HB, Upshur JK, Newman RB. Myocardial necrosis in a newborn after long-term maternal subcutaneous terbutaline infusion for suppression of preterm labor. AM J OBSTET GYNECOL 1991;165:1401-4) detailing a case of neonatal myocardial necrosis possibly caused by prolonged subcutaneous terbutaline tocolysis. Unfortunately, the case as presented lacks a number of cogent facts that may have had an impact on the occurrence of fetal adverse events. For instance, during the subcutaneous therapy how rapid was the fetal heart rate (as a possible indication of fetal drug level)? How frequent were uterine contractions during the reported 12-week time period (recognizing the importance of repetitive obstruction of the uterine circulation on the fetus, compression of the umbilical cord, or both)? What was the status of the patient's diabetes during this interval (realizing the effect hyperglycemia, ketosis, or both, may have on the fetal myocardium)? And finally, what transpired at delivery (e.g., length of labor, route of delivery, Apgar scores, cord pH)? We would find it extremely difficult to evaluate adequately any event in the neonatal course with the paucity of antenatal and intrapartum data given in the article.

However, even more alarming than the lack of information was the astoundingly high dosage of terbutaline used both initially and during the last 2 weeks of gestation. The usual initial dose of terbutaline given subcutaneously via infusion pump is a basal rate of 0.050 mg per hour.[1] Even when it is taken into consideration that the bioavailability of terbutaline given subcutaneously is in excess of 90% (compared with oral drug), the 0.50 mg per hour reported by the authors is literally an overdosage by a factor of 10. Added to this are bolus doses of 0.3 mg per hour, resulting in a total dose of 0.80 mg per hour. This yields a total daily dose of 19.2 mg per day for the last 2 weeks of pregnancy. This approaches the oral dosages used by some authors; these oral dosages can be clinically ineffective after short intervals (not to mention the differences in bioavailability).[2] Because it is well known that any adverse cardiac effects of β-sympathomimetic drugs are in part related to total dosage, it would be no surprise if the mother or the infant were to have some ill effects of this clearly excessive level of terbutaline.

In conclusion, we reiterate that the report by Fletcher et al. is, first, difficult to analyze conclusively given the lack of appropriate obstetric information. Second, because the usual total daily dose of subcutaneous terbutaline for tocolysis (including both basal rate and bolus dosages) is on the order of 3.0 to 5.0 mg per day, it is not surprising that a triple or quadruple overdose would have resulted in an adverse event for either mother or baby. This result should not negatively influence obstetricians planning to use subcutaneous terbutaline in appropriate doses for long-term tocolysis.

Reply

To the Editors: We thank Bey et al. for their comments. They have raised some interesting points regarding parts of the obstetric history that were omitted in our manuscript because of editorial limitations. The patient's antepartum records indicated that she began receiving subcutaneous terbutaline pump therapy at approximately 24 weeks' gestation and continued through 36 weeks' gestation. The subcutaneous terbutaline infusion pump was discontinued at approximately 36 weeks because of significant maternal side effects, including jitteriness and tachycardia. Fetal tachycardia was not identified during the antepartum period, with the fetal heart rate recorded as being within normal limits at each antepartum visit. Unfortunately the data on the frequency of uterine contractions recorded by the home uterine activity monitoring device during the 12 weeks of subcutaneous therapy are not available to us. However, the antepartum record indicates that the patient's uterine contractions exceeded protocol limits on a daily basis. Antepartum uterine activity monitoring performed in the obstetrician's office revealed "strings of contractions."

The patient also had diet-controlled gestational diabetes. The results of a glucola screen were 145 mg/dl. This test was followed by a standard oral 3-hour glucose tolerance test that revealed abnormal values at 2 and 3 hours. The patient given a 2000-calorie American Dietetic Association diet and follow-up fasting; 2-hour postprandial blood glucose levels were <100 mg/dl. The patient was admitted at 37 weeks' gestation in latent phase labor with the cervix dilated to 3 cm. After several hours without cervical change, oxytocin augmentation was begun. Labor progressed over the ensuing 8 hours resulting in delivery of a normal spontaneous vaginal delivery of a 6 lb. 11 oz. infant with Apgar scores of 9 and 9 at 5 and 10 minutes. Neither umbilical artery nor umbilical vein cord gases were obtained. The fetal heart rate monitoring was reported as being normal throughout labor, and the only analgesia used was a combination of propiomazine hydro-

chloride (Largon) and nalbuphine hydrochloride (Nubane) during the active phase of labor.

We agree with Bey et al. that the dosages of terbutaline used both initially and during the last 2 weeks of gestation, when the patient complained of increased heart rate, palpitations, tremulousness, and anxiety, were in excess of those dosages commonly used with subcutaneous terbutaline pump therapy. The concerns of Bey et al. that the ill effects suffered by this infant may be attributable to this excessive level of terbutaline is obviously well taken.

The purpose of our article was to report the occurrence of myocardial necrosis that we *speculate* was caused by the subcutaneous terbutaline tocolytic infusion. The obstetric literature has reported success with this type of therapy, and the importance of avoiding premature delivery of infants is obvious. As with any medication or intervention, the risk/benefit ratio should always be considered when prescribing. We hope that this case report will stimulate other obstetricians and pediatricians to report similar occurrences and to initiate scientific investigations as to the effect of continuous subcutaneous terbutaline infusion on fetal and neonatal cardiovascular performance.

Fetal choroid plexus cysts and trisomy 18

To the Editors: In their article Platt et al. (Platt LD, Carlson DE, Medearis AL, Walla CA. Fetal choroid plexus cysts in the second trimester of pregnancy: a cause for concern. Am J Obstet Gynecol 1991;164:1652-6) argue that it is reasonable to offer amniocentesis to all patients who have ultrasonographically identified choroid plexus cysts in the second trimester. This view is supported by the available prospective literature. Nine prospective studies (including that of Platt et al.) provide data sufficient to calculate predictive values.[1-8] A total of 35,668 patients have been screened in the second trimester, with 324 fetuses having choroid plexus cysts (prevalence 0.9%). Excluding the other chromosomal aneuploidies identified, 11 (3.4%) of the 324 fetuses with choroid plexus cysts had trisomy 18. If 70% of these fetuses had ultrasonographically identified anomalies that characterized them as being at increased risk for trisomy 18,[9] then 3 (0.9%) of 324 would have choroid plexus cysts as the only ultrasonographically detected abnormality (predictive value 1 in 108). This number lies within current thresholds for amniocentesis and also corresponds closely to theoretical projections based on a sensitivity of 30%, a specificity of 99.1%, and a prevalence of 1 in 1000 for second-trimester trisomy 18.[10] The theoretic predictive value of 3.2% is independent of associated anomalies.

Reply

To the Editors: Bernstein has nicely reviewed the prospective literature with regard to the identification of a choroid plexus cyst as an indication for amniocentesis. I concur that the main purpose of our article was to emphasize that in spite of sophisticated ultrasonography, not all malformations will be detected. Although Bernstein's review does not include this premise, the data he presents further emphasize the correlation of aneuploidy with choroid plexus cysts even in the absence of identifiable malformations. I believe that his comments and our article continue to support offering amniocentesis to these patients in spite of the apparent risk of this procedure. I thank Bernstein for his timely comments.

Laser therapy for intraepithelial cancer of the vagina

To the Editors: We were most interested in the article by Hoffman et al. (Hoffman MS, Roberts WS, LaPolla JP, Fiorica JV, Cavanagh D. Laser vaporization of grade 3 vaginal intraepithelial neoplasia. Am J Obstet Gynecol 1991;165:1342-4) because we recently published an article on the same subject.[1]

The conclusions of Hoffman et al. are the complete opposite of ours. We do agree with Hoffman et al. that careful evaluation and an accurate appraisal of the ex-

tent and severity of the disease should be made before laser therapy and that every mode available for evaluation and appraisal should be used. Multiple selected biopsies are most important to rule out the possibility of underlying invasive disease.

However, we believe that once invasive disease has been ruled out a laser ablation of the affected area and its immediate surrounding tissue is the best way to eliminate preinvasive disease and give the patient the best result with the least degree of morbidity and complications and with improved subsequent sexual function. Some authors[1] who have dealt with this problem cite the difficulty of the technical ability to eradicate adequately those pits and deep scars that may occur in the vault of the vagina and in the corner recesses. We believe our technique allows us to apply the laser therapy accurately and adequately to accomplish the result. The use of appropriately placed wire sutures allows better visualization and accessibility of the laser beam to the tissue. In addition, the use of submucosal infiltration allowed us to accomplish our published results. Since the publication of our article our continued successful results have convinced us of the appropriateness of the procedure with the guidelines suggested. Furthermore, we are sorry that Hoffman et al. did not find it convenient to include our article in their list of references.

Reply

To the Editors: I indeed overlooked Sherman's article, and I apologize to him for this. I have now reviewed his article and find that it contains a large series of patients who were successfully treated by laser vaporization.[1] The successful treatment in his study was attributed to patient selection, infiltration of fluid into the submucosa, and the use of wire sutures for exposing scarred and recessed areas. We have also used submucosal infiltration in some patients and have found it helpful for hemostasis, but we have not used it in the manner described by Sherman. We and others have also used skin hooks in a manner probably similar to the wire sutures to gain exposure to recessed areas. We find the techniques described by Sherman to be interesting and will certainly consider using them in the future. Our findings and conclusions on the basis of our experience with grade 3 vaginal intraepithelial neoplasia are quite different from those of Sherman's, and there may be reasons for these differences besides technique. Although all of our patients had grade 3 intraepithelial neoplasia, it is unclear whether this was the case in Sherman's paper. Our study was much smaller than Sherman's and it would not be appropriate to make a more in-depth comparison between the two studies. We, however, are particularly concerned about the use of laser vaporization for grade 3 vaginal intraepithelial neoplasia diagnosed at or near a vaginal cuff scar, particularly when there is marked distortion around this area or when the previous hysterectomy had been done for squamous cell neoplasia. In our limited experience with such patients we have seen a high rate both of recurrence and of occult invasive carcinoma.[1-3]

Initiation of antepartum testing in the hypertensive gravid woman

To the Editors: We read with interest the article by Pircon et al. (Pircon RA, Lagrew DC, Towers CV, Dorchester WL, Gocke SE, Freeman RK. Antepartum testing in the hypertensive patient: when to begin. Am J Obstet Gynecol 1991;164:1563-70). We are concerned that their conclusions are not substantiated by the data as presented. The stated purpose of their investigation was to determine the gestational age at which antepartum testing should begin in various subgroups of hypertensive gravida women. However, the data do not tell the reader how many or with what frequency antepartum tests were done at various gestational ages.

We are concerned that the study analyzed the data as the percentage of abnormal antepartum tests *per number of patients*. To determine the sensitivity and specificity of any test, the results must be analyzed as the percentage of abnormal tests *per number of tests performed* at a given gestational age. Only in this way can meaningful conclusions be drawn regarding the differential use of these tests in various subgroups of patients with hypertension. For example, if diabetic and nondiabetic patients with hypertension are equally at risk for abnormal test results but the patients with diabetes are tested earlier in pregnancy and more often, it is to be expected that the patients with diabetes would have a higher percentage of abnormal test results *per patient*. However, the patients with diabetes would have the same percentage of abnormal test results *per number of tests performed*.

In addition, we were unable to delineate the test results by group and by subsequent management. Are the 53 patients with positive contraction stress tests included in the 119 with "abnormal test results"? Were the abnormal test results separated into the categories of abnormal contraction stress test, abnormal nonstress

test, and abnormal biophysical profile? The data also fail to indicate how often and under what circumstances an abnormal test result was ignored and the pregnancy allowed to continue for an extended period.

The statement of Pircon et al. that antepartum testing in diabetic patients with hypertension should be started at viability is apparently based on the two late second-trimester stillbirths that occurred during the study period. Pircon et al. acknowledge that both fetuses had true knots in the umbilical cords; these knots could have had a role in their deaths. Are there data demonstrating that diabetic patients with hypertension are at increased risk of umbilical cord knotting resulting in stillbirths?

The question of when to begin fetal testing in patients with hypertension is extremely important. A retrospective analysis could be quite informative. We believe that the data presented by Pircon et al. should be reanalyzed, taking into account the number of tests performed at any given gestational age, with a more complete data presentation. Then justifiable conclusions could be drawn as to when antepartum testing should be initiated in the patient with hypertension.

Avick G. Mitra, MD, and William N.P. Herbert, MD
Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of North Carolina School of Medicine, CB# 7570, Chapel Hill, NC 27599-7570

Reply

To the Editors: We thank Mitra and Herbert for their interest in our study of antepartum testing in patients with hypertension. The answers to their questions can be found in the text of our original publication; however, we are happy to review the results again. Our objectives were to evaluate when fetal compromise occurs in this patient population and to make recommendations as to when to initiate antepartum testing.

Contrary to the suggestion of Mitra and Herbert, the data were not analyzed as a percentage of abnormal antepartum tests per number of patients. We were not interested in the age-old issue of sensitivity or specificity of a testing method in patients with hypertension; rather, we were interested in when compromise occurs. We defined compromise by several parameters, one of which was a positive contraction stress test. Test results were recorded prospectively and were retrospectively queried by first positive test, not by the number of positive tests the patients had. In evaluating the data in this fashion we found that hypertensive patients with concomitant diagnoses of diabetes demonstrated compromise at an earlier gestational age when compared with hypertensive patients without diabetes.

Subsequent management was not the topic of study. When patient management is modified because of an antepartum test, there is evidence of fetal compromise. To reiterate, we were interested in when this occurred. We all agree that follow-up of an abnormal test can be managed numerous ways. Although it seems that Mitra and Herbert have expressed an interest in our management protocol, that protocol would not affect our results or our conclusions in this study. Consequently we do not believe it is appropriate to review that topic here.

We recommended that testing in the diabetic patient with hypertension start at viability. As listed in our original publication, this was based on two observations. First, there were two patients with late second-trimester stillbirths and concomitant diagnoses of a true knot in the umbilical cord. It is difficult to attribute the losses solely to the knots in the cords because this is a common finding at the deliveries of normal, viable term infants. We did not suggest that there is an increased risk of cord knotting in diabetic patients with hypertension. Second, a clinician would prefer to initiate testing in a patient before fetal compromise. The earliest gestational age that intervention was necessary in the diabetic patient with hypertension was 28 weeks. Therefore testing would need to start at 26 to 27 weeks or near the time of viability.

Legal thoughts on malpractice claims: Causes and prevention

To the Editors: As a professor of consumer law married to a physician, I read with great interest Ward's article (Ward CJ. Analysis of 500 obstetric and gynecologic malpractice claims: causes and prevention 1991; 165:298-306). I believe the article would have been improved and Kirkley's comments muted by a change in the classification method. Ward divides the cases into "defensible" and "indefensible," and Kirkley has a number of problems with this categorization. So do I, but for a different reason. There is simply no division in the law which corresponds to the defensible-indefensible dichotomy. The law divides cases into three categories, not two. In the first the plaintiff has no case and the defendant wins on summary judgment. In the second the defendant has no case and the plaintiff wins on summary judgment. In the third the issue is presented to the jury for determination of the disputed facts. Given Ward's description of his method it would appear that most, though not all, of his indefensible cases fall into the second category, where the plaintiff might win on summary judgment. The defensible cases would be in the other two categories. However, even if a case can be made for a physician's actions, it does not mean that the physician will win.

Ward's article may give physicians the unwarranted belief that if they lose a "defensible" case, the system has somehow failed them presumably because of perjured expert testimony, idiot jurors, and corrupt lawyers. This is simply not the law, just as it is not the law that a bad outcome means that there was malpractice. The legal system recognizes that there are often factual disputes on which reasonable people can differ and

assigns the resolution of such disputes to juries. The burden of proof is only the preponderance of the evidence that the physician violated the appropriate standard of care. In a standard of preponderance of the evidence we accept that there will be a certain number of "incorrect" verdicts and that verdicts do not establish truth but only solve the operative question of who wins the case. This type of error is inherent in the legal system. Including this understanding in the method used in the research would make the conclusions of much greater practical use.

I do not mean this comment to imply criticism of the obvious effort and skill Ward brought to this difficult issue and the real value of his advice to physicians (I assume the statement that human papillomavirus is "not" a likely cause of cervical cancer is a typographical error). However, I have a few replies to the comments of the other discussants.

Kirkley confuses the "standard of care" required by the law with the practice patterns of the "20,000 to 30,000 members of the American College of Obstetricians and Gynecologists who actually establish the standard of care in their localities." The standard of care is not how the typical physician practices any more than it is how the typical driver drives. The typical driver is negligent some of the time. Good drivers and good physicians sometimes make mistakes, with terrible consequences. The standard of care is an abstract ideal, and it is possible for an entire profession or industry to fall below a standard of care at least some of the time.

I am surprised that Kirkley's admonitions against changing medical records are seemingly based on the probability of being caught rather than the fact that changing records is a disgraceful, unethical act by anyone who claims to be a physician. I also question his statement that you "never tell a patient that you did wrong." Physicians owe patients a fiduciary duty to disclose errors. Failure to comply with this duty is itself actionable, and more practically may extend the statute of limitations under a theory of fraudulent concealment.

As a professor I was appalled that Blanchard would try to use a department chair to "take a stand" against an expert testifying in litigation. Virtually all states have civil or criminal penalties for those who tamper with witnesses in civil litigation, and any decent university respects the academic freedom of its professors.

Ward's article is a useful addition to the medical-legal literature. I only add that the real goal is not to avoid liability, but to avoid the injury that leads to the claim of liability.

Vincent Brannigan
University of Maryland, College Park, MD 20742

Reply

To the Editors: I appreciate Brannigan's comments and attention to my manuscript. His comment concerning human papillomavirus was correct. The "not" was a typographic error. The sentence from my article should have read "Human papillomavirus is *now* considered to be a likely cause of cervical cancer, even though Koch's postulates have not been fulfilled."

I recognize the insightful comments regarding definitions of "indefensible" and "defensible." In this study all the claims reviewed were open claims and not settled cases. Judgments were made without the benefit of the opinion of a jury; therefore the third category referred to by Brannigan could not have been used.

In reviewing a claim, if the medical evidence or lack of same revealed a breach in the standard of care resulting in damage, then the claim was deemed indefensible and settlement was advised. However, if malpractice did not exist, I classified the case as defensible. In these latter claims I recommend that the case be defended, even if a defendant's summary judgment was not obtained.

Laparoscopic hysterectomy: Reinventing the wheel?

To the Editors: Laparoscopic surgery is back on the scene. Ten years ago it might have been predicted that laparoscopy would be a dying procedure replaced by more advanced assisted reproductive technologies. However, the development of conventional[1] and laser[2, 3] laparoscopic accessories and the incorporation of video imaging technologies[4] into the armamentarium of the endoscopic operating theater has made it possible to perform more radical procedures safely and to establish training programs for advanced laparoscopy.

On the other hand, aggressive marketing of medical treatments coupled with public knowledge fed by eager journalism may be creating a misinterpretation of "new" applications such as "laparoscopic hysterectomy." At a recent international scientific event one of the keynote speakers stated " . . . none of my patients accept any longer the idea of conventional hysterectomy." These types of comments subsequently become headlines in women's magazines, proclaiming "New way of removing your womb."

The situation is reminiscent of Hans Christian Andersen's famous story, "The Emperor's New Clothes." Is this procedure new? Or is it in fact a laparoscopy-assisted vaginal hysterectomy or sometimes a laparoscopy-monitored vaginal hysterectomy? An experienced vaginal surgeon can perform a vaginal hysterectomy (with or without adnexectomy[5]) in <25 minutes.[6] Sir Norman Jeffcoate stated, "vaginal hysterectomy has an important place, not as a part of an operation for prolapse, but as the best means of removing the uterus when prolapse is not present."[7] Although there are indications in which laparoscopic assistance for adhesiolysis, confirming diagnosis, or minimizing complications are beneficial, it is doubtful that potential candidates for surgery who prefer the "modern approach" are even aware of proper patient selec-

tion. In a recent presentation of supracervical (real) laparoscopic hysterectomy[8] the question of its place and potential hazards were critically discussed.

Having been involved with the development of endoscopic accessories and techniques in the last 13 years, I truly believe that future surgery is connected to endoscopes. The sooner a gynecologist becomes familiar with the endoscopic equipment, different hand-eye coordination with video monitors, and proper patient selection the better. However, as one of Joel Cohen's past residents, I believe that the following message should be delivered: Let's not (1) forget the classic approach or (2) reinvent the wheel or even replace it with "square wheels." Let's be honest with each other and recognize what is really new. Present technology offers enough room for new ideas.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

WOMEN & INFANTS HOSPITAL OF RHODE ISLAND
Department of Obstetrics and Gynecology
Specialist in Maternal-Fetal Medicine and Genetics

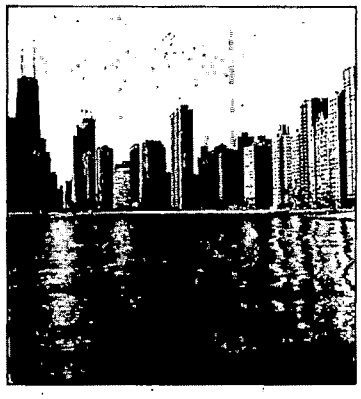
Women & Infants Hospital of Rhode Island, is seeking a physician to serve as a specialist in Maternal-Fetal Medicine and Genetics. The Hospital cares for 9500 births per year and houses a 65 bed Level III neonatal unit. The Division is composed of five MFM faculty, an internist, two MFM fellows and two Masters level genetic counsellors. Division staff actively collaborate with a biochemist and a cytogeneticist at WIH, both of whom are active, funded researchers focused on prenatal diagnosis. The Division is housed in newly constructed office space in the hospital and has a new 6000 square foot Prenatal Diagnosis Center providing genetic counselling, sonography, amniocentesis, CVS and PUBS. The person assuming this position will function as Director of Prenatal Diagnostic Services and will also be expected to share clinical responsibilities for MFM patients. Candidates must be certified in or be active candidates for Medical (or Clinical) Genetics (American Board of Medical Genetics) and Obstetrics and Gynecology (American Board of Obstetrics and Gynecology) at the time of taking the position. Completion of an approved fellowship in Maternal-Fetal medicine is highly desirable. The candidate should be actively engaged in a defined area of research, have a proven interest in medical education, and qualify for a full-time appointment at the rank of Assistant or Associate Professor at Brown University. Women & Infants Hospital and Brown University are equal employment opportunity institutions.

Interested parties should send their curriculum vitae and the names of three references to Marshall W. Carpenter, Director of Maternal-Fetal Medicine, Women & Infants Hospital of Rhode Island, 101 Dudley Street, Providence, Rhode Island 02905-2401 by September 1, 1992. Screening will begin on that date and continue until a candidate is selected or the search is closed.

FACULTY POSITION IN OB/GYN MATERNAL-FETAL MEDICINE

Wright State University School of Medicine, Department of Obstetrics and Gynecology, invites applications for a full-time faculty position in maternal-fetal medicine at the Assistant/Associate Professor level.

Primary faculty duties will consist of medical student and resident teaching and supervision. Other duties will include full participation in clinical care activities of the night and week-end coverage of Labor and Delivery. The candidate must be licensable to practice medicine in Ohio. Other qualifications include board certification in obstetrics and gynecology and completion of a fellowship and board certification or active candidacy in Maternal-Fetal Medicine. Academic rank and salary dependent upon qualifications. Women and minorities are encouraged to apply. Please send curriculum vitae and the names and addresses of three references to:



Dennis D. Barber, M.D.
Chair and Program Director
Department of Obstetrics and Gynecology
Wright State University School of Medicine
One Wyoming Street
Dayton, Ohio 45409

All applications received by August 15, 1992, will be considered; if the position is not filled therefrom, applications will be considered as received until the position is filled. Wright State University is an Affirmative Action and Equal Opportunity employer.

Specialty Review in Obstetrics and Gynecology: Practical Aspects

October 24 – 30, 1992

AUSTRALIA

Staff Director/Specialist

Department of Medical Imaging

This is an excellent opportunity for a qualified medical practitioner to join the Royal Hospital for Women - 204 bed, teaching hospital of the University of New South Wales.
As director of the Department of Medical Imaging, you will be responsible for the administration of the department, together with continuing the high quality of clinical, teaching and research work the department is world-renowned for.
Extensive experience in diagnostic ultrasound and strong research skills are vital, as are specialist obstetrical or radiological qualifications recognisable in Australia. The position is available on a full time or part time basis, and salary and conditions will be in accordance with the Medical Officers - Hospital Specialists (State) Award.
Applicants should indicate whether they wish to be considered for the position of Director of Medical Imaging.
Further details are available from Dr P. Garvey on (612) 339-4139.
Send applications by 28 August, 1992 to: The Director of Medical Services, Royal Hospital for Women, 188 Oxford Street, Paddington NSW 2021 Australia.

Royal Hospital for Women

WHERE WOMEN'S HEALTH COMES FIRST

THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY UNIVERSITY OF WISCONSIN MEDICAL SCHOOL

is seeking applicants for two (2) full-time faculty positions for a new women's health center and academic program at its Milwaukee Clinical Campus.

Sinai Samaritan Medical Center has recently consolidated its obstetrical and gynecological services in a redesigned facility in downtown Milwaukee. The department supports a residency program, the largest perinatal service in Wisconsin (5500 deliveries), consultative ultrasound, genetic and infectious disease programs, and reproductive/endocrine services (including an IVF program). The department is affiliated with Planned Parenthood of Wisconsin and St. Luke's Medical Center in Milwaukee.

Qualifications include a board candidacy or certification in obstetrics and gynecology and a commitment to teaching residents, medical students, and clinical research. Qualifications for the two positions for GENERAL OB/GYN can take into consideration special individual interests. Special expertise of interest for the department are:

—STATEWIDE FAMILY PLANNING
(Part-time medical director, Planned Parenthood)
—OPERATIVE LAPAROSCOPY, HYSTEROSCOPY
—UROGYNECOLOGY
—OB/GYN ULTRASOUND

Private practice opportunities are also available in an associated offsite multispecialty clinic and all faculty members participate in a group practice at the institution. Contact:

CHARLOTTE, NORTH CAROLINA

DIRECTOR OF PERINATOLOGY

The Carolinas' leading maternity hospital with over 6,500 deliveries per year, Presbyterian Hospital, is seeking a **BE/BC PERINATOLOGIST** to develop comprehensive Maternal and Fetal Medicine services for this 642-bed, not-for-profit regional acute care center. Candidates will find many excellent services with over 80 OBG's on staff, a level III NICU with 24-hour neonatology coverage, excellent antenatal, postpartum, laboratory and pathology services, as well as a new geneticist starting this fall. Appropriate candidates will have 2-5 years experience, strong interpersonal and communication skills, enjoy a team approach, and offer some administrative and marketing expertise. Contact: Mary Wynkoop, Tyler & Company, Suite 1400, 1000 Abernathy Road, NE, Atlanta, Ga, 30328. 800-883-8803, or 404-396-3939. Fax: 404-396-6693. Your inquiries will be handled CONFIDENTIALLY.

PERINATAL ASSOCIATES OF NORTHERN CALIFORNIA

Are you a clinical perinatologist? There is still time to join 4 perinatologists and one medical geneticist looking for one more perinatologist who: desires superior environment for patient care, in a private, modern level 3 facility doing 6,000 deliveries a year with superior perinatal outcome; likes personal, direct hands-on patient care; needs PUBS, IUTxF, CVS and complicated pregnancies, level 2 ultrasound; demands partners, not superiors; wants to live in clean, warm, not humid, snow-free (but 60 minutes from skiing) Sacramento, California; feels one's family has priorities; and is committed to the private practice of medicine. For more information, call (916) 733-1755.

Roger L. Wallace, D.O.
Perinatal Associates

◆ CHRIST HOSPITAL AND MEDICAL CENTER ◆

PERINATOLOGIST

Christ Hospital and Medical Center is an 827-bed tertiary care facility and a member of Evangelical Health Systems—Chicago's largest multi-hospital system. We're also one of Illinois' largest private teaching medical centers.

Our established Level III Perinatal Center is expanding its perinatal program. Today, we seek an experienced individual to help develop and promote this outstanding program.

BC/BE PERINATOLOGIST

Our Center averages over 4,100 deliveries annually, has an active maternal and neonatal transport system, and a Level III Neonatal Intensive Care Unit staffed by seven neonatologists. Complete laboratory facilities are available including cytogenetic analysis of both amnionic fluid and trophoblastic tissue. Our Antepartum Testing Unit is equipped with color flow Doppler ultrasound.

EHS brings together the best benefits, compensation, and lifestyle opportunities for qualified candidates. Learn more by calling (708)346-5138 or by sending your CV to: Tom Bergmann, Human Resources Manager. EOE m/f.

EHS BRINGING THE BEST *Together*

◆ CHRIST HOSPITAL AND MEDICAL CENTER ◆

◆ CHRIST HOSPITAL AND MEDICAL CENTER ◆

Well established Northern Virginia OB/GYN practice with three satellite offices seeks a highly qualified, highly motivated BE/BC physician interested in providing comprehensive OB/GYN care in a progressive setting. Affiliated with a non-profit community hospital and a well respected tertiary care center, the practice averages 50-60 deliveries a month. This practice provides the opportunity for academic affiliation with The George Washington University School of Medicine.

The practice's main office is located in a suburban community located 25 miles south of Washington, D.C. which has a young population which has experienced tremendous growth in recent years. The community hospital has a completely updated MCH Unit which includes 6 LDR's, 16 bassinet nursery, Level II NICU, and outstanding support including Neonatology and 24 hour dedicated Anesthesiology.

Competitive salary, productivity bonuses, outstanding benefits including paid vacation/CME leave, health, disability, and life insurance, profit sharing and more.

If you seek a dynamic practice opportunity where your hard work will be generously compensated, please forward your curriculum vitae to:

Kimberly Amsley, Practice Administrator
The Adler Group
2296 Opitz Boulevard,
Suite 350
Woodbridge, Virginia

Applications Invited for Fellowships in Geriatric Gynecology

Applications are invited for the Hartford Foundation/AFAR Fellowship Program in Geriatric Gynecology.

The program, funded by the *John A. Hartford Foundation of New York City* and administered by the American Federation for Aging Research (AFAR), is designed to develop a cadre of gynecologists committed to an academic career with specialized training in the geriatric aspects of their specialties.

Two Fellowships will be awarded in 1992, each offering a grant of $50,000 annually, for the two-year period beginning July 1, 1993.

Applicants must be affiliated with or must plan to pursue their fellowship at one of the institutions which participate in the Hartford Foundation's Academic Geriatric Recruitment Initiative. These institutions are: Bowman Gray School of Medicine, Case Western Reserve University, Duke University, Harvard University, Johns Hopkins University, Mount Sinai School of Medicine, Stanford University, St. Louis University, University of California at Los Angeles, University of Connecticut, University of Michigan, University of Pennsylvania, and University of Washington.

Applications must be filed by an institution on behalf of an individual candidate and must include a statement of plans for the development of curriculum materials related to geriatric gynecology. The application must bear the endorsement of institutional mentors representing the gynecology and geriatric departments or divisions.

Applicants must be board certified or eligible by July 1, 1993 and need not have had previous training in geriatric medicine or gerontology.

Applications must be accompanied by letters of reference from three individuals who know the candidate and by the *curricula vitae* of the candidate and the designated mentors. The deadline for the submission of applications is September 30, 1992. Awards will be announced by October 31, 1992.

Applications and further information may be secured from:

American Federation for Aging Research (AFAR)
725 Park Avenue
New York, NY 10021

BRIGHAM AND WOMEN'S HOSPITAL - HARVARD MEDICAL SCHOOL are soliciting applications for the **Chair of the Department of Obstetrics and Gynecology** at the Brigham and Women's Hospital. The Department is one of the largest of its kind in the USA, and the Hospital has had a long-standing commitment to women's health. Candidates should have outstanding academic records and the ability to lead clinical, research, and training programs. Applications, to include a curriculum vitae and the names of three potential referees, should be sent to Dr. Ramzi S. Cotran, Chairman, Search Committee, Brigham and Women's Hospital, 75 Francis Street, Boston, MA 02115. The Brigham and Women's Hospital and the Harvard Medical School are equal opportunity employers.

Mosby Year Book

Provide vital information to those who need it most...
with article reprints from Mosby-Year Book periodicals

Article reprints are your best means of distributing the information published in Mosby-Year Book's medical, dental, and nursing periodicals. These papers will enhance the value of your information programs.

Not just for authors, reprints are an effective tool for health care professionals, sales and marketing staffs, and advertisers.

Use reprints to:

- Train and educate your sales and marketing staff
- Support your seminar topic
- Inform your health care staff of new developments
- Reach your product users with vital information

Article reprints...another valuable service from Mosby-Year Book.

Orders (minimum of 100 copies) of all previous and future articles in Mosby-Year Book periodicals are available from the Publisher.

For more information, contact:
Mosby-Year Book, Inc.

DEPARTMENT OF OBSTETRICS, GYNECOLOGY AND REPRODUCTIVE SCIENCES

UNIVERSITY OF PITTSBURGH SCHOOL OF MEDICINE

The Department of Obstetrics, Gynecology and Reproductive Sciences at the University of Pittsburgh has the following full-time faculty positions available:

Assistant Professor of Obstetrics and Gynecology: A position is available for an individual with a basic science background studying the biochemistry and molecular biology of endothelial cell responses. This individual should have extensive laboratory experience, be able to work independently and be competent to train fellows and graduate students. Salary will be commensurate with experience, training, and achievements.

Assistant Professor of Obstetrics and Gynecology: A position is available for a basic scientist with a primary interest in molecular biology. The individual should be experienced in the molecular biology of connective tissue and be interested in participating in studies related to productive physiology. Experience and the ability to work independently is required, as is the willingness and ability to teach and train postdoctoral fellows and graduate students. Salary will be commensurate with experience, training, and achievements.

Professor of Obstetrics and Gynecology: Two positions are available for basic scientist experienced in the physiology of pregnancy and parturition. Individuals should have a clear record of experience in working with groups of researchers, have a national reputation, and should be willing and able to train graduate students and postdoctoral fellows.

Send inquiry and curriculum vitae for any of the above positions to: James M. Roberts, M.D., Professor and Vice-Chairman, Research, Department of Obstetrics, Gynecology and Reproductive Sciences, Magee-Womens Hospital, 300 Halket Street, Pittsburgh, PA 15213-3180.

The University of Pittsburgh is an equal opportunity, affirmative action employer.

Geisinger Clinic

Perinatology

The Department of Obstetrics and Gynecology of the Geisinger Medical Center is actively recruiting an eligible/board certified Perinatologist to develop and build a regional perinatal service. This is an opportunity to practice Level III care at a regional medical center located in a rural setting, in Northeastern Pennsylvania.

Geisinger Medical Center is a 577-bed, tertiary referral center offering state-of-the-art facilities, with a current medical staff of 300 physicians. The medical center has a Level III NICU Unit and a 14-bed Stepdown Unit. Deliveries are approximately 1200 each year with a significant number of those being "high risk".

Responsibilities include student and resident teaching, prenatal diagnosis and perinatal consultation. Skills in clinical research are also preferred.

An excellent benefit package is offered including, competitive salary, professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. Please forward inquiries along with a curriculum vitae to: **T.K. Ghosh, M.D., Division of OB/GYN, Geisinger Medical Center, 100 North Academy Avenue, Danville, PA 17822-1329.**

The one drug test a woman can't afford to fail.

Knowing the right answers to this test can mean the difference between life and death to a woman and her unborn child. Cut it out now and give copies to all your patients, even if you don't suspect a drug problem. Even if they are not pregnant. Because if your patients don't know the right answers, now's the time to talk with them and help them to understand.

Drugs and Pregnancy: Did you know?

1. Did you know that if you use cocaine while you're pregnant, you have a much greater chance of having a miscarriage? ☐ YES ☐ NO

2. Did you know that if you use cocaine, you can pass it on to your baby through your breast milk? ☐ YES ☐ NO

3. Did you know that if you use any illicit drug while you're pregnant, there's a greater chance that you will have a low-birthweight baby? ☐ YES ☐ NO

4. Did you know that low birthweight is associated with a greater risk of infant death and mental and physical handicaps? ☐ YES ☐ NO

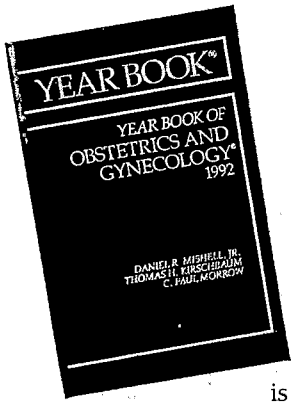
5. Did you know that heroin use during pregnancy increases the likelihood of stillbirth and death among newborns? ☐ YES ☐ NO

6. Did you know that if you or any of your sexual partners ever used an illicit IV drug, you may be infected with the AIDS virus (HIV), and that you can pass that virus on to your unborn child? ☐ YES ☐ NO

7. Did you know that if you use cocaine, are addicted to heroin, or are methadone-dependent, your children will be at a greater risk for sudden infant death syndrome (SIDS)? ☐ YES ☐ NO

8. Did you know that if you use barbiturates during your pregnancy you can change your child's normal patterns of growth and behavior? Your child might also suffer withdrawal symptoms for months after birth, including high-pitched crying, irritability, and sleep disturbances. ☐ YES ☐ NO

9. Is your doctor aware of all the prescription and/or illicit drugs you may be taking? ☐ YES ☐ NO



Did you know that if you have a drug problem, there are many people and resources you can turn to for help? Just ask your doctor.

Cut along dotted line, copy, and distribute to patients as you see fit.

LWS-0964B

"Smart, current, in-depth, tough, unique, charismatic, authoritative, handy, relevant, lucid, thorough, convenient, detailed, pithy, top-notch, helpful, sagacious, indispensable, comprehensive, timely, thought-provoking, incisive, straightforward, lively, astute, invaluable, concise, fact-packed, and one-of-a-kind."

Okay. So maybe we're going a little overboard. But our subscribers are an opinionated and enthusiatic bunch. Nearly one in four physicians practicing today is a Year Book subscriber and they are vocal in their loyalty.

And why not? A subscription to the Year Book gives you all the past year's most essential ob/gyn articles condensed for quick and easy reading, and expert advice to help you put the latest findings and techniques to work immediately.

Let's be honest, though, no list of two-dollar words can really convey a book's usefulness and value. *You've got to evaluate it for yourself.*

That's why we're offering you this no-risk, no-obligation, 30-day free trial of the Year Book. Just call or mail the attached coupon and we'll send you a free examination copy. Put it to work for a month, and if you're not completely satisfied for any reason, just send it back and owe nothing.

But we hope you might want to send us a few adjectives of your own instead–extraordinary, versatile, and revolutionary are still available.

❑ Yes! Please send my 30-day free approval copy of the *1992 Year Book of Obstetrics and Gynecology* (22636) according to the service terms described below. If I decide to keep the book I'll pay just $59.95 (plus shipping, handling, and state sales tax where appropriate).

The Year Book of Obstetrics and Gynecology Service Guarantee:
When you subscribe to the Year Book, we'll send you an advance notice of future volumes about two months before they publish. This automatic notice system is designed to take up as little of your time as possible. If you do not want the Year Book, the advance notice makes it it quick and easy for you to let us know your decision; and you will always have at least 20 days to decide. If we don't hear from you, we'll send you the new volume as soon as it's available. And, of course, the Year Book is yours to examine free of charge for 30 days (postage, handling and applicable sales tax are added to each shipment).

21- and 28-day regimens

ORTHO-NOVUM 777 Tablets

TRADE MARK

norethindrone/ethinyl estradiol

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiform. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

A PILL WITH A PROGRAM

Only TRI-NORINYL starts your OC patients with The TRI-NORINYL Total Health Program.™

When you start your OC patient with The TRI-NORINYL Total Health Program sample package, you provide the benefits of oral contraception *plus* an exciting new patient-support program.

The TRI-NORINYL Total Health Program sample package contains one cycle of TRI-NORINYL; the attractive Wallette® Pill Dispenser; and a patient Q&A booklet—*plus* the video and instruction guide, *The ACOG Balanced Fitness Workout;* and program membership. The TRI-NORINYL Total Health Program provides a variety of fitness and health information to help women achieve healthier lifestyles.

As part of that goal, Syntex Laboratories is proud to be a sponsor of the American Medical Association's Women's Health Campaign.

For details about The TRI-NORINYL Total Health Program, please contact your Syntex Representative.

Serious as well as minor side effects have been reported following the use of oral contraceptives. These include thrombo-embolic disease.

Please see adjacent page for brief summary of prescribing information.

TRI-NORINYL
(NORETHINDRONE AND ETHINYL ESTRADIOL)

ORAL CONTRACEPTIVE AGENTS: BRIEF SUMMARY

DESCRIPTION

TRI-NORINYL 21-DAY Tablets provide an oral contraceptive regimen of 7 blue tablets followed by 9 yellow-green tablets and 5 more blue tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg and each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg.

TRI-NORINYL 28-DAY Tablets provide a continuous oral contraceptive regimen of 7 blue tablets, 9 yellow-green tablets, 5 more blue tablets, and then 7 orange tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg, each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg, and each orange tablet contains inert ingredients.

INDICATIONS AND USAGE

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use these products as a method of contraception.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions: Thrombophlebitis or thromboembolic disorders • A past history of deep vein thrombophlebitis or thromboembolic disorders • Cerebral vascular or coronary artery disease • Known or suspected carcinoma of the breast • Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia • Undiagnosed abnormal genital bleeding • Cholestatic jaundice of pregnancy or jaundice with prior pill use • Hepatic adenomas, carcinomas or benign liver tumors • Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long-term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users, cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS,** section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4.6 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40–49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1970s—but not reported in the U.S. until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral contraceptive use to women who do not have the various risk factors listed in this labeling.

Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular disease risks may be increased with oral contraceptive use after age 40 in healthy non-smoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception.

Therefore, the Committee recommended that the benefits of oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out.

Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING.**

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section): Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: • Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation: • Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use: • Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

Teenage pregnancy prevention: The vital importance of the medical community's involvement 299

Willette L. LeHew, MD

Norfolk, Virginia

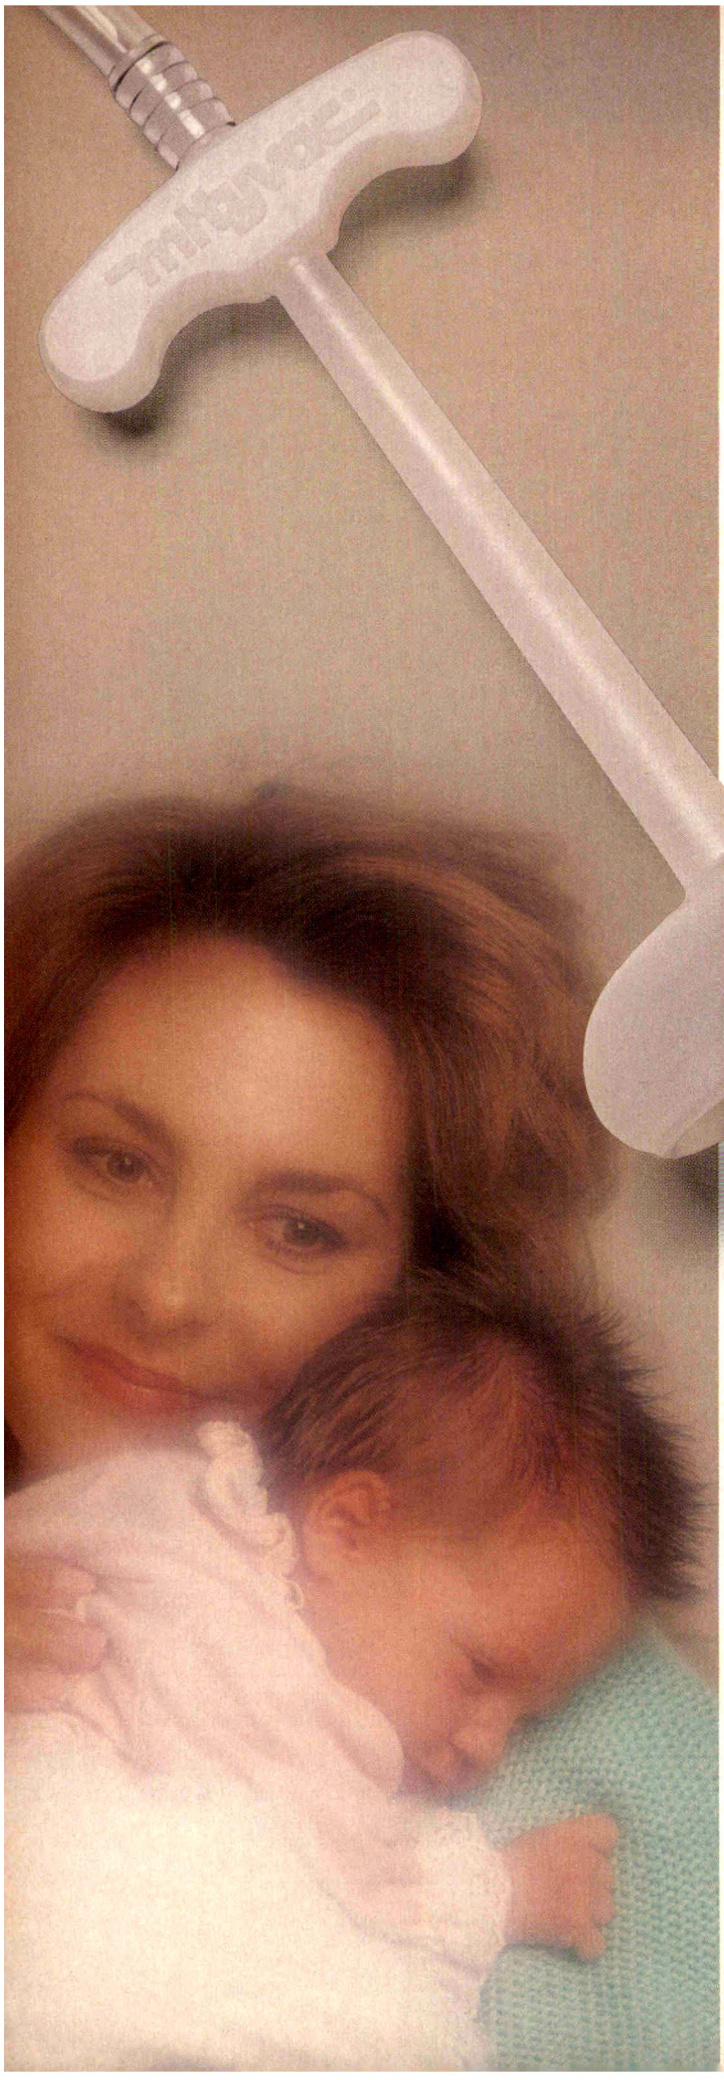
Attenuated proestrous luteinizing hormone surges in middle-aged rats are associated with decreased pituitary luteinizing hormone-β messenger ribonucleic acid expression 303

Barbara B. Hogg, BA, Dennis W. Matt, PhD, and Timothy E. Sayles

Richmond, Virginia

Before the luteinizing hormone surge, pituitary luteinizing hormone-β messenger ribonucleic acid expression, but not luteinizing hormone content, is decreased in middle-aged rats with attenuated luteinizing hormone surges.

Outcome of corticotropin stimulation testing in women with androgen excess and ovulatory dysfunction 308



G. William Bates, MD, G. Martin French, MD, Betty B. Humphries, MN, and Dawn W. Blackhurst, MS

Greenville, South Carolina

Seventeen (41.5%) of 41 women with a dehydroepiandrosterone sulfate value >2.8 μg/ml had a positive corticotropin stimulation test result; 50% of those with a positive test result conceived within 6 months of receiving prednisone suppression therapy.

NEW FROM MITYVAC®

"M" STYLE MECHANICAL PULL VACUUM EXTRACTOR

Mityvac®'s new "M" Style Vacuum Extractor Cup is uniquely shaped to provide greater traction and excellent manipulation during vacuum assisted deliveries. The extractor cup is softly contoured and the flexible stem bends into a 90-degree angle, providing the "M" Style Cup with several distinct advantages:

- **Newly styled cup is shaped to provide mechanical pull for greater traction**
- **Even at 90-degree angle, extractor cup holds tight vacuum and continues to perform throughout delivery**
- **Manipulable design provides optimum angle of application when minimal space is available**
- **Smooth, low profile cup and flexible stem provide safe, easy insertion**
- **Lightweight, flexible material enhances manipulation capabilities**
- **Technologically advanced one-piece ventouse is fully assembled and ready for immediate use**
- **Individually prepackaged in sterile pouches, the extractor cup, tube and filter are disposable**
- **Fully compatible with all Mityvac® pumps**

The "M" Style Cup provides firm control throughout delivery.

The patented manipulable design draws vacuum and remains fully functional even at a 90-degree angle.

As pioneers of vacuum delivery technology in childbirth for more than 20 years, Mityvac® products of quality and reliability fulfill obstetrical needs around the world.

Etiologic factors of recurrent abortion and subsequent reproductive performance of couples: Have we made any progress in the past 10 years? 313

Leo Plouffe, Jr., MD, Evelyn W. White, MD, Sandra P. Tho, MD, Craig S. Sweet, MD, Lawrence C. Layman, MD, Gail F. Whitman, MD, and Paul G. McDonough, MD

Augusta, Georgia

In 76% of 131 patients investigated for recurrent abortion during 1987-1991 a diagnosis could be made, compared with only 63% for 100 patients studied between 1968-1977 in the same unit.

Electroejaculation in combination with in vitro fertilization and gamete micromanipulation for treatment of anejaculatory male infertility 322

Andrew A. Toledo, MD, Michael J. Tucker, PhD, James K. Bennett, MD, Bruce G. Green, MD, Hilton I. Kort, MD, Sharon R. Wiker, and Graham Wright, BSc

Atlanta, Georgia

When poor semen samples obtained by electroejaculation are unsuitable for intrauterine insemination, a combination of electroejaculation with in vitro fertilization and gamete micromanipulation improves chances of fertilization and pregnancy.

Red blood cell transfusion and cesarean section 327

Laurel A. Dickason, BA, and Mara J. Dinsmoor, MD

Richmond, Virginia

Only the presence of antepartum bleeding and a low preoperative hemoglobin are predictive of the need for blood transfusion associated with cesarean section.

Amnioinfusion: An aid in the ultrasonographic evaluation of severe oligohydramnios in pregnancy 333
Thomas A. Quetel, MD, Andres A. Mejides, MD, Fawwaz A. Salman, MD, and Mayra M. Torres-Rodriguez, BS, RDMS
Miami, Florida

Amnioinfusion enabled a more comprehensive ultrasonographic evaluation of pregnancy complicated by severe oligohydramnios.

Long-term outcome in fetal hydrops from parvovirus B19 infection 337
Asad U. Sheikh, MD, Joseph M. Ernest, MD, and Michael O'Shea, MD
Winston-Salem, North Carolina

Neonatal outcome in two cases of fetal parvovirus B19 infection with spontaneous resolution of hydrops fetalis.

Experience with mepivacaine paracervical block in an obstetric private practice 342
J. Robert Goins, MD
Hickory, North Carolina

Effects of mepivacaine paracervical block on a series of 182 obstetric patients are presented.

Refining the biophysical profile with a risk-related evaluation of test performance 346
Lawrence D. Devoe, MD, Alaaeldin A. Youssef, MD, Paula Gardner, RN, Cheryl Dear, RN, BSN, and Cheri Murray, RN
Augusta, Georgia

Correlation of pregnancy outcome with results of fetal biophysical tests suggests that variables are interdependent and prognosis is related to specific combinations of abnormal variables.

Excessive maternal weight and pregnancy outcome 353
John W.C. Johnson, MD, Jeffrey A. Longmate, PhD, and Barbara Frentzen, RN, MSN
Gainesville, Florida

The correlation between maternal weight gain and cesarean section rate warrants a careful reappraisal of weight gain recommendations in pregnancy.

A prospective randomized clinical trial comparing two oxytocin induction protocols 373
Peter R. Muller, MD, Thomas M. Stubbs, MD, and Sherry L. Laurent, PhD
Charlotte, North Carolina

Larger-dose increments of oxytocin in association with slower time intervals may improve efficacy without an associated increase in hyperstimulation or poor neonatal outcome.

CEFOTAN® IM/IV
(cefotetan disodium)
Available in 1-gram and 2-gram vials

For Intravenous or Intramuscular Use
PLEASE SEE FULL PRESCRIBING INFORMATION FOR A COMPLETE DESCRIPTION.
A BRIEF SUMMARY FOLLOWS.

INDICATIONS AND USAGE
TREATMENT

CEFOTAN is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary Tract Infections caused by *E. coli, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis,* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).

Lower Respiratory Tract Infections caused by *Streptococcus pneumoniae* (formerly *D. pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K. pneumoniae*), *E. coli, Proteus mirabilis,* and *Serratia marcescens**.

Skin and Skin Structure Infections due to *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes, Streptococcus* species (excluding enterococci), *Escherichia coli, Klebsiella pneumoniae, Peptococcus niger**, *Peptostreptococcus* species.

Gynecologic Infections caused by *Staphylococcus aureus* (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *Streptococcus agalactiae, E. coli, Proteus mirabilis, Neisseria gonorrhoeae,* Bacteroides species (excluding *B. distasonis, B. ovatus, B. thetaiotaomicron*), *Fusobacterium* species*, and gram-positive anaerobic cocci (including *Peptococcus niger* and *Peptostreptococcus* species).

Cefotetan, like other cephalosporins, has no activity against *Chlamydia trachomatis.* Therefore, when cephalosporins are used in the treatment of pelvic inflammatory disease, and *C. trachomatis* is one of the suspected pathogens, appropriate antichlamydial coverage should be added.

Intra-abdominal Infections caused by *E. coli, Klebsiella* species (including *K. pneumoniae*), *Streptococcus* species (excluding enterococci), *Bacteroides* species (excluding *B. distasonis, B. ovatus, B. thetaiotaomicron*) and *Clostridium* species*.

Bone and Joint Infections caused by *Staphylococcus aureus**.

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic *in vitro* against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

PROPHYLAXIS

The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (e.g., cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

BEFORE THERAPY WITH CEFOTAN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOTETAN DISODIUM, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. IF THIS PRODUCT IS TO BE GIVEN TO PENICILLIN-SENSITIVE PATIENTS, CAUTION SHOULD BE EXERCISED BECAUSE CROSS-HYPERSENSITIVITY AMONG BETA-LACTAM ANTIBIOTICS HAS BEEN CLEARLY DOCUMENTED AND MAY OCCUR IN UP TO 10% OF PATIENTS WITH A HISTORY OF PENICILLIN ALLERGY. IF AN ALLERGIC REACTION TO CEFOTAN OCCURS, DISCONTINUE THE DRUG. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE TREATMENT WITH EPINEPHRINE AND OTHER EMERGENCY MEASURES, INCLUDING OXYGEN, INTRAVENOUS FLUIDS, INTRAVENOUS ANTIHISTAMINES, CORTICOSTEROIDS, PRESSOR AMINES AND AIRWAY MANAGEMENT, AS CLINICALLY INDICATED.

Pseudomembranous colitis has been reported with nearly all antibacterial agents, including cefotetan, and may range from mild to life-threatening. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment or surgical prophylaxis. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is a primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to discontinuation of the drug alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *Clostridium difficile.*

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity and, possibly, subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional state, the elderly, and patients with cancer. Prothrombin time should be monitored and exogenous vitamin K administered as indicated.

PRECAUTIONS

General: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Information for Patients: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

Drug Interactions: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

Drug/Laboratory Test Interactions: The administration of CEFOTAN may result in a false-positive reaction for glucose in the urine using Clinitest®†, Benedict's solution, or Fehling's solution. It is recommended that glucose tests based on enzymatic glucose oxidase be used.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

Pregnancy: Teratogenic Effects. Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies, the following adverse effects were considered related to CEFOTAN therapy. Those appearing in italics have been reported during postmarketing experience.

Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700); *pseudomembranous colitis.* Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment or surgical prophylaxis. (See WARNINGS.)

Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300); *agranulocytosis, hemolytic anemia, leukopenia, thrombocytopenia,* and *prolonged prothrombin time.*

Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700); *anaphylactic reactions.*

Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

Miscellaneous: *Fever*

In addition to the adverse reactions listed above which have been observed in patients treated with cefotetan, the following adverse reactions and altered laboratory tests have been reported for cephalosporin-class antibiotics: urticaria, pruritis, Stevens-Johnson syndrome, erythema multiforme, toxic epidermal necrolysis, vomiting, abdominal pain, colitis, superinfection, vaginitis including vaginal candidiasis, renal dysfunction, toxic nephropathy, hepatic dysfunction including cholestasis, aplastic anemia, hemorrhage, increased BUN, increased creatinine, elevated bilirubin, pancytopenia, and neutropenia.

Several cephalosporins have been implicated in triggering seizures, particularly in patients with renal impairment when the dosage was not reduced (see DOSAGE AND ADMINISTRATION and OVERDOSAGE). If seizures associated with drug therapy occur, the drug should be discontinued. Anticonvulsant therapy can be given if clinically indicated.

DOSAGE AND ADMINISTRATION
TREATMENT

The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Skin & Skin Structure		
Mild-Moderate[a]	2 grams	2 g every 24 hours IV 1 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6 grams[b]	3 g every 12 hours IV

[a] *K. pneumoniae* skin and skin structure infections should be treated with 1 or 2 grams every 12 hours IV or IM.

[b] Maximum daily dosage should not exceed 6 grams.

If *C. trachomatis* is a suspected pathogen in gynecologic infections, appropriate antichlamydial coverage should be added, since cefotetan has no activity against this organism.

PROPHYLAXIS

To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION

When renal function is impaired, a reduced dosage schedule must be employed. See FULL PRESCRIBING INFORMATION for a complete description.

NOTE: Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

The use of carbon dioxide laser laparoscopy in the treatment of tubal ectopic pregnancies 382
John D. Paulson, MD
Annandale, Virginia

Laser laparoscopy for removal of unruptured ectopic pregnancies may be the treatment of choice in selected individuals.

Intrauterine pressure and fluid absorption during continuous flow hysteroscopy 386
Spyro P. Vulgaropulos, MD, Leigh C. Haley, MD, and Jaroslav F. Hulka, MD
Chapel Hill, North Carolina

Fluid overload during hysteroscopy with continuous-flow distention may be caused by partial perforations or transected venous channels rather than elevated pressures.

Obesity and lower urinary tract function in women: Effect of surgically induced weight loss 392
Richard C. Bump, MD, Harvey J. Sugerman, MD, J. Andrew Fantl, MD, and Donna K. McClish, PhD
Richmond, Virginia

Significant subjective and objective improvement in lower urinary tract function was demonstrated in 13 morbidly obese women after massive, surgically induced weight reduction.

The incidence of genital prolapse after the Burch colposuspension 399
Anne K. Wiskind, MD, Sarah M. Creighton, MD, and Stuart L. Stanton
Atlanta, Georgia, and London, England

The development of postoperative enterocele, rectocele, and uterine descent are significant late complications of the Burch colposuspension operation.

Evaluation of pretreatment transvaginal ultrasonography in the management of patients with endometrial carcinoma 406
Charles F. Shipley III, MD, Sidney T. Smith, MD, Edward J. Dennis III, MD, and George H. Nelson, PhD, MD
Columbia, South Carolina

Pretreatment ultrasonographic measurements of tumor grade, depth of invasion, uterine volume, and tumor volume are useful in the management of endometrial carcinoma.

The treatment of pelvic soft tissue radiation necrosis with hyperbaric oxygen 412
James A. Williams, Jr., MD, Dick Clarke, William A. Dennis, MD, Edward J. Dennis III, MD, and S.T. Smith, MD
Columbia, South Carolina

A series of patients with radiation-induced vaginal necrosis treated with hyperbaric oxygen is presented.

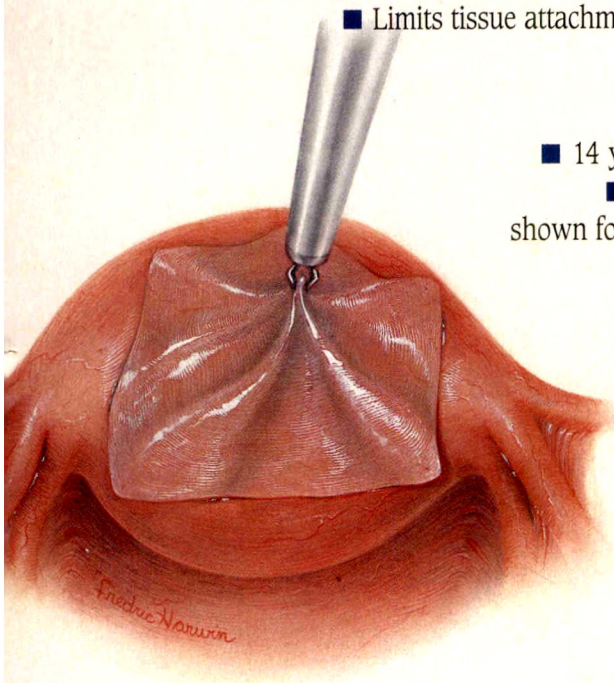
Invariant Performance in Peritoneal Reconstruction of Myomectomy Sites



...The GORE-TEX® Surgical Membrane
The Choice in Peritoneal Reconstruction

Incision sites for myomectomy can be a significant post-operative problem. Hemostatically difficult to control, they demand an adjuvant unaffected by the biological processes that occur following deperitonealization...The GORE-TEX Surgical Membrane.

Performance by Design

- Composed of the inert biomaterial, expanded polytetrafluoroethylene (e-PTFE)
- Limits tissue attachment with an extremely small pore size

Proven and Established

- Long record of safety and effectiveness
- 14 years of reliability demonstrated among cardiac surgeons
- Safety substantiated and invariant performance shown for myomectomy site protection in a multi-center clinical study

Convenient

- Configured for Peritoneal Reconstruction
- Packaged sterile and **can be resterilized**

To receive further information on the GORE-TEX Surgical Membrane or to consult an application specialist, call **1-800-437-8181**. For orders and overnight delivery, 24 hours a day, please call **1-800-528-8763**.

Use of the fetal chest in estimating fetal weight 448
Hung N. Winn, MD, Phillip N. Rauk, MD, and Roy H. Petrie, MD, ScD
St. Louis, Missouri, and Pittsburgh, Pennsylvania

The fetal chest circumference can be used in combination with the biparietal diameter or the humeral length to estimate the fetal weight.

Oral condyloma lesions in patients with extensive genital human papillomavirus infection 451
Pierluigi Benedetti Panici, MD, Giovanni Scambia, MD, Lidia Perrone, MD, Francesco Battaglia, MD, Paola Cattani, MD, Carla Rabitti, MD, Giuseppe Dettori, MD, Arnaldo Capelli, MD, Alexander Sedlis, MD, and Salvatore Mancuso, MD
Rome, Italy, and Brooklyn, New York

Human papillomavirus–associated lesions were found in the oral cavities of patients with genital condylomatosis; colposcopy was found to be useful in detecting oral condyloma lesions.

A comparison of circulating hormone levels in postmenopausal women receiving hormone replacement therapy 459
Raymond W. Jurgens, Jr., PhD, Laurence J. Downey, MD, William D. Abernethy, BS, Neal R. Cutler, MD, and Julie Conrad, RN
Marietta, Georgia, and Beverly Hills, California

There were no significant differences among the hormone replacement therapy treatment groups with respect to concentrations of estrone and estradiol over time.

Prenatal diagnosis of human parvovirus B19 in nonimmune hydrops fetalis by polymerase chain reaction 461
Bruce W. Kovacs, MD, Dru E. Carlson, MD, Bejan Shahbahrami, MS, and Lawrence D. Platt, MD
Los Angeles, California

Human parvovirus B19 was identified with the polymerase chain reaction in fetal blood and amniotic fluid in cases of nonimmune hydrops fetalis.

Angina and normal coronary arteries in women: Gynecologic findings 467
Philip M. Sarrel, MD, David Lindsay, MA, Giuseppe M.C. Rosano, MD, and Philip A. Poole-Wilson, MD
New Haven, Connecticut, and London, England

17 β-Estradiol deficiency may induce pathophysiologic changes contributing to anginal symptoms in women diagnosed with syndrome X.

Modulation of cell-to-cell coupling between myometrial cells of the human uterus during pregnancy 472
Nobuyoshi Sakai, MD, PhD, Thomas Tabb, MD, and Robert E. Garfield, PhD
Galveston, Texas

Electric and metabolic coupling between human myometrial cells in intact uterine tissues was shown to be regulated by both appearance and permeability of gap junctions.

Serial measurements of platelet angiotensin II binding in two patients with hypertension in pregnancy: Case reports 487

Philip N. Baker, DM, and Fiona Broughton Pipkin, DPhil

Nottingham, England

The fall in platelet angiotensin II binding that is seen in normotensive pregnancy did not occur in two patients who had hypertension in pregnancy.

Ifosfamide alone and in combination in the treatment of refractory malignant gestational trophoblastic disease 489

Gregory P. Sutton, MD, John T. Soper, MD, John A. Blessing, PhD, Kenneth D. Hatch, MD, and Danny R. Barnhill, MD

Indianapolis, Indiana, Durham, North Carolina, Buffalo, New York, Tucson, Arizona, and Washington, D.C.

Ifosfamide is an active agent alone and may be curative in combination with etoposide and cisplatin in refractory choriocarcinoma.

Circulating concentrations of fetal fibronectin do not reflect reduced trophoblastic invasion in preeclamptic pregnancies 496

Steven A. Friedman, MD, Christianne J.M. de Groot, MD, Robert N. Taylor, MD, PhD, and James M. Roberts, MD

San Francisco, California

We are unable to demonstrate decreased maternal plasma fetal fibronectin at 16 to 20 weeks' gestation in women who subsequently have preeclampsia.

Resident research in obstetrics and gynecology: Development of a program with comparison to a national survey of residency programs 498

Patricia J. Sulak, MD, Julie A. Croop, RN, Argye Hillis, PhD, and Thomas J. Kuehl, PhD

Temple, Texas

A program was developed to initiate resident research and a Resident Research Day; it was compared with a national survey of residency programs in obstetrics and gynecology.

Nonimmune fetal hydrops caused by bilateral type III congenital cystic adenomatoid malformation of the lung at 17 weeks' gestation 503
David M. Sherer, MD, Jacques S. Abramowicz, MD, Leon A. Metlay, MD, Michele Roberts, MD, PhD, and James R. Woods, Jr., MD
Rochester, New York

Massive cardiac compression caused by bilateral congenital cystic adenomatoid malformation of the lung (type III) resulted in nonimmune fetal hydrops and oligohydramnios at 17 weeks' gestation.

Case Reports

Pregnancy complicated by chronic cardiomyopathy and an automatic implantable cardioverter defibrillator 506
Jeanna M. Piper, MD, Michael Berkus, MD, and Louis E. Ridgway III, MD
San Antonio, Texas

We describe a successful pregnancy outcome in a patient with chronic dilated cardiomyopathy and malignant arrhythmias that required an automated implantable cardioverter defibrillator.

Repeated external cephalic version at term 508
Doron J.D. Rosen, MD, Jeffrey S. Illeck, MD, and Jeffrey S. Greenspoon, MD
Los Angeles, California

External cephalic version was performed three times at term for spontaneous reversion to breech.

Congenital deficiency of α-fetoprotein 509
Frank Greenberg, MD, Andrew Faucett, MS, Esmie Rose, PhD, Lisa Bancalari, MS, Nataline B. Kardon, MD, Gerald Mizejewski, PhD, James E. Haddow, MD, and Elliot Alpert, MD
Houston, Texas, Flushing and Albany, New York, and Scarborough, Maine

Congenital deficiency of α-fetoprotein in two otherwise normal infants suggests that this condition is a benign trait analogous to analbuminemia.

Successful pregnancy outcomes after amniotic fluid embolism 511
Steven L. Clark, MD
Salt Lake City, Utah

After near-fatal amniotic fluid embolism, two patients underwent recurrent uneventful pregnancy and delivery.

Hepatotoxicity with the administration of nifedipine for treatment of preterm labor 512
George F. Sawaya, MD, and Patricia A. Robertson, MD
San Francisco, California

Hepatotoxicity possibly caused by the administration of nifedipine for the treatment of preterm labor is reported in a previously healthy primiparous woman.

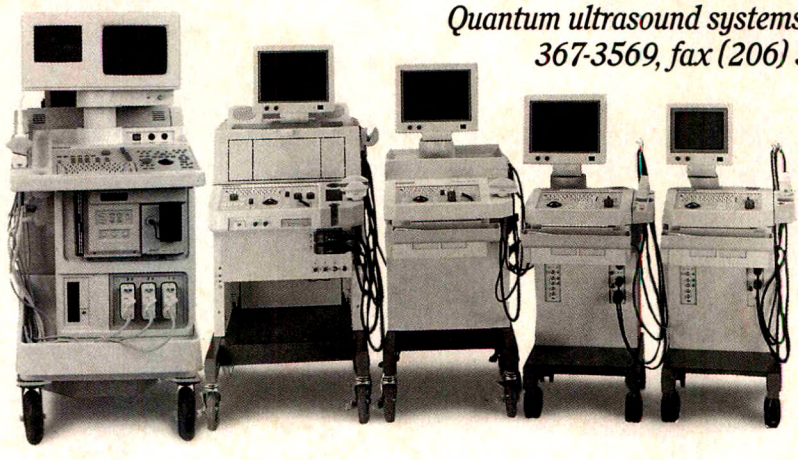
You Have All Kinds Of Reasons To Stay At The Forefront Of Ultrasound.

We Have The Technology To Keep You There.



In offices, clinics and hospitals worldwide, Siemens Quantum is changing the way doctors look at their patients.

Our imaging systems and state-of-the-art diagnostics are pushing the limits of ultrasound. Providing more and better information at every level. Performing more types of obstetric and gynecologic studies than ever before.

The Siemens Quantum alliance joins two powerful forces: Siemens, the world's largest medical imaging company, and Quantum, a pioneer and technological leader in ultrasound.

Together, we're committed to maintaining our leading edge. Which means keeping our systems—and our customers—at the forefront of diagnostic imaging.

The Siemens SONOLINE® SI-200 & 250 are versatile, affordable, compact and easy to use.

And they come with the most advanced, multi-frequency, patient-friendly endovaginal probe on the market.

The Siemens SONOLINE® SI-450 offers superb image quality and a comprehensive set of reports and measurement packages. For complete transabdominal, endovaginal and spectral Doppler capabilities, there's no better equipment for the price.

The Quantum 2000 is a high-performance, high-end, all-purpose system that's unsurpassed for high-definition gray scale and ultra-sensitive color flow. Its advanced technology lets you see subtle differences in tissue, accurately image the tiniest flows, and detect even the smallest details at depth.

To receive more information on Siemens Quantum ultrasound systems, call 1-800-367-3569, fax (206) 391-9161, or write us at 1040 12th Ave. N.W., Issaquah, WA 98027.

Effects of sustained hypoxemia on the sheep fetus at midgestation: Endocrine, cardiovascular, and biophysical responses 531
Yoshio Matsuda, MD, John Patrick, MD, Lesley Carmichael, BSc, John Challis, PhD, and Bryan Richardson, MD
Kagoshima, Japan, and London, Ontario, Canada

The sheep fetus at midgestation demonstrates minimal change in cardiovascular and biophysical activity in response to sustained hypoxemia with progressive acidemia.

Intracellular calcium and the signaling mechanism of luteinizing hormone–releasing hormone in rat granulosa cells 541
Jian Wang, PhD, Gillian L. Steele, MSc, Kenneth G. Baimbridge, PhD, Marie R. Rodway, PhD, and Peter C.K. Leung, PhD
Vancouver, British Columbia, Canada

Rat granulosa cells respond to luteinizing hormone–releasing hormone with a single transient increase in intracellular Ca^{++}, which appears to be a result of its release from intracellular stores.

Comparative analysis of normal and growth-retarded placentas with phosphorus nuclear magnetic resonance spectroscopy 548
Helen H. Kay, MD, Saralyn R. Hawkins, MD, John D. Gordon, MD, Yuping Wang, MD, Anthony A. Ribeiro, PhD, and Leonard D. Spicer, PhD
Durham, North Carolina

Phosphorus nuclear magnetic resonance spectroscopic analysis demonstrates differences between normal placentas and growth-retarded placentas of unknown cause, which may represent response to hypoxia.

Electrocortical activity, electroocular activity and breathing movements in fetal sheep with prolonged and graded hypoxemia 553
Bryan S. Richardson, MD, Lesley Carmichael, BSc, Jacobus Homan, BSc, and John E. Patrick, MD
London, Ontario, Canada

Chronic induced fetal hypoxemia must approach the level at which acidemia becomes apparent before a marked change in fetal behavioral activity is noted.

An immunochemical and immunocytologic study of the increase in myometrial gap junctions (and connexin 43) in rats and humans during pregnancy 559
Thomas Tabb, MD, Gisela Thilander, VMD, Ashok Grover, PhD, Elliott Hertzberg, PhD, and Robert Garfield, PhD
Galveston, Texas, Hamilton, Ontario, Canada, and Bronx, New York

Gap junctions were shown to be significantly elevated in rat myometria during term and preterm birth and also in humans during late pregnancy with antibodies to connexin 43 for immunocytochemistry and immunoblots.

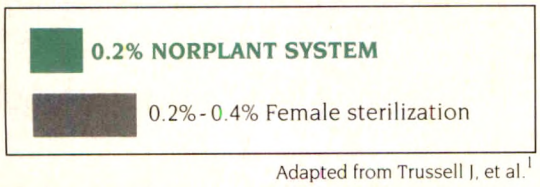
NORPLANT® SYSTEM

levonorgestrel implants



Six reasons why you can feel comfortable recommending it to your patients

Effectiveness comparable to tubal ligation

Although no contraceptive is 100% effective, the NORPLANT SYSTEM is one of the most effective forms of birth control ever developed. The average annual gross pregnancy rate over a five-year period is less than 1%.

Lowest expected and typical failure rates with NORPLANT SYSTEM vs. sterilization during first-year use[1]

Adapted from Trussell J, et al.[1]

Long-term convenience... estrogen-free

NORPLANT SYSTEM, a progestin-only contraceptive, is an excellent option for women desiring a long-term method. Its effectiveness lasts for five years and is not dependent on compliance.

Reversible, with prompt return to previous level of fertility

NORPLANT SYSTEM is reversible at any time; the contraceptive effect ceases when the capsules are removed. In one study, 40% of women wanting to conceive did so within 3 months of removal, 63% by 6 months, 76% by 12 months, and 90% by 24 months.[2]

High patient acceptance despite menstrual pattern changes

NORPLANT SYSTEM causes menstrual irregularities (the most common complaint),* which occur in many women during first-year use and diminish over time. Only 9.1% of patients discontinued during first-year use due to these changes.[3†]

Women who are thoroughly informed of potential menstrual changes and side effects are more tolerant of them when they occur.[4]

Well-received, well-liked by American women

One study of 140 users revealed that 94% were satisfied with NORPLANT SYSTEM, 91% recommended it to their friends, and 74% wanted to use it again.[5]

A 10- to 15-minute office procedure

A local anesthetic and a small 2 mm incision...little or no discomfort during insertion...proper placement should not leave a noticeable scar...in most cases sutures are not needed.

*Serious as well as minor side effects may occur (see prescribing information).

† Based on multicenter trials of 2,470 women.

Please see brief summary of prescribing information on adjacent page.

NORPLANT® SYSTEM
levonorgestrel implants

Lasts 5 years...yet is reversible

COLLEGE OF MEDICINE LIBRARY

NORPLANT® SYSTEM

levonorgestrel implants

Lasts five years…yet is reversible

BRIEF SUMMARY OF PRESCRIBING INFORMATION. CONSULT THE PACKAGE LITERATURE FOR FULL PRESCRIBING INFORMATION.

Indications and Usage

The NORPLANT SYSTEM is indicated for the prevention of pregnancy and is a long-term (up to 5 years) reversible contraceptive system. The capsules should be removed by the end of the 5th year. New capsules may be inserted at that time if continuing contraceptive protection is desired.

Contraindications

1. Active thrombophlebitis or thromboembolic disorders. 2. Undiagnosed abnormal genital bleeding. 3. Known or suspected pregnancy. 4. Acute liver disease; benign or malignant liver tumors. 5. Known or suspected carcinoma of the breast.

Warnings

A. WARNINGS BASED ON EXPERIENCE WITH THE NORPLANT SYSTEM

1. *Bleeding Irregularities* — Most women can expect some variation in menstrual bleeding patterns. Irregular menstrual bleeding, intermenstrual spotting, prolonged episodes of bleeding and spotting, and amenorrhea may occur, and could mask symptoms of cervical or endometrial cancer. Overall, these irregularities diminish with continued use. Because amenorrhea may occur, missed menstrual periods cannot serve as the only identifier of early pregnancy. Perform pregnancy tests whenever pregnancy is suspected. If pregnancy occurs, the capsules must be removed. Hemoglobin concentrations found in clinical trials generally indicated that reduced menstrual blood loss is associated with NORPLANT SYSTEM use. Blood loss resulting in hemoglobin values consistent with anemia occurred rarely.

2. *Delayed Follicular Atresia* — Atresia of the follicle is sometimes delayed, resulting in enlarged follicles that are clinically indistinguishable from ovarian cysts. In the majority of women, enlarged follicles disappear spontaneously. Rarely, they twist or rupture and surgical intervention may be required.

3. *Ectopic Pregnancies* — Ectopic pregnancies have occurred among NORPLANT SYSTEM users, although clinical studies have shown no increase in the rate of ectopic pregnancies per year among NORPLANT SYSTEM users as compared with users of no method or of IUDs. The incidence among NORPLANT SYSTEM users (1.3 per 1000 woman-years) was significantly below the rate estimated for noncontraceptive users in the U.S. (2.7 to 3.0 per 1000 woman-years). Ectopic pregnancy risk may increase with duration of NORPLANT SYSTEM use and increased weight of the user. Rule out ectopic pregnancy in any patient presenting with lower-abdominal pain.

4. *Breast-feeding* — Steroids are not the contraceptives of first choice for lactating women. Levonorgestrel has been identified in breast milk. Limited data suggests no significant effects on infant growth or health when mothers used the NORPLANT SYSTEM beginning 6 weeks after parturition.

5. *Foreign-body Carcinogenesis* — Rarely, cancers occur at foreign-body intrusion sites or old scars. None has been reported in NORPLANT SYSTEM clinical trials and risk to users is judged to be minimal.

6. *Thromboembolic Disorders* — Remove capsules if active thrombophlebitis or thromboembolic disease develops. With prolonged immobilization removal should be considered.

B. WARNINGS BASED ON EXPERIENCE WITH COMBINATION (PROGESTIN PLUS ESTROGEN) ORAL CONTRACEPTIVES (OCs)

Note: Many of the side effects or risks listed below are thought to be estrogen-related; the association of the NORPLANT SYSTEM progestin-only method to these risks is unknown.

1. *Cigarette Smoking* — Cigarette smoking increases the risk of serious cardiovascular side effects from combined OC use. Risk increases with age and heavy smoking (≥15 cigarettes/day) and is quite marked in women over 35 years old.

2. *Elevated Blood Pressure* — Increase in blood pressure has been reported in combination OC users; prevalence increases with long exposure.

3. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease is associated with combination OC use. Estimate of relative risk is 4- to 11-fold higher for users vs. nonusers.

Cerebrovascular Disorders: Combination OCs increase the relative and attributable risk of cerebrovascular events (thrombotic and hemorrhagic strokes). Generally, risk is greatest among hypertensive women > 35 years of age who smoke.

Myocardial Infarction (MI): An increased risk of MI has been attributed to combined OC use. This is thought to be primarily thrombotic in origin and related to the estrogen component. Increased risk occurs primarily in smokers or women with other underlying risk factors for coronary-artery disease. Relative risk of heart attack for combined OC users is estimated as 2 to 6 times that for nonusers. Absolute risk is very low for women under 30 years old.

Studies indicate a significant trend toward higher MI and stroke rates with increased progestin doses in combination OCs. However, recent data indicated no increased MI risk with past use of levonorgestrel-containing OCs.

4. *Carcinoma* — Recent evidence in the literature suggests no association between OC use and increased risk of breast cancer in the overall population of users. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on breast cancer risk for at least a decade following long-term use. Some of these same studies have shown an increased relative risk of breast cancer in certain subgroups; no consistent pattern has been identified. Some studies suggest an association between combination OCs and an increase in the risk of cervical intra-epithelial neoplasia in some populations of women. The extent to which such findings may be due to differences in sexual behavior and other factors remains controversial. A cause-and-effect relationship between combined OC use and breast or cervical cancer has not been established. Combination OCs may decrease ovarian and endometrial cancer risk. Irregular bleeding patterns associated with NORPLANT SYSTEM use could mask cervical or endometrial cancer symptoms.

5. *Hepatic Tumors* — Hepatic adenomas are associated with combination OC use; estimated incidence is 3 events per 100,000 users per year. Risk increases after 4 or more years of use. Hepatic adenomas are benign but may rupture and cause death through intra-abdominal hemorrhage.

6. *Ocular Lesions* — Retinal thrombosis is associated with OC use and is believed to be related to the estrogen component. However, NORPLANT SYSTEM capsules should be removed if there is unexplained partial or complete vision loss; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Undertake appropriate diagnostic and therapeutic measures immediately.

7. *Use Before or During Early Pregnancy* — Extensive epidemiological studies reveal no increased risk of birth defects when OCs are used prior to pregnancy. Studies also do not suggest a teratogenic effect when taken inadvertently during early pregnancy. No evidence suggests that risk with NORPLANT SYSTEM use is different.

8. *Gallbladder Disease* — Early studies reported an increased lifetime relative risk of gallbladder surgery in OC or estrogen users. More recent studies, however, indicate that the relative risk of gallbladder disease with OC use may be minimal; this may be related to use of OCs with less estrogen and progestin content.

Precautions

GENERAL

1. *Physical Examination and Follow-up* — A complete medical history and physical examination should be taken prior to implantation or reimplantation of NORPLANT SYSTEM capsules and at least annually during its use. Exams should include special reference to the implant site, blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. Rule out malignancy in cases of undiagnosed, persistent or recurrent abnormal vaginal bleeding. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. *Carbohydrate Metabolism* — Altered glucose tolerance is found in some combination and progestin-only OC users. Effects of NORPLANT SYSTEM on carbohydrate metabolism appear minimal. Observe diabetic and prediabetic patients carefully while using the NORPLANT SYSTEM. Follow women being treated for hyperlipidemias closely if using the NORPLANT SYSTEM. Some progestins may elevate LDL and may render control of hyperlipidemias more difficult. (See **Warnings**.)

3. *Liver Function* — Consider removing capsules if jaundice develops. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. *Fluid Retention* — Steroid contraceptives may cause some degree of fluid retention. Prescribe with caution, and careful monitoring, in patients with conditions possibly aggravated by fluid retention.

5. *Emotional Disorders* — Consider removing capsules if significant depression occurs since the symptom may be drug-related. Observe carefully those with history of depression and consider removal if depression recurs to a serious degree.

6. *Contact Lenses* — Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. *Insertion and Removal* — Insertion is advised during the first 7 days of the cycle or immediately following abortion to insure that the woman is not pregnant and to assure contraceptive effectiveness during first cycle of use. Capsules may be inserted at any time during the cycle provided pregnancy has been excluded and a nonhormonal contraceptive method is used for the remainder of the cycle. Insertion is not recommended before 6 weeks postpartum in breast-feeding women. Follow insertion and removal instructions closely. Healthcare professionals are strongly advised to be instructed in the procedures before they attempt them. Proper insertion just under the skin facilitates removals; proper insertion and removal should result in minimal scarring. If all capsules cannot be removed at first attempt, attempt removal later when the site has healed. Bruising may occur at implant site during insertion or removal. Hyperpigmentation may occur over implant site but is usually reversible following removal. **See Full Prescribing Information for Detailed Insertion/Removal Instructions.**

8. *Infections* — Implant site infection has been uncommon (0.7%); aseptic technique and proper insertion/removal reduces possibility of infection. Institute treatment if infection occurs; remove capsules if infection persists.

9. *Expulsion* — Expulsion of capsules was uncommon; frequency increased when capsule placement was extremely shallow, was too close to incision, or when infection was present. Replace expelled capsule with new sterile capsule. Treat and cure any infection before replacement. Contraceptive efficacy may be inadequate with fewer than 6 capsules.

10. *Provisions for Removal* — Advise women that capsules may be removed at any time for any reason. Personnel instructed in removal technique should perform removal on request or at the end of 5 years of usage. Upon removal, dispose of capsules in accordance with Centers for Disease Control Guidelines for biohazardous waste.

DRUG INTERACTIONS: Reduced efficacy (pregnancy) in NORPLANT SYSTEM users has been reported when phenytoin or carbamazepine were used concomitantly. Warn NORPLANT SYSTEM users of possible decreased efficacy with use of related drugs.

DRUG/LABORATORY TEST INTERACTIONS: 1. Sex-hormone-binding globulin concentrations are decreased. 2. Thyroxine concentrations may be slightly decreased and triiodothyronine uptake increased.

CARCINOGENESIS: See **Warnings** section and Full Prescribing Information.

PREGNANCY: Pregnancy Category X. See **Warnings** section and Full Prescribing Information.

NURSING MOTHERS: See **Warnings** section and Full Prescribing Information.

INFORMATION FOR THE PATIENT: See Patient Labeling. Provide copy of patient labeling to the patient. Advise patients that Prescribing Information is available upon request. Inform prospective users of risks and benefits associated with NORPLANT SYSTEM use, with other forms of contraception, with no contraception, and about insertion/removal procedures. Informed consent from all patients may be desired in light of techniques involved with insertion and removal.

Adverse Reactions

The following have been associated with the NORPLANT SYSTEM during first year of use: many bleeding days or prolonged bleeding (27.6%); spotting (17.1%); amenorrhea (9.4%); irregular (onsets of) bleeding (7.6%); frequent bleeding onsets (7.0%); scanty bleeding (5.2%); pain or itching near implant site - usually transient - (3.7%); infection at implant site (0.7%); removal difficulties affecting subjects - based on 849 removals - (6.2%).

Controlled clinical studies suggest that the following, occurring during the first year, are probably associated with NORPLANT SYSTEM use: headache; nervousness; nausea; dizziness; adnexal enlargement; dermatitis; acne; change of appetite; mastalgia; weight gain; hirsutism, hypertrichosis, and scalp-hair loss. The following were reported with a frequency of 5% or greater during the first year and possibly may be related to NORPLANT SYSTEM use: breast discharge; cervicitis; musculoskeletal pain; abdominal discomfort; leukorrhea; vaginitis.

Overdosage

Overdosage may cause fluid retention with its associated effects and uterine bleeding irregularities.

Dosage and Administration

The NORPLANT SYSTEM consists of six Silastic® capsules, each containing 36 mg of the progestin, levonorgestrel. The total administered (implanted) dose is 216 mg. Implantation of all six capsules should be performed during the first 7 days of the onset of menses by a healthcare professional instructed in the NORPLANT SYSTEM insertion technique. Insertion is subdermal in the midportion of the upper arm about 8 to 10 cm above the elbow crease. Distribution should be in a fanlike pattern, about 15 degrees apart, for a total of 75 degrees. Proper insertion will facilitate later removal. **(See Full Prescribing Information for Detailed Insertion/Removal Instructions.)**

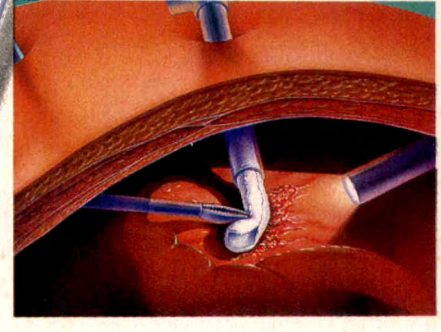
Endo-Avitene™

Microfibrillar Collagen Hemostat in an Endoscopic Delivery System.

Avitene® Microfibrillar Collagen Hemostat (MCH) is now packaged ready for use in a unique delivery system designed for endoscopic procedures. This 100% collagen topical hemostat:

- eliminates risk of thermal damage.
- adheres tenaciously to the bleeding site.
- allows for the easy removal of excess by irrigation and suction.
- is effective in controlling delayed bleeding.
- is absorbable.



The Endo-Avitene device makes delivery and application of Avitene MCH to the bleeding site easy. Simply insert the delivery system through a 10 mm trocar sheath and deliver Avitene MCH directly to the bleeding site. Avitene MCH is positioned using a unique blunt plunger tip that can be used to apply pressure during placement.

MCH potentiates the clotting mechanism by attracting platelets.

We control bleeding. We reduce risk. And we deliver.

Contact us to arrange a demonstration. We'll supply the Endo-Avitene device free of charge. Call us today, and we'll deliver: 1-800-451-4716 (in Massachusetts, 617- 938-9328).

Endo-Avitene, for use in endoscopic procedures.

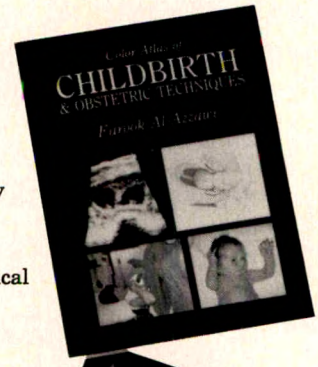
Important subject.
Important hands-on methodology.

Exceptional skills are born of exceptional training. And there are none better than skills gained on a live, pregnant patient. For the last decade, we've emphasized not only the *how* of the science of ultrasound, but also the *why* behind each technique.

We offer comprehensive training seminars in abdominal, vascular, obstetric/pelvic, and cardiac ultrasound. And, for your convenience, our seminars are held in major cities across the United States as well as at our modern new facility in the Dallas area. We offer a variety of two-, three-, and five-day programs at reasonable fees. Classes are roughly half theory and half intensive hands-on training. Class size is strictly limited, and postconference support is free to our guests--*forever.*



All of our seminars are SDMS-approved for CEUs. Call KMA 24 hours a day for a free information kit that tells you about us and any of the twenty different seminars we conduct regularly. For exceptional abdominal/obstetric/pelvic imaging, put your hand in our hands. Just call (214) 402-8250.

Hands-On Abdominal Imaging
July 20-24, Sept 14-18, Nov 2-6, Dallas.
Advanced Abdominal Imaging Interpretation
July 24-25, Dallas.
Advanced Obstetric/Pelvic Imaging Interpretation
July 31-August 1, Dallas.
Hands-On Obstetric/Pelvic Imaging
July 27-31, Sept 21-25, Nov 9-13, Dallas.
Hands-On Abdominal/Pelvic Doppler
July 27-29, Dallas.

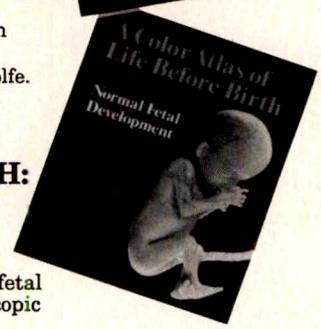
VIVIDLY ILLUSTRATED:
Fetal Development and Childbirth



New!
A COLOR ATLAS OF CHILDBIRTH AND OBSTETRIC TECHNIQUES
Farook Al-Azzawi, MBChB, MA, MRCOG

- Uses step-by-step, high quality photographs, diagnostic ultrasound images, and line artwork to bridge the gap between the textbook and clinical practice.
- Covers normal labor, complications, twins, and the three main types of caesarean section.

1991. 144 pages, 341 ills. MYB-Wolfe. (Book Code: 06287)

COLOR ATLAS OF LIFE BEFORE BIRTH: Normal Fetal Development
Marjorie A. England

- Depicts the stages of normal fetal development from its microscopic beginning to its final form at birth.
- Detailed illustrations include 710 full color photographs.

1990. 216 pages, 767 ills. MYB-Wolfe. (Book Code: 20326) Paper.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors (N Engl J Med 1991;324:424-8). Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern and southeastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. J. Peter Van Dorsten, P.O. Box 34, MCV Station, Richmond, VA 23298.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's suggested reviewers. When authors submit their manuscripts, they must provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. If not completed in full, it will be returned to the author for completion. The copyright statement and checklist form may be torn from the JOURNAL or photocopied for submission.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) or some of the same authors has been previously published in any medium that deals in any respect whatsoever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article(s) or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. Two copies of a new manuscript being prepared for possible publication also must be submitted. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and nonhuman experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the

requisite authority. Human experimentation that requires local institutional approval must have this approval *before the experiment is started* and approval must be so indicated in the *Material and Methods* section of the submitted manuscript. Reports of experiments on nonhuman animals or other species must *state in the* Material and Methods *section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The type of nonhuman animals or other species used in an investigation must be named in the title, abstract, key words, and *Material and Methods* section of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. *In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.*

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of black-and-white glossy prints of illustrations are required. See "Color figures" and "Computer-generated figures" for special requirements. Manuscripts must be submitted in English.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. *At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).*

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page including key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Below the abstract, list 3 to 5 *key words or short phrases* for indexing purposes.

A structured abstract is required for certain types of articles and a *standard abstract format* is required for other types of articles; therefore the author(s) should select and prepare the appropriate abstract to be used in the submitted manuscript. This applies to both independently submitted and society manuscripts.

Structured abstract. A structured abstract, limited to 150 words, is to be used for regular articles and society articles; excluded are Clinical Opinion, Current Development, case report, and brief communication articles. The structured abstract is to contain the following major headings: *Objective(s); Study Design; Results;* and *Conclusion(s).* The *Objective(s)* reflects the purpose of the study, that is, the hypothesis that is being tested. The *Study Design* should include the setting for the study, the subjects (number and type), the treatment or intervention, and the type of statistical analysis. The *Results* include the outcome of the study and statistical significance if appropriate. The *Conclusion(s)* states the significance of the results.

Standard abstract. The standard abstract format is required for Clinical Opinion, Current Development, case report, and brief communication articles. The standard abstracts for Clinical Opinion and Current Development articles are to be 50 to 150 words and standard abstracts for case reports and brief communications are limited to 50 words. Even though the formal names of these four types of articles are not used, an author should determine his/her type of manuscript and prepare the appropriate standard abstract, regardless of whether it is to be submitted independently or as a part of a society's transactions.

Text. Do not hesitate to write your manuscript in the first person and active voice if they are more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through *Comment* section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

Council of Biology Editors Style Manual or the AMA's *Manual of Style.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify *Material and Methods, Results,* and *Comment.* Authors may wish to summarize their findings in a short paragraph at the end of the *Comment* section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to repeat the study) the plan, the patients, experimental animals or other species, material, and controls, the methods and procedures utilized, and the statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare your observations with those of others. Such comparisons and comments are reserved for the *Comment* section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the *Results* section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (N Engl J Med 1991;324:424-8). Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. *This signed permission must accompany the manuscript when it is submitted to the Editor.* Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page if the color balance is appropriate.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should follow the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed together in numeric order double-spaced on one sheet of paper (or more if necessary) separate from the text of the manuscript. This page must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from *the copyright owner and original author* along with complete reference information. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for certain types of manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include *standard abstract format*, of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Clinical Opinion. Limit of 3000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include *standard abstract format* of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. *Letters to the Editors* must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name[s] and address[es] of the signer[s], and the phrase "To the Editors"). The submitted *Letter to the Editors* must be accompanied by a signed copyright statement. If there are two or more signers of the *Letter to the Editors,* one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all cosigners." These requirements apply to all types of *Letters to the Editors.* Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A *Letter to the Editors* commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a *Letter to the Editors* will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (1-800-325-4177, ext. 4306, or 314-453-4306).

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The completed checklist is enclosed. The assignment of copyright signed by **all** authors accompanies the manuscript.
—Human experimentation has been approved by the local institution as stated in the *Material and Methods* section.
—Guidelines for the care and use of *nonhuman* animals or *other species* approved by the institution have been followed as indicated in the *Material and Methods* section. *The species is named in the title, abstract, key words, and* Material and Methods *section.*
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed in English double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, structured or standard abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any coauthors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author and/or some of the coauthors have previously published, have submitted for possible publication, or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities, differences and explanation are provided in the covering letter that accompanies the submitted manuscript.

Reviewers

—Names and addresses of three suggested reviewers are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title.
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than United States in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the institutional affiliation(s) of the author(s) at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract and key words or short phrases

—The abstract (structured or standard format) is typed double-spaced with required margins on page 3 headed by the title and author(s) name(s). Beneath the abstract 3 to 5 key words or short phrases are typed.
—A *structured abstract,* with 150 words or less, is submitted as required for regular articles and society regular-type articles. The abstract contains the four required major headings: Objective(s), Study Design, Results, and Conclusion(s), each with a brief adequate presentation.
—A *standard abstract* is submitted as required for Clinical Opinion and Current Development articles with 50 to 150 words and for case reports and brief communications articles with a maximum of 50 words, be they independent or society articles.

References

—Are typed double-spaced.
—Are numbered consecutively in the order they are cited in the text.
—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors have been followed.
—Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Figures

—Each is numbered with an Arabic numeral and cited in numeric sequence in the text.
—Three sets of unmounted glossy prints for *black-and-white* figures are submitted, properly numbered, labeled, and *top indicated* on the back of each print.
—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back and *top indicated* are submitted. None are dot matrix or photographic prints.
—Original transparencies of *color photographs* appropriately numbered and identified and *top indicated* are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

Figure legends

—Are provided for each figure.
—Are numbered and typed together in numeric order on one sheet of paper (more if necessary). The page is numbered in sequence after the References page(s).

Tables

—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.
—Tables are cited in numeric sequence in the text.

AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

COPYRIGHT STATEMENT

Must be signed by ALL authors

"The undersigned author(s) transfers all copyright ownership of the manuscript entitled

to Mosby–Year Book, Inc., in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. Teenage pregnancy prevention: The vital importance of the medical community's involvement

Presidential address

Willette L. LeHew, MD
Norfolk, Virginia

Prevention is an active process creating conditions and fostering personal attributes that promote the well-being of people. As physicians who are influential in our communities and states, who are experts in the health care field, and who provide primary and specialty care for the majority of female teenagers, we must take a more active advocacy role in teenage pregnancy prevention if we are going to be successful in reducing this devastating medical and social problem.

We all know that adolescent sexuality is complex and that solutions for preventing pregnancies must be multifaceted, and, although each state's efforts are unique, there is clearly a collective sense of what needs to happen in our states to make a difference. Our strategic efforts must include public awareness events, media campaigns, and family life education and health services in our schools, with a strong emphasis on family planning. In all of these we must encourage family-based communication about sexuality. Today I will briefly outline the problems that most of you are aware of and suggest some solutions that I hope you will take back to your community and state to be used in preventive efforts.

Any successful solution in teen pregnancies will also greatly affect and reduce school dropouts, substance abuse, poverty, and crime as these elements increasingly seem to have a synergistic effect. One study[1] estimated that one in four children aged 10 to 17 were at risk for at least one of the following: teenage pregnancy, failing in school, abusing drugs, or becoming delinquent. And at least one in nine were at risk for all of these things happening to them at once. Therefore we need to promote comprehensive, community-based initiatives that help combat these problems and increase young people's community involvement.

We must refocus our main efforts from the futility of providing services to babies already born with birth defects and severe prematurity and providing life-long welfare payments to teen mothers unable to work and live independently to more positive preventive steps. To do this, we must remind ourselves, and convince others, that teen pregnancy continues at epidemic proportions and realize that no mass disorder that has ever affected mankind has been brought under control by attempts to treat already afflicted persons one by one.

We must then focus our energies, thinking, and resources on prevention by concentrating on several general areas. The first is delaying and reducing high-risk sexual behavior. The second is promoting contraception and contraceptive use. The third is using our school systems more efficiently for providing health and education about sexuality. Finally, we must promote programs providing meaningful alternatives to pregnancy. These programs must gain wide support

Presented at the Fifty-fourth Annual Meeting of The South Atlantic Association of Obstetricians and Gynecologists, Palm Beach, Florida, January 26-29, 1992.

from the medical community; local, state, and federal government; businesses; and the church community to be successful. We must also place this issue on the agenda of our state and local medical societies and our specialty societies.

More specific categories of prevention would be to encourage adolescents to abstain from sexual activity, to include more programs involving and targeting teenage boys, to support family life education, to support comprehensive health services in our schools, to encourage greater involvement of individual practitioners with their teenage pregnancies, and to obtain greater availability of contraceptive services for adolescents. After relating a few facts about the scope of the problem, I will discuss several of these specific areas where the medical community should be most influential and effective.

I would encourage each of you to learn your current community and state's statistics on total teen pregnancies, abortions, and live births and their comparison to other areas. Your health department or teen pregnancy council will be happy to supply you with these facts.

One very disturbing fact is that the percentage of teen births outside of marriage increased by 61% nationwide between 1970 and 1988, and in fact in 1988 two thirds of the births to teenagers in this country were illegitimate.[2] For our five states during this period the rate in Virginia increased by 26%, in North Carolina by 34%, in South Carolina by 49%, in Florida by 86%, and in Georgia by 87%.

Teenagers establishing families is particularly troubling because of the high probability that families headed by unwed mothers will spend some and perhaps most of their lives in poverty. In fact, there is increasing evidence that having children at a young age is a major barrier to ever escaping the cycle of poverty that seems to be both a cause and consequence of teenage pregnancy. Statistically, <50% of teen mothers finish high school and only about 2% complete college.[3] People do not choose to be poor. Their choices, however, can keep them so.

Early childbearing has a number of other significant negative consequences. The offspring of teenagers are at increased risk for numerous health problems, including birth defects, low weight at birth, a high infant death rate, and many serious intrapartum problems. These children are also at substantial risk for lower intellectual and academic achievement, social behavior problems, and becoming teenage parents themselves. In essence, these young mothers who are unskilled, unschooled, and inexperienced are creating a very large number of our new families.

The significance of new families from teen birth is a particularly severe problem in our states.[3] In 1988 South Carolina was ninth in the country with new families begun with a teenage mother, Georgia was twelfth, North Carolina fourteenth, Florida twenty-second, and Virginia twenty-eighth. These new families contribute tremendously to the dollars we spend for teenage childbearing each year for aid to families with dependent children, food stamps, and Medicaid. In the last year for which figures are available,[4] the fiscal year 1986 through 1987, these amounts were $378 million dollars in Florida, $355 million in Georgia, $332 million in North Carolina, $198 million in Virginia, and $132 million in South Carolina. Specifically, in Virginia we have about 55 teenage pregnancies per day with 80% of them to unwed mothers.[5]

Virginia spent $198 million dollars in 1987 to support families that resulted from adolescent pregnancies and $126 million in 1988 to support the 8150 first birth babies born to teen mothers, or an average of $15,500 per baby. If we could have prevented 1% of the pregnancies that resulted in first birth babies that year, we could have saved $1,270,000 in 1988 and approximately $2 million in 1989. Also, just imagine what impact we could have with just 10% of the above amounts if it were used for prevention. Keep these figures in mind when you speak to your elected officials.

Specifically, there are several areas where your support and influence are most important. To have a significant impact, preventive programs must begin with very young children at a stage where the likelihood of developing strong socialization, communication, decision making, goal setting, and social resistant skills is the keenest. In this regard, one of our most important preventive programs is family life education, and we can be proud that our states all have a mandated policy for this in our public schools. In Virginia, Georgia, and North Carolina this begins in kindergarten and continues through at least the eighth grade.[6] Unfortunately, in Florida and South Carolina it is only mandated in the sixth, seventh, and eighth grades. I would encourage those of you from those two states to work to get this moved back to start in kindergarten.

When you consider the influence of the popular media on children's attitudes, the age of the onset of puberty, and the surmounting peer pressure to exploit sexual feelings associated with puberty, you will understand the importance of starting this program in kindergarten. Another important reason to begin early is the fact that the age of sexual initiation appears to be decreasing, as evidenced by the growing number of pregnancies in girls under the age of 15 and the estimate that in 1988 78% of adolescent girls and 86% of adolescent boys were sexually active by the age of 20. A more recent survey by the Centers for Disease Control showed that 40% of ninth graders were sexually active, and by the twelfth grade this figure was up to 72%.

Saying "no" and postponing sexual intercourse until a person is emotionally and psychologically ready is a value that should be the foundation of any family life education program. However, we must emphasize the well known fact that such a program has no impact on the behavior and attitude of students already sexually active at the start of the program. Therefore another essential part of family life education is information about contraception. Such information is inclusive in the programs in Virginia, Florida, and Georgia, but in North and South Carolina its inclusion is under local control of each community, which means great inconsistency as to its effectiveness.

In answering critics of family life education, we can assure them that the main purposes and objectives of any family life education programs are the promotion of positive health practices, critical thinking, learning to say "no," and avoiding risk-taking behavior and building skills in communication, responsible decision making, and assertiveness.

Schools cannot and should not replace the role played by family and religion in values education, but they can reinforce positive attitudes and behavior and counteract negative influences on the students.

Medical care to our teenagers provided by our schools and provided by us as health care providers can have a great impact on teenage pregnancy. Many teenagers, particularly the poor and minorities, have few resources to address their health needs because of inadequate health insurance, poor health care utilization, and a fragmented delivery system.[7] In the ideal situation comprehensive health care programs could respond with the health information and preventive care needs unmet by society. Such programs would have a high utilization rate because they are confidential, user friendly, and convenient.

Unfortunately, the status of school health care services in our states seems as fragile as the health of those they are designed to serve. We all have inadequate funding, inadequate school health personnel, and few opportunities for primary preventive care and health promotion activities. To be effective this is what we should strive for our school programs to be. First, there should be a comprehensive state health program that sets minimum standards for practice in all school districts. Second, adequate health care personnel with orientation, training, and health-related sources should be available in all the schools. Third, a school health advisory board for each community should monitor and evaluate the effectiveness of such programs. Finally, a commitment from the medical communities is needed to support and nurture these programs.

In our own specialty improved cooperation and communication with pediatricians and family physicians would improve the effectiveness of health care for adolescents, and of course, because of earlier sexual activity, the need is more urgent than it has ever been. One survey of college freshman showed that 78% had never received any counseling on sexually-transmitted diseases from their primary care physician and 70% had received no counseling on contraception.[8] As primary care providers and specialists, we should consider education regarding sexuality and sexually-transmitted diseases and counseling about contraception an essential part of our care for all teenagers. Adolescents should continually be queried about sexual activity and if they are sexually active, their sexual practices, feelings about sex, understanding of, and concern about the risk of pregnancies and sexually transmitted diseases, including acquired immune deficiency syndrome, should be discussed. In this setting confidentiality, empathy, and a nonjudgmental attitude are extremely important. Isn't it tragic when one of our patients needs treatment for a sexually transmitted disease or unplanned pregnancy because we did not take the time to present this information?

Our most urgent need in teen pregnancy prevention is greater availability of contraceptive services for adolescents, because accessible contraceptive availability is the only strategy documented to show a direct impact on teenage pregnancies. The real problem is that it is more comfortable for communities and parents to focus on abstinence rather than to work with sexually active adolescents to increase their access to contraceptive care. It is very clear from the literature that providing contraceptives will prevent pregnancy and not promote or encourage sexual promiscuity and that withholding contraception will not prevent sexual activity. These facts have been known for some time, which makes it hard to believe that the entire United States family planning program is funded only at about $130 million annually when the government could triple this investment for the cost of a single Stealth bomber.[9]

We must also work to overcome the numerous reasons teenagers do not use contraception. The most important is the lack of motivation to prevent an unplanned pregnancy, but other reasons, including real and perceived barriers to health care, fear of specific methods, hesitancy to reveal sexual activity, and the sense of invulnerability that teenagers have.

Teen pregnancy prevention is a very complex problem that requires overcoming a number of roadblocks if we are going to be successful. We must respond with the facts to the belief by some that adolescent pregnancy is an issue that affects minorities and the poor and does not merit policy makers' attention and by responding to the belief that adolescent sexuality should be addressed only in the home. We must also overcome the very organized but small vocal group of parents and

community members who oppose comprehensive family life education, school-based health centers, and the provision of contraceptives to teenagers. To do this we must rapidly widen advocacy efforts and community support.

Unfortunately, adolescent pregnancy prevention has not been a "frontburner" issue for state policy and budget makers, so we must constantly remind them to pay now for the prevention of at risk behavior or pay later as we do now with an ill-equipped work force, crowded prisons, and increased expenses for welfare, Medicaid, drug rehabilitation, and treatment and law enforcement programs.

In conclusion, I hope this address will challenge each of you to become more vocal and perhaps outraged about the lack of attention to prevention efforts by our federal, state, and local governments. We must join with these bodies to give the problem of adolescent pregnancy visibility and make its prevention a priority. Individually, we must offer contraceptive advice and services as part of our care for adolescents and encourage and educate our pediatric and family practice colleagues to do the same. Collectively, in each state we must support a statewide council on teen pregnancy prevention and support an extensive network of individuals and organizations working together at all levels of government. We must encourage innovative reforms in the welfare system, such as was recently passed in New Jersey where they voted to reduce or eliminate welfare benefits to able bodied recipients whose children are over 2 and who refuse to work or go to school and to deny additional benefits other than medical care to women already on welfare who have additional children. To be effective, a coordinated system must be developed to meet the health, social, and educational needs of teenagers, both male and female, and must include increasing the life options available to them and increasing their capacity to make decisions, particularly in the area of sexuality. Even in this recession we must seek these services and resources and convince our legislatures that prevention is much cheaper in the long run than the treatment of the consequences of inadequate programs.

Attenuated proestrous luteinizing hormone surges in middle-aged rats are associated with decreased pituitary luteinizing hormone-β messenger ribonucleic acid expression

Barbara B. Hogg, BA, Dennis W. Matt, PhD, and Timothy E. Sayles
Richmond, Virginia

OBJECTIVE: This study determined whether attenuated preovulatory luteinizing hormone surges in aging rats are associated with a decrease in pituitary luteinizing hormone content or luteinizing hormone β-messenger ribonucleic acid expression on proestrus.
STUDY DESIGN: Blood samples were taken every 90 minutes from 1:30 to 10:30 PM on proestrus in young (n = 8) and middle-aged (n = 12), regularly cyclic rats for plasma luteinizing hormone determination. On the next proestrus at 12 noon, rats were killed and the pituitaries were removed for luteinizing hormone content determination by radioimmunoassay and luteinizing hormone β-messenger ribonucleic acid expression by dot blot analysis. Results were analyzed by one-way analysis of variance.
RESULTS: Seven of the middle-aged rats had attenuated luteinizing hormone surges while the remaining five females had surges similar to those of young rats. On the next proestrus, all rats had similar quantities of pituitary luteinizing hormone. However, luteinizing hormone β-messenger ribonucleic acid expression in middle-aged rats with attenuated luteinizing hormone surges was lower ($p < 0.05$) than that of middle-aged and young rats with normal surges.
CONCLUSION: Decreased luteinizing hormone β-messenger ribonucleic acid expression, but not pituitary luteinizing hormone content at 12 noon on proestrus is correlated with attenuated luteinizing hormone surges in middle-aged rats. (AM J OBSTET GYNECOL 1992;167:303-7.)

Key words: Luteinizing hormone, luteinizing hormone β-messenger ribonucleic acid expression, female reproductive aging, pituitary, ovulation

Aging in the female rat is characterized by a progressive loss of regular estrous cyclicity and reproductive function.[1-4] During middle age (10 to 12 months), the estrous cycle patterns of female rats change from regular 4-day cycles to irregular, extended cycles (≥6 days).[5] These irregular cycles are characterized by extended periods of vaginal cornification reflecting sustained estrogen release.[5] After a transitional period of irregular cyclicity, female rats display sustained cornified vaginal epithelium and enter the anovulatory condition described as persistent estrus.

Although the neuroendocrine mechanisms associated with the age-related loss in regular ovulatory cyclicity are currently unknown, previous studies have revealed that the proestrous luteinizing hormone (LH) surges are attenuated in some middle-aged rats.[6-8] Furthermore, female rats with attenuated proestrous LH surges cease to display regular estrous cyclicity within 2 months, whereas rats of similar age with normal LH surges continue to cycle regularly beyond 2 months.[9] Thus changes in neuroendocrine function can be identified in aging rats before the loss of regular estrous cyclicity.

The following experiments were conducted to investigate further the possible alterations in the hypothalamic-pituitary axis of the aging female rat, alterations that are associated with the loss of regular estrous cyclicity and ovulatory function. To determine if attenuated LH surges are related to decreases in pituitary LH synthesis, these studies examined the relation between the magnitude of the proestrous LH surge and pituitary LH content and LH-β gene expression in young and middle-aged rats.

Material and methods

Animals. Young (4 months) virgin and middle-aged (10 to 12 months) retired breeder female Long-Evan rats (Charles River Lab, Wilmington, Mass.) were maintained under standard laboratory conditions at room temperature (23° to 25° C) with a lighting schedule of

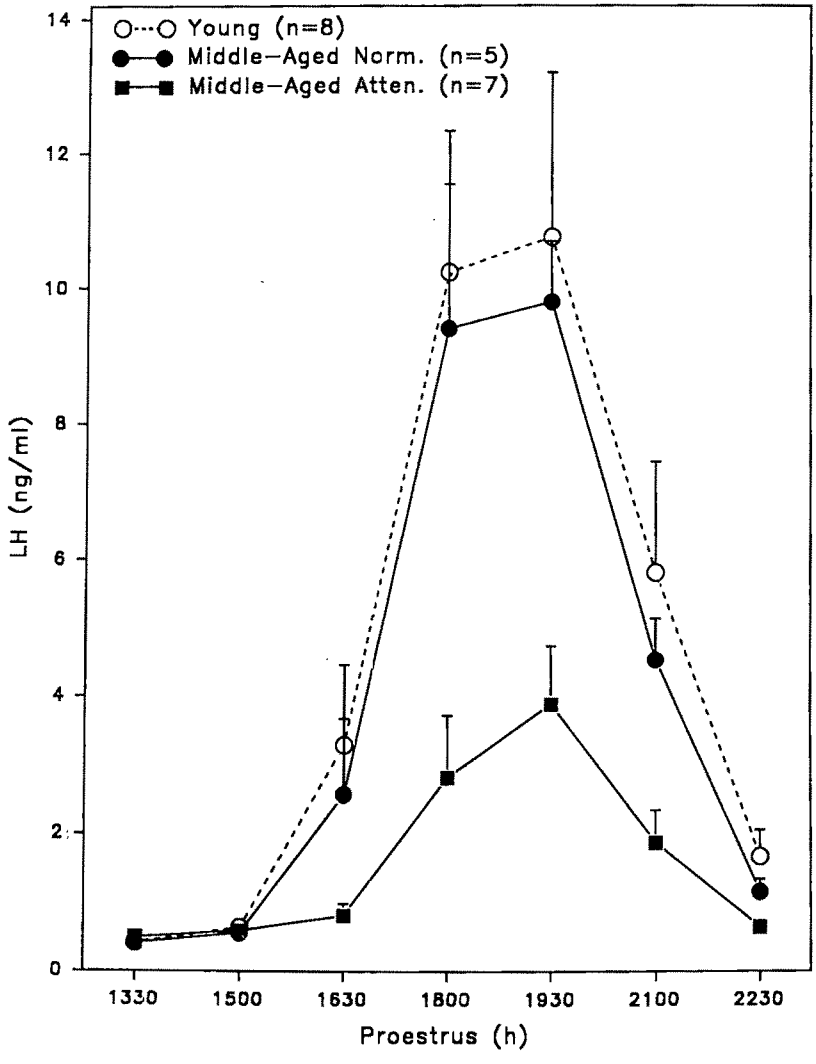

Fig. 1. Patterns of LH secretion in young *(open circles)* and middle-aged female rats from 1:30 PM *(1330 hours)* to 10:30 PM *(2230 hours)* on proestrus. Middle-aged females demonstrating peak LH values of >7 ng/ml were considered to have normal LH surges *(solid circles)*, whereas those middle-aged rats with peak LH values of <7 ng/ml were designated attenuated *(solid squares)*.

lights on from 5 AM to 7 PM daily. Food and water were available as desired. Daily vaginal smears were taken to monitor estrous cyclicity. Only animals demonstrating at least three consecutive 4-day estrous cycles were used for these studies. Guidelines for the care and use of these animals have been approved and followed in these experimental studies.

Experimental design. Groups of middle-aged (n = 12) and young (n = 8) regularly cycling rats were implanted with jugular vein catheters on diestrous day 2 between 10 AM and 1 PM according to the methods of Harms and Ojeda.[10] After this procedure, the rats were housed in individual cages, and on the next day, proestrus, blood samples were collected at 90-minute intervals from 1:30 to 10:30 PM for plasma LH determination by radioimmunoassay.

At 12 noon on the following proestrus, rats were killed by decapitation and the anterior pituitaries were rapidly removed, frozen, weighed, and stored at −80° C. At the time of assay, frozen pituitaries were thawed and sonicated in 300 μl of 0.01 mol/L phosphate-buffered saline solution (pH 7.5) for LH content determination and total ribonucleic acid (RNA) isolation. Before RNA extraction a small aliquot (20 μl) of homogenate was removed for determination of pituitary LH content. Total RNA was isolated by acid-guanidinium-thiocyanate-phenol-chloroform extraction followed by alcohol precipitation as previously described.[11]

Dot blot analysis. Total RNA (5 μg) from each pituitary was denatured and transferred to a Nytran nylon membrane through a 96-hole dot blot apparatus (Schleicher & Schuell, Keene, N.H.). To avoid differ-

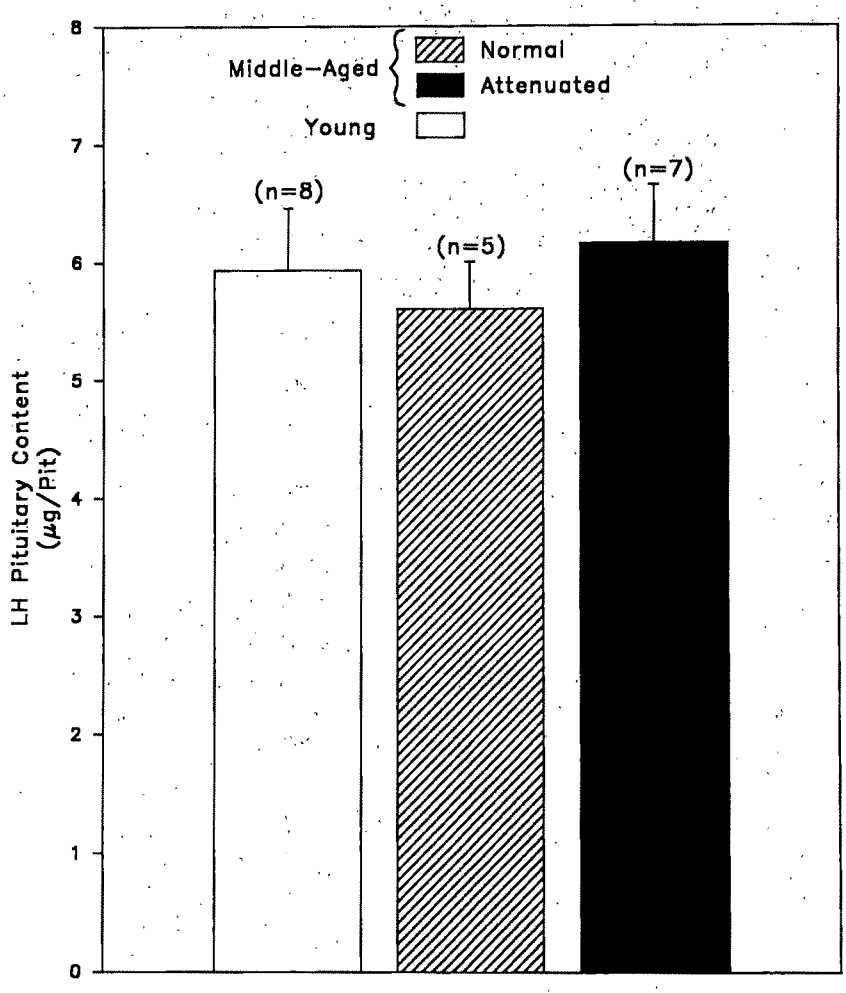

Fig. 2. Pituitary LH content at 12 noon in young *(open bar)* and middle-aged rats with previously normal *(striped bar)* or attenuated *(solid bar)* proestrous LH surges.

ences between dot blots, all samples from young and middle-aged rats were immobilized on one dot blot. Dot blots of standard dilutions of pooled pituitary RNA were also performed to verify linearity within the ranges of dot blot absorbances. The RNA dot blot was sequentially hybridized with denatured phosphorus 32–labeled deoxycytidine–labeled rat LH-β (kindly provided by Dr. W.W. Chin, Harvard Medical School) and chicken β-actin (kindly provided by Z.E. Zehner, Medical College of Virginia). Verification of each complementary deoxyribonucleic acid probe was determined by Northern blot analysis. The densitometric absorbance level of the dot blot autoradiographs was quantitated by laser densitometry. The relative absorbance of each sample as defined by the integrated hybridized area was expressed relative to that sample's β-actin absorbance to control for variation in RNA loading and transfer.

Hormone and data analysis. Quantitation of rat LH in plasma and pituitary homogenates was conducted by radioimmunoassay with reagents provided by the National Hormone and Pituitary Program. All LH values are expressed relative to the reference standard National Institute of Arthritis, Diabetes, Digestive and Kidney Diseases rat LH-RP-2. Intraassay and interassay coefficients of variation calculated from pools of plasma were 8% and 12%, respectively.

Comparisons in the levels of pituitary LH contents and messenger RNA (mRNA) expression were performed by one-way analysis of variance, followed by the Newman-Keuls post hoc test for multiple comparisons when appropriate. A value of $p < 0.05$ or less was considered statistically significant.

Results

Proestrous plasma LH profiles. Fig. 1 illustrates the patterns of the plasma LH levels in young and middle-aged rats on the afternoon and evening of proestrus. Young females had proestrous LH surges that reached a maximum of 10.75 ± 2.46 ng/ml (mean ± SEM) at 7:30 PM. In these studies middle-aged rats with a peak LH level that was <7 ng/ml were considered attenuated

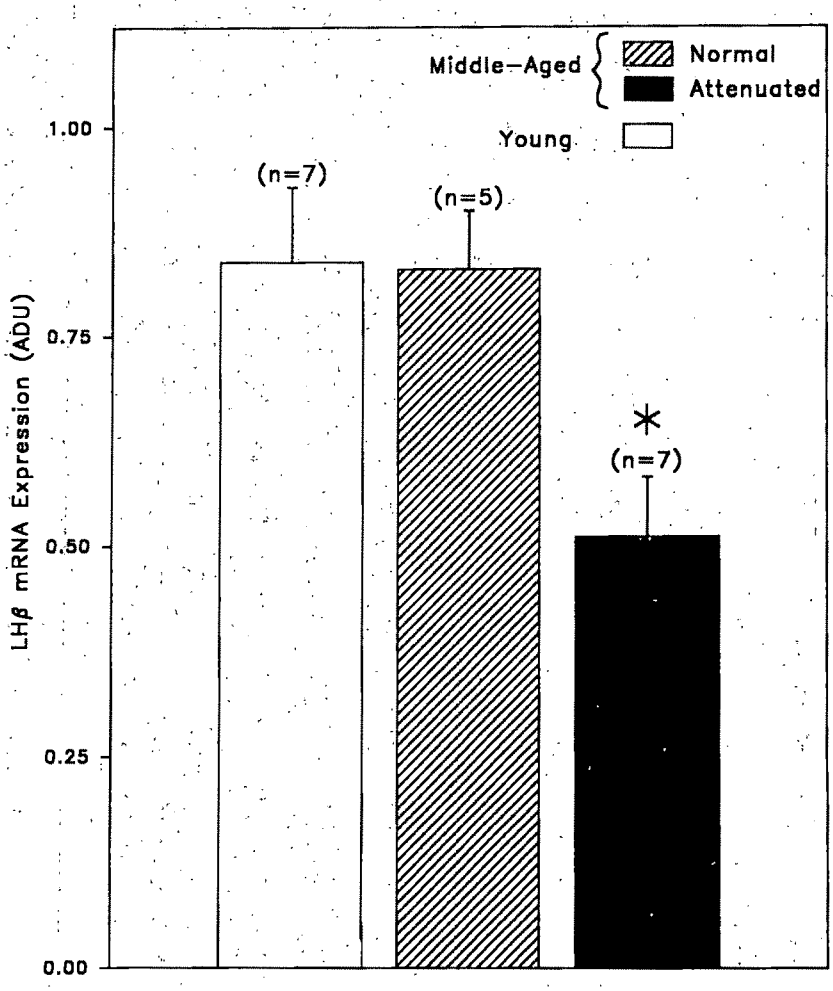

Fig. 3. Pituitary LH-β mRNA gene expression in young and middle-aged rats with previously normal or attenuated proestrous LH surges. Legend is same as for Fig. 2. *Asterisk*, $p < 0.05$ as compared with young and middle-aged normal rats.

whereas those with LH values >7 ng/ml were selected as normal. Five of 12 middle-aged rats had proestrous LH surges similar to those of young rats, reaching a maximum of 9.79 ± 0.90 ng/ml at 7:30 PM. The remaining seven middle-aged rats had markedly attenuated LH surges, which reached peak levels of only 3.87 ± 0.85 ng/ml at 7:30 PM.

Pituitary LH content. Fig. 2 illustrates the pattern of pituitary LH content in young and middle-aged rats on the following proestrus. The LH content of middle-aged rats with previously normal LH surges was 5.60 ± 0.41 μg per pituitary, similar to that of young rats (5.93 ± 0.53 μg per pituitary). Furthermore, the pituitary LH content of middle-aged rats with previously attenuated LH surges (6.17 ± 0.49 μg per pituitary) was similar to that found in both young and middle-aged rats with previously normal LH surges.

Pituitary LH-β mRNA expression. Fig. 3 illustrates the pattern of LH-β mRNA expression in young and middle-aged rats on the following proestrus. The relative mRNA expression of the LH-β subunit was similar in young rats (0.84 ± 0.09 arbitrary densitometric units) and middle-aged rats with previously normal LH surges (0.83 ± 0.07 arbitrary densitometric units). However, the relative expression of LH-β mRNA was markedly decreased ($p < 0.05$) in middle-aged rats with previously attenuated LH surges (0.51 ± 0.07 arbitrary densitometric units).

Comment

The present study characterized the relation in the magnitude of the proestrous LH surges in young and middle-aged rats to the pituitary LH content and LH β-subunit gene expression in the same animals at 12 noon on the subsequent proestrus. We hypothesized that the attenuated LH surges in middle-aged rats were related to decreased quantities of pituitary LH on proestrus. The results have demonstrated that the pituitary LH content is similar in young and middle-aged rats regardless of the magnitude of the LH surge. Thus it would appear that there are adequate quantities of LH for release in middle-aged rats with attenuated LH

surges. We further hypothesized that the attenuated surges were related to a decrease in pituitary LH synthesis. It is generally believed that the availability of the β-subunit is rate limiting for assembly and synthesis of this gonadotropin, whereas the common α-subunit is in excess.[12] This, in conjunction with the consensus that regulation of LH synthesis is at the transcriptional level,[12-14] indicates that measurement of LH-β mRNA expression may reveal differences in LH synthesis in middle-aged rats. Interestingly, the present study revealed that pituitary LH-β mRNA expression is decreased in middle-aged rats with attenuated LH surges before the onset of the surge. This may indicate several intriguing possible explanations that will require further investigation. The first possibility is that only the recently synthesized LH is available for release on proestrus. It has long been demonstrated that there are "releasable" and "nonreleasable pools" of pituitary LH.[15] Therefore, it is possible that in middle-aged rats with attenuated LH surges there is a limited amount of LH in the releasable pool, and this may be directly related to the quantities of newly synthesized LH β-subunits. Expression of LH-β mRNA is regulated by gonadotropin-releasing hormone (GnRH), which must be delivered to the pituitary at an appropriate frequency and amplitude for maximal expression.[16] These findings, combined with evidence that GnRH pulsatile frequency and amplitude are altered during aging,[17] may indicate that middle-aged rats with attenuated LH surges have an impairment in hypothalamic GnRH release. In addition to GnRH, estrogen also appears to play a major role in LH synthesis and LH-β mRNA expression.[18] Previous studies have shown that middle-aged rats with attenuated proestrous surges have elevated circulating levels of estradiol.[9] These elevated concentrations of estradiol could impair hypothalamic GnRH release and pituitary LH synthesis.

In summary, the study has revealed that pituitary LH-β mRNA expression is decreased in middle-aged rats with attenuated LH surges. This may indicate that alterations occur in ovarian steroid production, hypothalamic GnRH release, or pituitary LH synthetic and release mechanisms resulting in attenuated LH surges at middle-age and heralding the cessation of ovulatory function. These intriguing possibilities await further investigations.

Outcome of corticotropin stimulation testing in women with androgen excess and ovulatory dysfunction

G. William Bates, MD, G. Martin French, MD, Betty B. Humphries, MN, and Dawn W. Blackhurst, MS

Greenville, South Carolina

OBJECTIVE: Our objective was to evaluate women with clinical signs or chemical evidence of androgen excess by corticotropin stimulation testing.

STUDY DESIGN: Seventy-six women with evidence of androgen excess were evaluated by corticotropin stimulation testing. Results were examined by plasma levels of dehydroepiandrosterone sulfate, androstenedione, and testosterone. Conception in those infertile women with androgen excess was also assessed. Data were evaluated with Fisher's exact test.

RESULTS: Of 41 women with dehydroepiandrosterone sulfate levels >2.8 μg/ml, 17 (41.5%) had a positive corticotropin stimulation test (stimulated 17α-hydroxyprogesterone value exceeded baseline value by 2.7 times). No statistically significant association was found between androstenedione or testosterone excess and a positive corticotropin stimulation test. In 14 infertile women with dehydroepiandrosterone sulfate levels >2.8 μg/ml and a positive corticotropin stimulation test, 7 (50%) conceived when given low-dose prednisone ($p < 0.005$).

CONCLUSION: Corticotropin stimulation testing is warranted in women with clinical signs of androgen excess and dehydroepiandrosterone sulfate levels >2.8 μg/ml. (Am J Obstet Gynecol 1992;167:308-12.)

Key words: Corticotropin stimulation testing

Congenital adrenal hyperplasia was described in 1865 by an Italian patholoist, de Crecchio; in the 1930s the measurement of adrenal metabolites in urine of newborn infants with genital ambiguity suggested that the condition resulted from a biosynthetic steroid defect.[1] With the development of radioimmunoassay procedures for the identification of specific steroids in the biosynthesis of cortisol permitted a more definitive diagnosis of congenital adrenal hyperplasia.[2]

In 1957 Decort et al.[3] reported patients who were seen during the peripubertal years with chronic anovulation and signs of androgen excess who had biochemical abnormalities similar to but less severe than those in congenital adrenal hyperplasia.[3] This condition was subsequently termed late-onset adrenal hyperplasia.[4] It is difficult to diagnose the late-onset form of adrenal hyperplasia because it can mimic polycystic ovarian disease.[5] However, it is important to differentiate late-onset adrenal hyperplasia from polycystic ovarian disease because appropriate treatment depends on the diagnosis of the underlying disorder.

In this study we report the results of corticotropin (ACTH) stimulation testing in 76 women with clinical signs of androgen excess to identify those women with late-onset adrenal hyperplasia and to treat them with low-dose prednisone.

Material and methods

From April 1, 1990, through March 31, 1991, ACTH stimulation testing was performed in 76 women for evaluation of infertility or androgen excess. Of the women tested, 48 were infertile due to ovulatory dysfunction only, 18 were infertile due to multiple factors, and 10 were evaluated for acne and hirsutism. The latter group of women was not interested in pregnancy at the time of evaluation. All women were evaluated initially by measurement of plasma follicle-stimulating hormone, luteinizing hormone, prolactin, androstenedione, testosterone, and dehydroepiandrosterone sulfate (DHEAS). ACTH stimulation tests were performed primarily in women who had DHEAS levels >2.8 μg/ml ($n = 41$), in women with androstenedione levels >280 ng/dl or testosterone levels ≥0.8 ng/ml ($n = 24$), and in women with unexplained clinical signs of androgen excess ($n = 11$).

Blood samples were obtained by venipuncture at random in women who had a history of chronic anovulation and on any day between cycle day 7 and 11 in women who gave a history suggesting ovulation. Hormones were measured by radioimmunoassay by SmithKline Beecham Clinical Laboratories of Atlanta, Georgia.

ACTH stimulation testing was performed at random

Table I. Concentrations of androgens

Variable	*No.*	*Mean ± SD*	*Range*
DHEAS (μg/ml)	76	2.83 ± 1.03	1.0-5.9

in anovulatory women and on any day between cycle day 7 and 11 in women who gave a history suggesting ovulation. ACTH stimulation testing was performed as follows: Subjects were given 1 mg dexamethasone orally at 10 PM the night before the ACTH stimulation test. Dexamethasone was administered to suppress adrenal glucocorticoid secretion. The following morning at 8 AM, a scalp vein needle was inserted in the forearm of each subject. A baseline sample of 7 ml blood was obtained. Immediately thereafter, 250 μg ACTH (Cortrosyn, Organon, W. Orange, N.J.) was injected over 30 seconds. A heparin flush was placed in the intravenous line. One hour later, a second sample of 7 ml of blood was obtained.

The serum of the two blood samples was separated from the red blood cells and assayed by radioimmunoassay for 17α-hydroxyprogesterone. Results were expressed in nanograms per deciliter. An ACTH stimulation test result was considered to be positive if the stimulated (1-hour sample) was 2.7 times greater than the baseline sample.

Infertile women with positive ACTH stimulation tests were placed on 2.5 mg prednisone daily at bedtime. Those women who did not wish to conceive were placed on oral contraceptives along with prednisone.

Data were evaluated with Fisher's exact test. Differences were considered to be statistically significant if $p < 0.05$.

Results

The mean concentrations of androgens measured and the mean ratios of ACTH stimulation tests are presented in Table I. Associations of androgen studies with ACTH stimulation test outcome are presented in Table II. No statistically significant differences were found between the proportions of women with positive ACTH stimulation tests and the parameters set for normal and abnormal androgen values. However, 41% of women with DHEAS >2.8 μg/ml had a positive ACTH stimulation test compared with only 29% of those with DHEAS ≤2.8 μg/ml.

A statistically significant association was found between ACTH stimulation test results and subsequent pregnancy in women who received low-dose prednisone. Ten of 25 (40%) women with a positive ACTH stimulation test conceived within 6 months of the initiation of 2.5 mg prednisone daily (Table III).

Reasons for ACTH testing by test result and pregnancy are presented in Table IV. In the 14 women with DHEAS levels >2.8 μg/ml who subsequently had a positive ACTH stimulation test, seven (50%) concevied compared with only 1 of 19 (5.3%) who had a negative test. All conceptions occurred within 6 months of the initiation of low-dose prednisone therapy.

Comment

The most likely causes of acne, hirsutism, and irregular menstrual cycles are polycystic ovarian disease and late-onset adrenal hyperplasia. The differential diagnosis can be approximated by history, physical examination, and measurement of plasma gonadotropins and androgens, but definitive diagnosis of late-onset adrenal hyperplasia requires demonstration of excess of precursor hormone and deficiency of product hormone

at the point of enzymatic abnormality. DHEAS is a steroid conjugate that is primarily the product of adrenal secretion. In conditions of adrenal enzymatic deficiency that cause late-onset adrenal hyperplasia, DHEAS is usually elevated. However, this hormone is not always found in excess in men and women with this condition; additional screening is required to establish a diagnosis of late-onset adrenal hyperplasia.[6]

ACTH stimulation testing is considreed to be the diagnostic test of choice to establish the diagnosis of late-onset adrenal hyperplasia. However, not all women with acne, hirsutism, or ovulatory dysfunction should undergo testing. The plasma concentration of DHEAS or 17α-hydroxyprogesterone is used as the discriminating test to indicate performance of an ACTH stimulation test.[7]

In recent years there has been much debate about the value of ACTH stimulation testing.[8, 9] Moreover, there are several methods for peforming this procedure.[10] In this study we set the lower limit of follicular phase plasma DHEAS concentration at 2.8 μg/ml for subsequent ACTH stimulation testing. This cutoff value was not a good discriminator because 10 women (29%) with DHEAS levels ≥2.8 μg/ml had a positive ACTH stimulation test. If we had chosen a higher level, e.g., 4.0 μg/ml, the predictive value of DHEAS would have been greater; however, several infertile women in this study (who subsequently conceived) would have carried the diagnosis of polycystic ovarian disease and would not have received low-dose prednisone therapy. Perhaps these women would have conceived without prednisone, yet it is tempting to conclude that their prompt conceptions were related to the diagnosis and treatment of late-onset adrenal hyperplasia.

When we performed ACTH stimulation tests in women with unexplained clinical signs of androgen excess or in women with DHEAS levels <2.8 μg/ml but with androstenedione >280 ng/dl or testosterone ≥0.8 ng/ml, we were unable to find an association with a greater number of positive ACTH stimulation tests. Only five women with an elevated androstenedione or testosterone but a DHEAS <2.8 μg/ml had a positive ACTH stimulation test. None of 11 women with unexplained androgen excess had a positive ACTH stimulation test.

From this study we conclude that women with clinical signs of androgen excess who have a midfollicular phase DHEAS level >2.8 μg/ml should undergo subsequent ACTH stimulation testing. This level of discrimination will identify women with mild, late-onset adrenal hyperplasia who may otherwise go undetected. If pregnancy is the desired outcome, administration of low-dose glucocorticoid suppression therapy may facilitate conception by normalizing the female reproductive cycle.

Discussion

Dr. Richard L. Wing, Charlotte, North Carolina. The author has studied a group of patients with either clinical or biochemical evidence of androgen excess. On the basis of a discriminatory DHEAS level <2.8 μg/ml, an ACTH stimulation test was performed. A positive ACTH stimulation test in this study identified women with mild, late-onset adrenal hyperplasia. With low-dose prednisone therapy a statistically significant number of these patients conceived compared with those whose stimulation test was negative. The author's comments suggest that ACTH stimulation testing in an androgenic group of patients would differentiate between late-onset adrenal hyperplasia and polycystic ovarian disease.

Gynecologists who treat infertility patients must answer this question: should an ACTH stimulation test be performed on the appropriate patient, and which one is appropriate? If late-onset adrenal hyperplasia is diagnosed, the treatment with low-cost, low-dose glucocorticoids could be used to help these patients conceive before proceeding to more expensive treatment protocols.

Measurements of testosterone, androstenedione, DHEAS, and 17α-hydroxyprogesterone have been shown to overlap in late-onset adrenal hyperplasia and in patients with other causes of hirsutism.[1] In 1982 Ayers[2] published a report on 38 patients who were separated into high and low DHEAS groups. After ACTH stimulation, the mean 17α-hydroxyprogesterone values in the high DHEAS group only doubled compared with the basal level. His study also concluded on the basis of DHEAS levels that two groups of patients with polycystic ovarian disease existed. The low DHEAS group represented the classic Stein-Leventhal polycystic ovarian disease type I patient. The elevated DHEAS group represented the polycystic ovarian disease type II patient whose adrenal steroidogenesis was thought to be under tonic hyperstimulation to maintain normal cortisol production. Adrenal suppression was considered to be the more physiologic therapy for the latter group.

Accurate diagnosis of late-onset adrenal hyperplasia has been obtained by the measurement of 17α-hydroxyprogesterone after ACTH stimulation.[3, 4] In this presentation the authors state that an ACTH stimulation test result was considered positive if the stimulated sample was 2.7 times greater than the baseline sample. Where are the data to suggest that 2.7 times the baseline 17α-hydroxyprogesterone value is a positive test for ACTH stimulation? Would the basal levels obtained in this study group serve as a discriminating test for ACTH stimulation? On the basis of the nomogram produced by New et al.,[3] how many of the patients in this study would be considered to have positive results by those criteria?

Glucocorticoids have been beneficial in the treatment of infertile patients with hirsutism and with polycystic ovarian disease.[5, 6] Steinberger et al.[7] reported a 44% pregnancy rate in infertile women treated with 7.5 mg prednisone. Zarate et al.[8] reported a 36% pregnancy rate. Rodriguez-Rigau et al.[9] used 5 to 10 mg prednisone daily and induced ovulation in five of 14 amenorrheic hirsute women and 10 of 11 anovulatory patients. Prednisone therapy in a dosage of 2.5 to 10.0 mg/day was used by Farris et al.[10] to treat patients with late-onset adrenal hyperplasia diagnosed only on an elevated 17-ketosteroid level >15 mg/24 hours. All 13 patients with infertility conceived. How many of the prednisone-treated patients were ovulating before treatment? How many of the nontreated patients were ovulating? This information would be helpful in analyzing this study's findings. It would also be of great interest to give prednisone therapy to all of the patients in the author's study group and to determine their pregnancy rate.

Other interesting observations would be to measure the level of suppression of 17α-hydroxyprogesterone, DHEAS, testosterone, and cortisol with a bedtime 2.5 mg prednisone dose.

The author has, in this study, found an association between ACTH stimulation test results and subsequent pregnancy in women who received low-dose prednisone. Future studies may benefit by establishing a control group with positive ACTH stimulation testing that is not treated with prednisone. Likewise, the negative ACTH stimulation group might also be divided into a treated and nontreated group.

Dr. Bates (Closing). I think that Dr. Wing has come to the nub of the issue in making the diagnosis of late-onset adrenal hyperplasia. That is how you do it and how you differentiate this disorder from polycystic ovarian disease. The debate continues to rage and I do not think it will be settled this morning.

There is a lot of overlap between polycystic ovarian disease and late-onset adrenal hyperplasia. We know that the ovary produces a small amount of DHEAS and can also produce elevated levels of androstenedione. It can be very confusing as to the source of these precursor hormones in androgen excess disorders. The way we attempt to make a diagnosis is to collectively stimulate the adrenal glands. There is no uniformity in the literature as to how this test is best performed. Azziz and Zacur[1] in 1989 performed intravenous ACTH stimulation testing over 1 hour. They set the limits for positive tests so stringently that only 2% of their patients had a positive ACTH test. On the other hand, Seigel et al.[2] reported in 1990 a positive ACTH stimulation test at a change from 100 to 300 ng/ml in the concentration of 17α-hydroxyprogesterone. They tested by doubling the amount of ACTH infused by bolus administration and obtained blood samples 30 minutes later. Therefore one of the difficulties we have is standardizing of the testing procedure and evaluating the test outcome.

We selected a value 2.7 times because in the few normal patients in whom we have done this test the ratio of 17α-hydroxyprogesterone, stimulated as compared with suppressed, is approximately 2, and two standard deviations from this mean falls at about 2.7 times. Because we are testing at 1-hour intervals we will not produce as high a stimulated 17α-hydroxyprogesterone value as would a test peformed at 30-minute intervals.

It is also well known that the pregnancy rate is variable if you administer low-dose glucocorticoid therapy to women with polycystic ovarian disease. Perhaps the mechanism for this is to suppress the overall androgen milieu and to allow normal ovulatory function. Forty-one women in our study were ovulating. These women have been infertile for a long time and many have luteal phase defect, as diagnosed by low progesterone levels and shortening of the luteal phase of their menstrual cycle.

It would be nice to have a control group in this study. It is very difficult, though, in the private practice of infertility to establish a control group and alter their therapy. These are women who have been infertile for a long time and they have experienced the failure of not conceiving over a long period of time, but I do agree that it would be nice to have a randomized study and have a placebo versus a low-dose progesterone group.

Finally, congenital adrenal hyperplasia is probably the most widely studied metabolic disease. It is well known that the genetic disorder is carried on the short arm of chromosome six and the localization of this gene has been identified. Some authors have performed a number of studies and have isolated the gene for 21-hydrolase activity. It is known that a shift in the base paranucleotides from A to C or A to G will produce this disorder. Moreover, a shift in the exon isolating this gene from others will also produce late-onset adrenal hyperplasia. Approximately 1% of people in the United States carry this deficient gene. Approximately 5% of Ashkenazi Jews in eastern Europe carry this genetic disorder. Therefore it is a very common disorder. A specific diagnosis can be made by deoxyribonucleic acid hybridization but that is as yet not available in clinical practice.

Etiologic factors of recurrent abortion and subsequent reproductive performance of couples: Have we made any progress in the past 10 years?

Leo Plouffe, Jr., MD, Evelyn W. White, MD, Sandra P. Tho, MD, Craig S. Sweet, MD, Lawrence C. Layman, MD, Gail F. Whitman, MD, and Paul G. McDonough, MD
Augusta, Georgia

OBJECTIVES: We hypothesize that the diagnostic yield and pregnancy outcomes of patients with recurrent abortion have improved over the past 10 years.
STUDY DESIGN: The study was performed in an academic medical center. Diagnoses and outcomes for group A, a published series of 100 patients investigated for recurrent abortion in the section between 1968 and 1977, was compared with those for group B, the 131 patients seen between 1987 and 1991. A standardized protocol was followed, enhanced by new techniques and autoimmune investigations in the latter group. Results were compiled retrospectively. Descriptive statistics and χ^2 analysis were used.
RESULTS: No cause could be found in 37% of patients in group A compared with 24% of couples in group B ($p < 0.05$). No clear difference could be shown in the subsequent outcomes of pregnancies.
CONCLUSIONS: Our ability to establish a cause of recurrent abortion has improved slightly over the past 15 years. The gain is not yet reflected in successful pregnancy rates. Multicenter trials are indicated. (Am J Obstet Gynecol 1992;167:313-21.)

Key words: Recurrent abortion, pregnancy outcome, autoimmune disease

Diagnosis and management in the couple with recurrent abortion are still among the most difficult areas in reproductive medicine.[1] Uterine anomalies and balanced chromosomal rearrangements in parents are the only two universally accepted etiologic factors in humans. Corpus luteum defect, associated ovulatory disorders, and incompetent cervix are considered by most as likely causes. Many changes have occurred in this field over the past 10 years. The technology available for the workup of patients has improved. Autoimmune disorders have also gained broad acceptance as etiologic factors. The role of infections, alloimmune disorders, elevated gonadotropins and androgens, on the other hand, are still under debate.[2]

We have previously reported on a series of 100 couples with recurrent abortion studied during the period from 1968 through 1977.[3] In 37 of these couples no specific etiologic factor could be established. The purpose of the current report is to establish the diagnostic yield of an updated diagnostic protocol applied to a group of 131 couples seen from 1987 through 1991. These results were compared with those of our previously published series to see whether we have improved in our ability to make a diagnosis in couples with recurrent abortion. The outcomes of pregnancies are also assessed.

Material and methods

All the couples included in this study were seen in the Reproductive Endocrinology Section at the Medical College of Georgia. Patients seen from 1968 through 1977 are referred to as group A and were described in a previous report.[3] Group B patients included all patients first seen for recurrent abortion between July 1, 1987, and June 30, 1991. In both groups couples were eligible if they had two or more documented abortions or one abortion associated with a phenotypically abnormal child. In group A documentation of the abortion was histologic whereas in group B it could be based on either histologic evidence or ultrasonography.

Patient population. All couples were referred to our section from gynecologists in Georgia and surrounding states because of a history of recurrent abortion or abortions with a malformed child. A small number of these couples were self-referred or were seen for prenatal genetic counseling, at which time the abortion history was discovered. Nearly all patients benefited from comprehensive health care insurance coverage.

During our first study period we were involved in an outreach genetic program. Most of the couples with a phenotypically abnormal child were enrolled through this pathway. This was not the case in the recent series. From 1987 to 1990 we were involved in a National Institutes of Health (NIH) multicenter study in the management of autoimmune pregnancy loss. Patients referred to our unit for inclusion into this clinical trial were excluded from the current study. Only three patients from the current study were randomized to one of the treatment protocols from the NIH trial.

All the patients were advised to avoid pregnancy and use mechanical contraception during the evaluation period. A full medical history, including a thorough genetic evaluation, was obtained, followed by a complete physical examination. Patients were routinely screened for systemic disease, including thyroid dysfunction. Anyone with a history of alcoholism and substance abuse was excluded from the study.

Cytogenetic studies. Karyotypes were obtained on all couples. Banding resolution has improved between our first and second series. In all cases a minimum of 20 cells were counted with at least two being karyotyped. Further studies, including ultra-high-banding resolution, were performed whenever a karyotype was under question. When a balanced translocation was found in either parent, the couple was counseled as to its prognosis and the necessity for prenatal diagnosis.[4, 5]

Structural studies of the uterus. All women were offered a hysterosalpingogram unless pregnant at the time. For group A patients, any intracavitary defect that was demonstrated on hysterosalpingography was further delineated through gynecography. Metroplasty was performed when appropriate. For group B patients, the initial study consisted of either a hysterosalpingogram or hysteroscopy. Pregnant patients underwent an ultrasonographic study in an attempt to identify any mullerian anomaly. Any abnormal hysterosalpingogram was followed by a hysteroscopy laparoscopy, as judged appropriate. Resection of uterine septa and intrauterine synechiae was performed through the hysteroscope. Incompetent cervical os was suspected on historic information and confirmed by vigilant cervical examination during pregnancy.

Endocrine function. Dating of all endometrial biopsy specimens was done by the authors with established criteria.[6] All patients with one abnormal biopsy specimen were strongly encouraged to have a repeat biopsy. Two out-of-phase biopsy specimens were required to make a definitive diagnosis of corpus luteum defect.[7] A single anovulatory biopsy specimen and a compatible clinical history were required to make the diagnosis of an ovulation disorder.

The endocrine function of patients in group A was determined by basal body temperature readings and timed endometrial biopsy. The biopsies were performed with rigid metal cannulas. Women with secretory biopsy specimens showing a discrepancy in endometrial development of ≥3 days were treated with preimplantation progesterone vaginal suppositories.[8] Those displaying markedly heterogeneous biopsy specimens or proliferative endometrium were treated by a combination of clomiphene citrate and progesterone vaginal suppositories. In group B the same approach was most often enhanced by determination of ovulation with home urinary luteinizing hormone (LH) testing, ultrasonographic follicular monitoring, and estradiol and progesterone assays. Endometrial biopsies were almost exclusively obtained with a flexible plastic cannula (Pipelle). Treatment protocols were individualized and consisted of progesterone vaginal suppositories, clomiphene citrate, dexamethasone, and human menopausal gonadotropin, in various combinations.[8]

Autoimmune studies. Autoimmune studies were not performed on any patient in group A. All of the patients in group B underwent evaluation for anticardiolipin antibodies (ACA), antiphosphatidylserine antibodies (PS), and lupus anticoagulant (LAC). Levels of immunoglobulins M and G were measured with a modified Loizou enzyme-linked immunosorbent assay with the control population consisting of normal first- and second-trimester pregnancy values.[9] All these tests were performed in the same laboratory coordinated through the NIH multicenter trial (Dr. Susan Cowchock, Thomas Jefferson University, Philadelphia). The results were converted to multiples of the median and interpreted as negative (<2), low (2 to 3), mid (3.1 to 4), or highly positive (>4). The LAC assay was performed according to standard technique, in our own laboratory, on any patient with an elevated activated partial thromboplastin time. Any test with an abnormal result was repeated at least once to confirm a true-positive finding. Mid or highly positive ACA or PS antibodies or a positive lupus anticoagulant test was considered as evidence for a probable autoimmune cause. Included in the same category were patients with an established diagnosis for systemic lupus erythematosus or other advanced autoimmune disease. Low ACA or PS antibodies were labeled as possible autoimmune etiologic factor.

All couples in this category were offered randomization in the NIH multicenter trial.[9] Those who declined were still offered one of the treatment protocols. Treatment protocols included no treatment, 80 mg daily of aspirin alone, 80 mg daily of aspirin with subcutaneous heparin every 12 hours, or 80 mg of aspirin and 20 mg of prednisone twice daily.

Alloimmune studies. No alloimmune study protocol was available during the 1968 to 1977 period. For

Table I. Identified etiologic factors in group B (n = 131)

	Total
Unknown	22 (17%)
Incomplete workup/no etiologic factor	19 (15%)
Probable	72 (55%)
Balanced translocation in one parent	3 (2%)
Müllerian anomaly	2 (2%)
Significant uterine anomaly	13 (10%)
Incompetent cervix	3 (2%)

Other	5 (4%)
Hypothyroidism	11 (8%)
Hyperprolactinemia	10 (8%)
Diabetes	0
Minor ovulation disorder	14 (11%)
Infection	1 (1%)

Note: The same patient may have more than one diagnosis so that the subtotals exceed 131. The total equals 131.

patients in group B the available data about alloimmune etiologic factors in recurrent abortion was discussed.[10, 11] Couples were offered testing in the form of histocompatibility antigen typing followed by mixed lymphocyte cross-reactivity testing. Most couples declined this on financial grounds. Those individuals who underwent testing and were found to be positive were referred to outside centers for further evaluation and treatment but continued to undergo follow-up by our unit.

Other tests. The role of infection in recurrent abortion is highly debated.[12, 13] Patients in group A in whom no cause could be found were empirically treated with antibiotics. By contrast, patients in group B were evaluated through cervical cultures and a serum complement fixation assay for antichlamydial antibodies. Only those women with positive cultures or with high antibody titers (≥1:32) were treated.

During the 1987 through 1991 study period, several reports have appeared about the role of prolactin disorders, elevated LH, or elevated androgens in recurrent pregnancy loss.[14, 15] These were obtained liberally in patients presenting with suggestive histories and measured by radioimmunoassay. Women with elevated prolactin levels on the initial screen had a repeat study performed in a fasting state in the morning. If confirmed, computed tomographic or magnetic resonance imaging studies were obtained. If indicated, therapy was initiated with oral bromocriptine.

Management. Once all identifiable factors were corrected, patients were encouraged to achieve pregnancy. All couples were then allowed to conceive and to have postimplantation progesterone supplementation for up to 60 days of pregnancy. Other appropriate treatments were administered and monitored throughout the pregnancy.

Data analysis. Standard descriptive statistics were used for the analysis of our data accumulated between 1987 and 1991. Patients are counted only once and their further pregnancies are considered as outcome events only. Patients were grouped into five groups as listed in Table I. Confidence intervals were determined by the confidence interval for a population proportion within the same group and by the confidence interval for the difference between two population proportions formulas. A χ^2 analysis was also performed where appropriate.

Results

From 1968 through 1977 100 couples met the criteria for eligibility into the study. Thirteen of these couples were ascertained because of a history of one malformed child and at least one abortion. Because this particular subgroup was recruited through our genetic program, they will be excluded from the comparative study, leaving 87 couples from group A. During the 1987 through 1991 period, 131 couples were elevated for a history of two or more recurrent abortions.

Demographic data are not available for group A. The average age of women in group B was 30.0 years, with a range of 18 to 44. There were 108 white and 23 black women. The total number of pregnancies per patient ranged from two to eight. Eighty-seven women had no previous term pregnancy, 35 had one previous term

delivery, and nine had two or more term deliveries. Seventy-five patients had a pure history of loss, including stillbirths and ectopic pregnancies. This constitutes a group referred to by many as primary aborters. Consecutive pregnancy losses occurred in 116 of the couples, although they were interspersed in 16. The most common occurrence was one term delivery followed by consecutive abortions. Thirty-six couples also had a history of infertility, with an ovulation disorder, endometriosis, and tubal factors being the predominant diagnosis. Six patients were already diagnosed with hypothyroidism, two with systemic lupus erythematosus, one with mixed connective tissue disease, and one with compensated renal failure of unknown cause. One patient was found to have carcinoma in situ of the breast during her workup. All other patients were in good health.

All patients in group A underwent a complete diagnostic evaluation. Fourteen patients in group B were pregnant at the time of their initial presentation. Another 27 did not undergo all of the core investigations. The most common reasons for an incomplete evaluation were a pregnancy occurring before the workup could be completed and the identification of an etiologic factor or of pathologic conditions, such as the detection of a balanced translocation, that prompted the patients to interrupt their attempts at pregnancy. Therefore 90 patients in group B underwent a complete workup.

Table I presents the results of the diagnostic investigations in series B. Patients may have more than one etiologic factor identified, and therefore the sum of categories may exceed the total. Table II compares the frequency of probable diagnoses between both series. The number of couples in group B who underwent each diagnostic maneuver is indicated.

The frequency of balanced parental translocations is shown in Table II. In addition, four patients in group B showed a 9(p1q1) pericentric inversion. This was not considered significant as an etiologic factor.[16]

Uterine anomalies in group B were classified as significant and incidental, depending on their type and severity. Table III shows this breakdown. Only significant uterine anomalies were listed in Table II.

In group B, 91 patients underwent at least one endometrial biopsy. In 60 patients, at least one biopsy was read as in phase. Ten patients refused a second biopsy after the first one had been read as out of phase. They were empirically treated with progesterone supplementation and are considered as having a corpus luteum defect. Twenty-one patients showed two out-of-phase endometrial biopsy specimens. Fourteen women in group B had a severe ovulation disorder and were included in the endocrine category. Fourteen other women displayed only subtle ovulatory disorders that were detected but thought to relate more to infertility than recurrent abortion. These were not included and are not listed in Table II.

Autoimmune tests were only available for women in group B. The women in all 131 couples underwent these tests. Twenty-one women had mid or high levels of ACA, PS antibodies, or a positive LAC screen on two occasions. Three women also had active connective tissue disorder of autoimmune origin, as listed above. All

Table III. Uterine anomalies identified in groups A and B

Anomaly	Group A (n = 100)	Group B	
		Significant	Incidental
Septum	10	2	0
Fibroids	1	5	3
Adhesions	0	8	4
Incompetent cervix	4	3	0

these cases were viewed as having a probable autoimmune cause and are listed in Table II. In addition, nine women consistently had low levels of ACA. For this study these low levels were considered as a possible cause for abortion, and these women are not included in Table II.[9]

Thirty-three couples had two or more probable causes of abortion. This excludes the association of corpus luteum defect and ovulation disorders. No specific association was more prevalent. One couple had balanced translocation and high positive autoantibodies.

No cause for recurrent abortion could be identified for 37 couples in group A. A comparable figure is more difficult to define for group B. There are 22 couples for whom no diagnosis could be made after a complete workup. In five other couples medical problems, such as hypothyroidism, were identified and corrected. Because there is much debate about the negative impact of such factors on pregnancy outcome, we have added these to the list of unknown diagnosis, for a total of 27 couples. There were 19 couples in whom no diagnosis could be made but where the workup was not completed in its entirety. We excluded these from our list of unknown causes, and the denominator for the unknown diagnosis is therefore 112 couples.

Thirteen couples had possible factors that are hotly contested in terms of their potential for recurrent abortion. They are not listed anywhere in Table II.

Additional data are not available for patients in group A. All but four women in group B were screened for thyroid disease. Hypothyroidism was newly diagnosed in five women, whereas two of the six women who were known to have this disorder were found to be undermedicated. Screening for chlamydia was performed in 96 women and yielded a single positive serologic result at 1:64. Prolactin levels were obtained in 113 women, and 10 women were found to have persistently elevated levels that were corrected by therapy with bromocriptine. Serum levels of testosterone, dehydroepiandrosterone sulfate, LH, and follicle-stimulating hormone were obtained in fewer than one third of patients, mostly in the context of ovulation disorder. These substances were found to be abnormal in about 10% of the patients tested. The numbers are too small to draw any inferences at present.

Table IV compares the diagnostic yield between groups A and B in two different ways. Because 13 patients in group A were ascertained through genetic referrals, these are excluded from the analysis. Therefore 87 couples are considered from group A. From group B, we used only those 90 couples who were not pregnant at presentation and who completed a workup. Both probable and possible etiologic factors are combined under "known diagnosis." First, we compared both of these groups in toto. On the basis of this analysis, we have not improved our efficiency at making a diagnosis in these patients ($p = 0.082$). This is also illustrated by the 95% confidence interval between the two groups.

Next, we repeated the analysis excluding chromosomal anomalies from both groups. This was done because our figure of 12% of chromosomal anomalies in group A is greater than in most series, where the prevalence ranges between 3% and 5%.[16] With these new parameters, we have improved our ability to make a diagnosis by close to 20% ($p = 0.018$) (95% confidence interval = 4% to 34%). This is a small difference, however, which holds true only if we combine probable and possible causes.

The outcome of subsequent pregnancies for patients in group A has been reported.[3] In summary, 80 couples elected to attempt pregnancy; an additional nine couples also attempted pregnancy but were in the multifactorial genetic factor group. Of the couples in whom a diagnosis was made and who attempted pregnancy, 34 out of 43 (79%) achieved a successful pregnancy. In those couples where no diagnosis could be made, 37 attempted pregnancy and 23 were successful (62%). In group B 35 couples were either lost to follow-up or elected not to pursue pregnancy. In the 22 couples where no diagnosis could be made, we have follow-up on 17. Eight (36%) of these eventually achieved a successful pregnancy, whereas five had only losses and four failed to achieve a pregnancy. In the 72 couples where a probable diagnosis was made, 24 were lost to follow-up or decided not to pursue a pregnancy. Of the remaining 48, 35 (73%) had live births, five had spontaneous abortions only, and eight were unable to achieve pregnancy (Table V). The minimum follow-up interval is 6 months and the maximum 4 years. These

Table IV. Compared diagnostic yield of a completed diagnostic workup

	1968-1977	*1987-1991*	*Difference (%) and 95% confidence interval*
Adjusted groups—All diagnoses			
Total No.	87	90	
Diagnosis	50 (57%)	64 (71%)

numbers are too small to draw any conclusions in the outcomes between our various etiologic groups. No significant difference in outcomes is demonstrable between groups A and B.

Comment

The traditional workup of the patient with recurrent abortion has included structural evaluation of the uterine cavity, histologic assessment of the endometrium, parental chromosomal studies, and a thorough medical evaluation, looking for systemic disorders and thyroid dysfunction.[17] In the past 10 years several technologic changes have been recorded. Hysterosalpingography has been complemented by hysteroscopy. Endometrial sampling is easier because of the use of flexible sampling devices. Ovulation assessment is enhanced by urinary LH monitoring, ultrasonography, and hormonal assays. The banding resolution of chromosomal studies has improved. Screening for infections has improved through enhanced culture techniques and antibody assays.

In addition to the advent of this new technology, the area of immune pregnancy loss has come of age.[18, 19] Autoimmune factors, including the presence of ACA, PS, and LAC, have gained acceptance as etiologic factors in recurrent abortion. Alloimmune factors have been under scrutiny.[10, 11]

In this context it is important to assess if we have made any true progress in our management of couples with recurrent abortion. Various studies have looked at a similar breakdown of causes in this patient population.[1, 3, 20, 21] It is extremely difficult to compare series, however, because of varying definitions of what constitutes recurrent abortion, differing diagnostic protocols, and technical maneuvers.[2] The current study offers the opportunity of comparing the diagnostic yield of two standardized diagnostic protocols within the same institution at two different time periods. The protocol for the period of 1987 through 1991 is similar to that for the period of 1968 through 1977, except that it uses the latest available technology and includes testing for autoimmune disorders.

The breakdown of patients among the different categories, as outlined in Tables I and III, is consistent with other similar reports.[1, 20, 21] Chromosomal problems were seen less frequently in group B than in group A but are in effect closer to the majority of other surveys.[16, 22] Random clustering could account in part for this difference.[23] Another explanation is that referring physicians now order karyotype evaluations directly and manage these cases locally. The merits of uterine structural studies are confirmed by our data.

Evaluation of endocrine factors is now easier and more thorough with the advent of flexible sampling cannulas and urinary LH monitoring, coupled at times with ultrasonographic follicular monitoring. This remains a prevalent etiologic group and continues to gain broad acceptance.[8] The high prevalence of thyroid dysfunction and hyperprolactinemia supports routine screening for these disorders in this population.

Autoimmune antibodies were present in 16% of the total patient population. This figure is in line with previous reports from other sources.[19, 24] We feel it is well justified to obtain these in all patients with two or more abortions, although other reports contest this finding.[25] This may be linked to differences in laboratories. All of our assays were performed in the same laboratory, with high quality control. In parallel, our clinical experience with outside laboratories has been far less encouraging, and there is little correlation between different laboratories. These issues must be resolved before such tests become widely used clinically. In the meantime we would encourage interested clinicians to refer their samples to an established laboratory with a proved track record, specifically in the field of autoimmune pregnancy loss.

Table V. Outcomes of pregnancies by diagnostic categories in group B patients where a probable diagnosis was made

Diagnosis	*At least 1 live birth*	*Abortions only*	*No pregnancy achieved*
Balanced translocation (n = 1)	1	0	0
Uterine anomaly (n = 4)	3	0	1
Endocrine (n = 21)	14	1	6
Autoimmune (n = 8)	6	2	0
Translocation and autoimmune (n = 1)	1	0	0
Endocrine and uterine (n = 3)	3	0	0
Endocrine and autoimmune (n = 10)	7	2	1

We found little support for infection as an etiologic factor. This is in contrast with the findings of other investigators with comparable techniques.[12] It may reflect population differences or technical problems with the culture and assay systems.

The 33 couples who had more than one etiologic factor identified highlight the need for a complete workup in these patients. Stopping once a single cause is identified is ill-advised and may lead to inaccurate counseling and therapy. The couple with a balanced paternal translocation and high positive immunoglobulin G ACA titers in the wife is an excellent case in point.

When we tried to compare the results from the two series, several difficulties emerged. First was the ascertainment bias. Our referral base had evolved between the two study periods. We clearly saw fewer referrals for genetic indications. We must also wonder whether referring physicians now feel more comfortable ordering karyotypes in these couples and handling counseling issues when balanced translocations are identified. The same could be true of the diagnosis and management of müllerian anomalies. Second, we are still plagued by the fact that only two causes are clearly established for recurrent abortion: balanced parental translocations and severe uterine anomalies. Last, even with the accumulation of data over a relatively long period of time in a tertiary referral center, numbers remain small and it is difficult to draw definitive conclusions.

After appropriate adjustments, our study does show a slight improvement in our ability to diagnose etiologic factors in women with two or more abortions. This is by a narrow margin. In terms of outcome, we could not show any significant improvement. This is related in part to the restricted number of patients. It may also reflect the poor efficacy of currently available treatments for the newly identified causes.

It is somewhat discouraging to realize how little ground we have gained in this field over the past 10 years. The improved technology has not been matched by an equal diagnostic yield. This underlines the dire need for increased research in this area. Multicenter trials appear to offer the best hope because of their ability to acquire large numbers in a relatively short period of time.

In terms of daily practice, this study reemphasizes the need for a complete workup in all couples with a history of recurrent spontaneous abortions. The finding that the same team can experience such wide variations in the prevalence of etiologic factors should cast an appropriate skepticism in applying the data of any study to one's practice. Instead, large pools of data from several centers appear more appropriate. It is hoped that the next decade will finally see major progress accomplished in this area.

Discussion

DR. RAMEZ S. AZOURY, Norfolk, Virginia. This study compares 131 patients (group B) investigated between 1987 and 1991 with another group of 100 patients (group A) investigated between 1968 and 1977, for recurrent abortion in the same academic center. A standardized protocol is followed and the results are compiled retrospectively.

The diagnostic advances made include improved karyotyping with G- and C-banding techniques and ultra-high-banding resolution, laparoscopy replacing gynecography, hysteroscopy used as a complement to hysterosalpingography, a flexible sampling device for sampling the endometrium, urinary LH monitoring, coupled at times with ultrasonographic follicular monitoring, screening for infections, and tests of autoimmune and alloimmune factors suspected to be causes of habitual abortion. The authors stress that at present the diagnosis of autoimmune disease is unreliable, because of variability in laboratory technique throughout the country, and that this obviously needs improvement.

Currently, there are no standardized tests or reporting criteria for the LAC. Dudley and Branch[1] found that there is marked variation in the ability to detect LAC in standardized samples from one laboratory to another and that controversy and personal bias make the task of standardization difficult.

The importance of a complete study to make the etiologic diagnosis is emphasized and the difficulties are apparent. The authors point out the importance of identifying medical disease, thyroid disease and hyperprolactinemia especially. Both of these can interfere with the hormonal milieu during the menstrual cycle, thus inducing ovulatory and luteal phase defects and thereby spontaneous abortions. Chronic illnesses of course, mainly tuberculosis, can do this and can be easily missed.

I would like also to comment that in this study the most common causes of repeated spontaneous abortions seem to be luteal phase defect and associated ovulatory defects. The first report on this condition by Delfs and Jones[2] stated that 35% of the patients studied at The Johns Hopkins Hospital for repeated spontaneous abortions were identified as having such defects. However, Plouffe et al. repeatedly mentioned in their article that uterine anomalies and balanced chromosomal rearrangements are the only two accepted etiologic factors.

The therapy for recurrent losses in group B differs from that of group A. Hysteroscopic resection of uterine septum has replaced metroplasty. Only those women with positive cervical culture for general microbiologic results and chlamydia or a high antibody titer for chlamydia are treated. All couples for whom no cause can be found are treated with postimplantation progesterone, whereas those identified as having a corpus luteum defect are treated with preimplantation progesterone vaginal suppositories, and patients with autoimmune disorders receive either aspirin alone or aspirin and heparin or aspirin and cortisone. However, there are reports about the use of intravenous immunoglobulin for the treatment of recurrent abortions caused by antiphospholipid antibodies.[3] Would the author care to comment about this modality?

What criteria do the authors use to include some conditions under "possible" and others under "probable" in Table II?

Alloimmune factors are mentioned briefly. I would like to ask the author to comment on the current thoughts of his group about this cause. Should we pursue this investigation all the way in a couple where no etiologic factor could be detected? What are your current thoughts about therapy?

Do the authors believe that a male factor should be considered, in view of some anecdotal reports of repeated spontaneous abortions in four women married to the same husband? The experience at the Jones In-

stitute shows that there is a trend for repeated abortions in patients whose husband has poor sperm morphologic characteristics, i.e., <4% normal forms, by means of strict criteria developed by Tiggerberg and his group[4] in South Africa. However, the number is too small to draw a conclusion.

It would have been interesting to "revisit" the patients in group A to obtain a longer follow-up and predict what would happen to the patients in group B if they underwent follow-up for a longer period of time.

This is an excellent article by a group well known for scientific performance and expertise in the area of reproduction. It is disappointing to learn that, although their ability to diagnose the etiologic factors of recurrent abortion has improved, there has not been a perceptible increase in successful therapy for this intriguing problem.

Dr. Plouffe (Closing). With regard to the autoimmune issue, there are two camps that are evolving and for those of you with a strong interest in the area I would encourage you to look at *The American Journal of Human Genetics*, January 1992, where there is a beautiful editorial by Dr. Gill from Pittsburgh that really crystallizes the whole debate.[1] Dr. Gill was on the autoimmune-immune side and now is on the autoimmune-genetic side. Basically, the concept is that if there is a high level of shared loci in parents this may indeed represent failure of the normal immunologic mechanism in pregnancy. It may be a problem of lack of recognition of the pregnancy as a foreign allograft and lack of elaboration of the blocking antibodies. That is one concept, and under that theory one would want to initiate immune therapy. Another group, though, believes that those are immune markers for genetic markers, and therefore what you are identifying is couples that share many genetic loci that are critical to normal embryonic development and normal life.

In looking at the outcome of pregnancies in parents who share many loci, it is apparent that not only do they have a high incidence of infertility and a higher incidence of recurrent pregnancy loss, but they also have a higher incidence of cancers that are genetically related. Because of this we believe that the autoimmune etiology may be a reflection of shared genetic load. In our center this is our experience. Couples with many shared loci who have had autoimmune therapy have not had much success and those who have tried without autoimmune therapy have been successful after multiple attempts at pregnancy. Therefore the debate continues and we do not have the answers, but it is one area that needs follow-up.

In terms of male factor infertility, we have the same gut feeling as those in Norfolk, Virginia, that this is a factor. We have had some couples over the years in which the man had highly abnormal sperm parameters. I could not establish a threshold level. Our experience is too small to draw any conclusions on this, but it is one area that needs to be looked into, as well as the presence of antisperm antibodies in either the male or the female partner, which has been thought by some groups to be related to recurrent pregnancy loss.

The role of immunoglobulin for autoimmune therapy is extremely interesting; the data are very promising. The multicenter trial in which we were enrolled compared aspirin and heparin versus aspirin and prednisone. We were able to randomize 20 couples and found a small increase in side effects from the aspirin-prednisone therapy compared with the aspirin-heparin therapy. We were not able to show that there was any benefit of one treatment over the other in terms of pregnancy outcome. At that time the NIH determined that because we had higher side effects in the aspirin-prednisone group, the study should be dropped. That was the only effort of which we are aware of a multicenter trial looking at autoimmune disease. It is hoped that the NIH will revise its policy and we will be able to initiate further studies in this very difficult area. Also at that time we could include γ-globulin therapy and immunoglobulin therapy as part of the study trial.

With regard to the question about possible or probable etiologic factors, we have tried to be as objective as possible. The reason that chromosomal anomalies are recognized by all is that one can look at the outcome. It is possible to look at the fetus and document unbalanced translocations. In looking at uterine anomalies, most people agree, although we do not have a randomized trial of couples treated and not treated with uterine anomalies. We strongly believe that luteal phase defect falls into the known causes of recurrent loss, but we know that other people, including Dr. Grimes, would debate the issue. Therefore we tried to include those factors for which there is a consensus that they are definite causes. Probable causes and those that are hotly debated get more into the issue of possible causes.

Electroejaculation in combination with in vitro fertilization and gamete micromanipulation for treatment of anejaculatory male infertility

Andrew A. Toledo, MD,[a] Michael J. Tucker, PhD,[a] James K. Bennett, MD,[b] Bruce G. Green, MD,[b] Hilton I. Kort, MD,[a] Sharon R. Wiker,[a] and Graham Wright, BSc[a]

Atlanta, Georgia

OBJECTIVE: Failure to ejaculate may be overcome by use of electroejaculation. However, such semen samples are often unsuitable for therapies like intrauterine insemination. The combination of electroejaculation with in vitro fertilization, including gamete micromanipulation, should improve chances of fertilization and pregnancy in such cases.

STUDY DESIGN: Within a private infertility clinic electroejaculation in combination with intrauterine insemination was carried out in 18 cycles (10 couples). Four couples went on to receive therapy by electroejaculation plus in vitro fertilization, along with six other couples (15 cycles total) with semen too poor for intrauterine insemination.

RESULTS: One term pregnancy arose in the electroejaculation–intrauterine insemination group, and one term pregnancy plus one continuing pregnancy arose from two couples (three cycles) who underwent in vitro fertilization with conventional insemination after electroejaculation. Six couples (nine cycles) had embryos arising only from gamete micromanipulation transferred, and this yielded two term pregnancies, one spontaneous abortion, and a biochemical pregnancy. Two couples (three cycles) failed to achieve fertilization even with micromanipulation; however, donor-inseminated eggs gave rise to two term pregnancies and one continuing pregnancy in these patients.

CONCLUSIONS: This report confirms the feasibility of in vitro fertilization in conjunction with electroejaculation and extends the therapy to incorporate gamete micromanipulation. (AM J OBSTET GYNECOL 1992;167:322-6.)

Key words: Electroejaculation, anejaculatory infertility, gamete micromanipulation

The combination of electroejaculation and intrauterine insemination has given rise to several reports of successful pregnancies for couples in whom the male partner suffers from paraplegic anejaculation.[1,2] However, it is common in such men for spermatozoal counts to be low and progressive motility to be poor, possibly because of either testicular hyperthermia or negative influences of the electroejaculation procedure on semen production. For example, electroejaculation may not initiate a full ejaculatory response.[3] These factors militate against success with timed intrauterine insemination alone, and Ayers et al.[4] reported the first successful application of in vitro fertilization (IVF) and embryo transfer in combination with electroejaculation in a case of oligoasthenozoospermia. Recently gamete micromanipulation procedures have been developed to enhance fertilization during IVF for severe male factor infertility,[5,6] and such approaches may be appropriately applied to the poorer cases of electroejaculation–IVF.

In addition to performing electroejaculation in combination with intrauterine insemination, we have also adopted IVF in cases untreatable by intrauterine insemination or after repeated failure with electroejaculation–intrauterine insemination. In several cases where spermatozoal performance was particularly poor, we have undertaken partial zona dissection[7] and in three cases subzonal spermatozoal insertion[8] in an attempt to improve chances of fertilization during IVF.

Material and methods

Patients. Ten women underwent 18 intrauterine insemination cycles with spermatozoa previously collected by electroejaculation. One other woman whose partner's semen was inadequate for intrauterine insemination on two occasions underwent insemination with frozen-thawed donor semen at the second failed electroejaculation attempt. All naturally ovulatory women received one intrauterine insemination midcycle according to ovulation estimates, on the basis of a urinary luteinizing hormone surge, except two women in whom

Progression (0-4)	2.6 ± 0.4	
Outcome		
Term pregnancy	1†	

*All samples.
†One male infant per 18 cycles of intrauterine insemination.

intrauterine insemination was performed twice midcycle.

Of these 10 couples, four subsequently undertook treatment by IVF (five cycles). A further six couples underwent IVF–electroejaculation treatment directly (10 cycles) because of poor spermatozoal quality. Male partners all were anejaculatory, one being quadriplegic and seven paraplegic after spinal cord injury. The other two men had postoperative damage subsequent to retroperitoneal lymph node dissection. Six of the female partners also had secondary complicating infertilities including anovulation, mild endometriosis, adhesions, polycystic ovarian syndrome, microadenoma and mild endometriosis, and fibroids. Average ± SD age of these 10 women at the time of treatment was 34.3 ± 2.9 years. A variety of ovulation induction protocols was used to achieve superovulation. In four cycles a combination of clomiphene citrate and human menopausal gonadotropin was used, and in one cycle human menopausal gonadotropin only was used. There were nine cycles of long-protocol leuprolide acetate treatment coupled with pure follicle-stimulating hormone and human menopausal gonadotropin, and one cycle used a short-protocol leuprolide acetate regimen in combination with follicle-stimulating hormone and human menopausal gonadotropin. Ovulation was triggered in all cases with human chorionic gonadotropin when estradiol rise and follicular growth patterns were optimal. Additionally, all women received midcycle corticosteroids and antibiotics[9] in anticipation of transfer of embryos with perforated zonae pellucidae.

Electroejaculation. With the male partner in a lateral decubitus position, anoscopy was performed to ascertain that there were no rectal hemorrhages, mucosal ulcerations, or neoplasms. Next urethral catheterization was carried out to drain the bladder, and the bladder was refilled with approximately 30 to 60 ml sterile Hepes-buffered minimum essential medium with 2.5% bovine serum albumin before removal of the catheter. The electroejaculator was inserted atraumatically into the rectum, and an electroejaculatory stimulation of 5 to 35 V and 100 to 600 mA (sine wave–alternating current) was delivered. All antegrade ejaculation was collected in a sterile specimen container and immediately examined for the presence of spermatozoa. At the end of the procedure the man again underwent anoscopy to check for any rectal lesions, and the bladder was recatheterized to obtain any retrograde ejaculation. Blood pressure was monitored throughout the procedure.

Intrauterine insemination, IVF, partial zona dissection, and subzonal spermatozoal insertion. Semen samples were prepared by washing and sedimentation under mineral oil[10] or by a mini-Percoll technique.[11] Pentoxifylline (2.5 mmol/L) and 2′-deoxyadenosine (2 mmol/L) were used in the spermatozoal preparation for subzonal spermatozoal insertion.[12] Intrauterine insemination was performed with a Wallace embryo replacement catheter (H.G. Wallace, Colchester, United Kingdom) placing between 0.25 and 1.0 ml processed spermatozoal suspension close to the uterine fundus. IVF, partial zona dissection, and subzonal spermatozoal insertion procedures were performed as previously described.[7, 8] Embryo transfers were performed with a Wallace catheter, and all patients received luteal phase support as either human chorionic gonadotropin on days 2 and 4 after the oocyte retrieval or progesterone daily until pregnancy testing.

Results

Table I indicates the averaged seminal profile for both antegrade and retrograde ejaculates before processing for 18 cycles of intrauterine insemination. Because of the need to dilute samples, volumes collected are relatively large and vary according to the ease of collection. Likewise spermatozoal counts vary radically.

*Five-cell embryo frozen after reinsemination by subzonal spermatozoal insertion.

†One spontaneous abortion and one biochemical pregnancy.

Progressive motility is low in all cases, and >70% of all samples collected contained considerable contamination, particularly blood cells and nondescript cellular debris. One pregnancy with delivery of a male infant arose from these 18 cycles, and interestingly it was from one of the two cycles in which insemination was carried out twice midcycle, the total motile spermatozoal counts being 6 and 17 million on these occasions.

Table II considers the combined antegrade and retrograde seminal profiles in the 15 electroejaculation–IVF cycles undertaken. Spermatozoal counts and progressive motility were low in all cases, especially in the three cycles where fertilization failed with husbands' spermatozoa, although oocyte numbers were low in these cases. In two couples (three cycles) conventional insemination of oocytes alone was carried out with a 62% fertilization rate, 12 embryos were cryopreserved, and nine embryos were transferred to give one pregnancy with delivery of a female infant and one continuing pregnancy. In nine cases conventional insemination was also backed up by partial zona dissection and subzonal spermatozoal insertion in a greater proportion of the oocytes collected. One fertilized oocyte from the conventional group (7.7% fertilization rate) did not develop for transfer, whereas 11 partial zona dissection oocytes were fertilized (30.6% fertilization rate) and nine cleaved to be transferred to give two pregnancies with delivery of male infants, one spontaneous abortion at 10 weeks of pregnancy, and a biochemical pregnancy. Two oocytes unfertilized by partial zona dissection underwent reinsemination by subzonal spermatozoal insertion, and one fertilized to be frozen as a five-cell embryo. In two cycles fertilization arose only from subzonal spermatozoal insertion with a 31.2% fertilization rate (5/16). All embryos were transferred but without pregnancy. Finally, in two couples (three cycles) in whom fertilization was not achieved with the husband's spermatozoa a total of four embryos (80% fertilization rate) from donor insemination were transferred to give one pregnancy with delivery of a male infant, one pregnancy with delivery of a female infant, and one continuing pregnancy.

Comment

The inability to achieve seminal ejaculation can in many instances be overcome by the use of electroejaculation. This procedure, however, does not in all cases provide semen of sufficient quality for use in intrauterine insemination. Where semen quality is poor, IVF can be adopted to enhance chances of fertilization and pregnancy,[4] and our results here confirm that as a realistic course of treatment. In addition, chances of fertilization may be further improved by the implementation of some form of gamete micromanipulation, especially when seminal quality is actually suboptimal, even for use in conventional IVF. Again the few cases reported here seem to bear this out, with three pregnancies being initiated and two male infants delivered from the six cycles in which embryos arose from partial zona dissection micromanipulated oocytes. Subzonal spermatozoal insertion reinsemination of two oocytes that failed to fertilize after conventional insemination

gave rise to one late-fertilized cleaved embryo that was frozen for later, more synchronous transfer after thawing.[13] Further, subzonal spermatozoal insertion in two cycles generated five embryos for two transfers, but pregnancy did not result.

As previously found,[7] no one particular seminal characteristic was clearly predictive of the need for gamete micromanipulation. There was, however, a suggestion that higher motility was associated with greater ease of fertilization in IVF, because this was highest in those two patients who only required conventional insemination, although this difference was not statistically significant. It is known that systemic antispermatozoal autoimmunity can occur in spinal cord–injured men,[14] and it is conceivable that this factor may have had some bearing on the poor spermatozoal motility and low fertilization outcome in some of the cases reported here. However, antispermatozoal antibodies were not assayed in this instance because of insufficient sperm numbers, and efforts were concentrated on obtaining sufficient spermatozoal suspension for insemination.

Continuing improvement in many areas of reproductive technologies underline the need for our constant reappraisal of what is possible in infertility therapy. Electroejaculation has enabled spermatozoa to be routinely collected from men previously thought of as untreatable. Gamete micromanipulation has allowed fertilization to be realized in cases of severe male factor infertility, otherwise considered untreatable by IVF. Indeed, further improvement of these latter techniques may eventually allow us to achieve fertilization in those cases where we still have had to resort to donor insemination when spermatozoal counts were too low, and progressive motility too feeble, or when oocyte numbers were limited. In any event we have established that electroejaculation of anejaculatory men in combination with IVF with or without gamete micromanipulation is a viable therapeutic approach.

Discussion

Dr. R. G. Brame, Greenville, South Carolina. This treatise addresses a topic that is rather unique but is an important subject, not only because it addresses the reproductive needs of a seriously impaired segment of the population but it also brings to our attention, again, some of the modern technology that may be brought to bear on the reproductive failures of the many others not so handicapped.

First, let me reemphasize some observations already made by the presentor: the women partners of these men suffered an unusually large number of concomitant reproductive problems, an interesting finding for which no explanation is apparent. Another observation: electroejaculation is a new technology, but early in its history rectal injuries could be caused both by direct trauma and electric shock. It appears now that those problems have been resolved and electroejaculation can be carried out without even minor complications for the male. Further, it is fairly obvious that neurologic impairment in the male, however mediated, results in poor semen quality. There are small numbers of sperm, poor motility, and contamination of the already poor samples by much cellular debris and blood.

I did struggle, Dr. Toledo, a great deal with some of your math. I can add up seven pregnancies in your abstract but only six that were conceived by IVF. I have made the presumption that you included the one pa-

tient who had intrauterine insemination. I have no problem with this except that it is not totally clear that that is the case, first, and second, I'm not sure why the patient having intrauterine insemination was included in the series, given the title. In addition, you speak to the issue of enhancing IVF by the addition of partial zona dissection, yet when I examine your tables, I find conventional IVF to have a 67% fertilization rate whereas conventional-partial zona dissection has a 28% rate and partial zona dissection with donor eggs has a 0% fertilization rate. If I have obviously misinterpreted your figures, as I'm guessing that I have, I'll be grateful for your help. Also, I did not identify in your data a recounting of how many IVF implants were made in each patient or over what amount of time. But none of this detracts from your success.

You do present an apparently effective approach to the loss of reproductive capacity in individuals who have experienced spinal cord or other neurologic injury, and although it is a problem that affects only a small number of patients, it is an important step in our attempts to make the benefits of modern medicine available to the entire spectrum of the handicapped.

Dr. Roger P. Smith, Augusta, Georgia. Would the authors please comment on whether they use alternating or direct current? If they use alternating current, would they comment on wave form and duty cycle?

Dr. Barry S. Verkauf, Tampa, Florida. We have been fortunate to have two of our first six patients seen with clomiphene citrate intrauterine insemination with electroejaculation. I like to ask Dr. Toledo several questions relative to handling the ejaculate. First, since there is a propensity to infection, were antibiotics used for both the male and female? Second, because antegrade specimens are not always obtained, was alkalinization of the urine done? Third, because experience around the country is quite limited with this technology, did you notice any improvement in the quality of the ejaculate with the number of electroejaculations that individual men were exposed to?

Dr. Toledo (Closing). In answer to Dr. Brame's question regarding the actual pregnancies, we included biochemical pregnancies as the seven, not the intrauterine insemination. The seven total pregnancies were in that particular group. Basically, we had a total of two cycles with a particular type of technique where we felt that initially the insemination specimen quality particularly with regard to motility was improving. Granted, 22% motility is not what we would consider normal, but we felt that particular percentage was going to be sufficient in allowing for conventional insemination. We inseminated all four of these oocytes that I showed you with conventional techniques using micromanipulation, obtaining roughly a 62% fertilization rate resulting in the delivery of one term pregnancy. Other pregnancies were a combination of two groups. The conventional group did not contribute because, although we did get one oocyte fertilized, there was no subsequent cleavage resulting in a nonviable embryo. All of these pregnancies resulted from partial zona dissection, giving about a 30% fertilization rate. In the subzonal insertion group, again as I emphasized, was not one where we were able to replace the embryo because of the time lag it is still in cryopreservation. In this particular group, the two delivered pregnancies were all an off-shoot of donor backup. I apologize for the confusion in the numbers.

In answer to the question regarding the current, I believe that it was alternating current with a sine waveform.

With regard to the collection of the ejaculate, we did cover both the female and her husband with antibiotics. Whenever we manipulate the zona pellucida, we are concerned about exposing the embryo to infection; therefore we do use antibiotic coverage in both the woman and her husband.

The husband's urine was alkalinized before the procedure. This is usually done with a sodium bicarbonate preparation.

With regard to the overall improvement of the semen specimen with repeated ejaculation, the answer was that it was very variable. We saw no consistent pattern. It was totally unpredictable. West of Houston has also pointed out that the response to electroejaculation is quite variable and is frustrating to those undergoing the treatment.

If we had to do it over again for the poor responders, we would automatically use our experience with primary subzonal insertion. The best shot at the oocyte in terms of fertilization is first-day exposure in the hope that donor backup would not have to be relied on.

Red blood cell transfusion and cesarean section

Laurel A. Dickason, BA, and Mara J. Dinsmoor, MD
Richmond, Virginia

OBJECTIVE: Our objective was to determine the incidence of blood transfusion in patients delivered by cesarean section and to identify factors predictive of the need for transfusion.
STUDY DESIGN: A chart review was performed on cesarean patients receiving blood transfusion over a year at the Medical College of Virginia Hospital and an equal number of randomly selected cesarean patients.
RESULTS: Sixty-one (6.8%) patients received a packed red blood cell transfusion intraoperatively or postoperatively. Transfusion was associated with lower gestational ages, antepartum bleeding, arrest of descent, and longer postoperative stays. After stepwise logistic regression analysis, only antepartum bleeding and preoperative hemoglobin were significant independent predictors of the need for blood transfusion.
CONCLUSION: Transfusion with cesarean section is common and is associated with antepartum bleeding and other primarily intrapartum and unpredictable factors. (Am J Obstet Gynecol 1992;167:327-32.)

Key words: Blood transfusion, autologous donation, cesarean section

Patient concerns about receiving a blood transfusion have progressively increased in the past decade, due primarily to concerns about infectious complications, specifically hepatitis and human immunodeficiency virus infections. In some preoperative patients, the risk of infectious complications can be minimized by the use of preoperative autologous blood transfusions. Blood donation for autologous transfusion has been performed in the third trimester of pregnancy without major complications.[1-3] However, in contradistinction to many other surgical patients, it is difficult to predict which obstetric patients will need blood transfusions. A recent retrospective study of over 30,000 deliveries reported that 2.6% of obstetric patients received ≥1 U of blood.[4] Patients at increased risk for transfusion included those with more than one prior abortion or a multiple gestation, patients undergoing cesarean section, particularly a primary cesarean section, and patients with abnormalities in placentation and amniotic fluid volume. Patients who received a transfusion also had a significantly lower gestational age and neonatal birth weight and a significantly higher estimated blood loss. However, many of these factors are closely interrelated, and no regression analysis was performed.

Because one group at relatively high risk for hemorrhage requiring transfusion consists of patients undergoing cesarean section,[4-6] our aim was to describe those patients requiring blood transfusion at the time of cesarean section in an attempt to identify factors that might predict a need for transfusion. In addition, we wished to determine whether those patients who underwent blood transfusion were at increased risk for prolonged hospital stay and other postoperative complications.

From the Department of Obstetrics and Gynecology, Medical College of Virginia/Virginia Commonwealth University.

Material and methods

All patients discharged between July 1, 1988, and June 30, 1989, with the diagnosis of cesarean section were identified and their blood bank records reviewed. Those patients who were identified as having received blood products during their hospitalization constituted our study group. To create a comparison group, we matched each transfused patient with the next cesarean section patient on the alphabetic discharge list in the same time period who did not receive a transfusion. We reviewed the hospital charts for these patients and extracted data on patient demographics, obstetric and medical history, type of cesarean section performed, indications for surgery, anesthesia, preoperative and postoperative blood counts, estimated blood loss at the time of surgery, postoperative complications, and postoperative stay. Timing of the transfusion in relation to surgery and vital signs at the time of transfusion were also recorded for the study group.

Statistical analysis was performed with True Epistat and SAS statistical packages. Fisher's exact test and χ^2 analysis were used, as appropriate, for discrete variables. The Student t test was used for continuous variables. The stepwise logistic regression analyses were performed with SAS software. A p value of ≤ 0.05 was considered significant.

Table I. Comparison of characteristics of mothers and babies delivered by cesarean section with and without blood transfusion

Variable	*Blood transfusion (n = 61)*	*No blood transfusion (n = 69)*
Age (yr)	25.6 ± 6.1	25.0 ± 6.0
Nulliparous (No.)	26 (43%)	29 (42%)

Prior cesarean section (No.)	17 (28%)	19 (28%)
Gestational age (wk)	35.3 ± 5.1	37.0 ± 4.1
Birth weight (gm)*	2456 ± 1150	2696 ± 883
Intrauterine growth retardation* (No.)	4/64 (6%)	8/76 (11%)

Values represent mean ± SD.

*Includes 10 sets of twins.

Results

Eight hundred ninety-nine patients were identified as having undergone cesarean section during this time period. Review of blood bank records revealed that 69 received blood products. Analysis of the hospital charts revealed that two patients in the study group did not, in fact, receive blood products. An additional two patients only received blood preoperatively, and four patients were transfused with platelets or fresh-frozen plasma but did not receive packed red blood cells. These eight patients were eliminated from further analysis; thus our study group comprised 61 patients (6.8% of all cesarean sections) who received packed red blood cells intraoperatively or postoperatively. Thirty-nine (64%) received the transfusion intraoperatively or immediately postoperatively.

There were no significant differences between the two groups in maternal age, incidence of prior cesarean section, neonatal birth weight, or intrauterine growth retardation (Table I). Although there was no significant difference between the two groups in gravidity, parity, or the number of prior abortions, there was a significant difference in the ratio of abortions to deliveries. The mean gestational age at the time of delivery was significantly lower in the transfused group, although the difference in the number of patients delivered prematurely (<37 weeks) was not statistically significant (51% vs 36%, p not significant).

Indications for cesarean section delivery included elective repeat cesarean section, active phase arrest, fetal distress, placenta previa, arrest of descent in the second stage, and abnormal presentation. Both placenta previa and arrest of descent were significantly more often cited as indications for cesarean section in the study group (Table II). There was no difference between the two groups in the frequency of repeat cesarean sections after a trial of labor (12% vs 10%).

Table II. Comparison of cesarean section characteristics in patients with and without blood transfusion

*When compared with all other types of cesarean section combined.

†When compared with all other forms of anesthesia combined.

Transfused patients were more likely to have a vertical uterine incision or cesarean hysterectomy and to have undergone general anesthesia.

As shown in Table III, placenta previa and third-trimester bleeding from causes other than placenta previa were significantly more common in the study group. There were no significant differences in the frequency of other antepartum complications, including chronic hypertension, diabetes, multiple gestation, and preterm labor.

There were no significant differences in the occurrence of preeclampsia, chorioamnionitis, and disseminated intravascular coagulation. Not unexpectedly, atony occurred significantly more frequently in the transfused patients, and the average estimated blood loss at the time of surgery was also greater, with 53 (87%) having an estimated blood loss >1000 ml, compared with 29 (42%) in the nontransfused patients ($p < 0.0001$). Although patients receiving blood had a longer mean postoperative stay, there was no difference between the two groups in the incidence of infectious complications or wound breakdown (Table IV). The number of patients with prolonged postoperative stays (≥5 days) was not significantly different (73% vs 58%, $p = 0.067$). In spite of transfusion, on the average, the

study group was discharged with a lower hemoglobin, although severe anemia at discharge (hemoglobin <8 gm/dl) was uncommon in both groups.

The hemodynamic parameters at the time of packed red blood cells transfusion were generally not indicative of shock (Table V). Twenty-one patients (35%) received more than two units of packed red blood cells; the mean number of units transfused was 2.8 ± 1.4. For patients with placenta previa, the mean number of units transfused was 3.2 ± 2.0 with a range from 2 to 7 U.

A stepwise logistic regression analysis was performed with variables with a p value of ≤0.1 on univariate analysis. These included ratio of abortions to deliveries, gestational age, cesarean section type, anesthesia, nonprevia antepartum bleeding, preoperative hemoglobin, and estimated blood loss. Only gestational age, bleeding from causes other than placenta previa, and estimated blood loss remained as significant predictors of the need for blood transfusion. Although the presence of placenta previa was strongly associated with the need for transfusion, it could not be used in this analysis because of its absence in the control group.

Because these variables cannot be used as predictors for the use of autologous transfusion, the analysis was then repeated with only those variables that might be useful predictors for the purpose of autologous donation. For this analysis, placenta previa was combined with other causes of antepartum bleeding. The presence of a low preoperative hemoglobin and antepartum bleeding (from any cause) remained significantly associated with the need for blood transfusion.

Comment

The frequency of blood transfusion in association with cesarean section in our population was 6.8%,

higher than some reports[5,6] and similar to others.[4] This relatively high rate of transfusion was surprising, especially given the fact that many obstetricians report decreasing their frequency of transfusion in the last 5 years (unpublished data). The frequency of transfusion may be partially explained by two factors. First, in a large urban hospital training program the surgeons are less experienced than those in some other hospitals. More importantly, this hospital serves as a tertiary referral center and treats a large proportion of indigent and high-risk patients. The decision to perform transfusion was made on a case-by-case basis by the physicians (faculty and senior house officers) caring for the patient.

The factors associated with blood transfusion in this study are remarkably similar to those found by Klapholz.[4] This includes the obstetric history, gestational age, birth weight, estimated blood loss, presence of antepartum bleeding, and abnormal placentation. After logistic regression analysis, however, many of these risk factors are eliminated.

Predictably, patients who ultimately required blood transfusion were more likely to have had preoperative bleeding complications, and as a result their preoperative hemoglobin was significantly lower. An increased incidence of blood transfusion after cesarean section for vaginal bleeding was also noted by Hill and Lavin,[6] who found no other associated risk factors. Rather than simply being a risk factor for transfusion, the presence of antepartum bleeding and a low preoperative hemoglobin may also lower the physician's threshold for initiating transfusion.

Vertical uterine incisions, cesarean hysterectomy, and the use of general anesthesia, all of which have been associated with increased intraoperative blood loss,[7,8] were more common in the transfused group. Rather than causing increased blood loss, these findings may instead reflect the emergent and complicated nature of many cesarean sections associated with excessive intrapartum bleeding.

Of interest is the fact that the only antepartum complications that were significantly increased in the transfused group were third trimester bleeding and placenta previa. The ability to predict that these patients might need a blood transfusion at the time of cesarean section does not necessarily allow autologous transfusion because patients with preexisting anemia and those at high risk for spontaneous hemorrhage are generally not acceptable candidates for autologous donation. Some authors, however, suggest that the diagnosis of placenta previa is an indication for autologous donation.[2,9] Whether there may be a subgroup of asymptomatic patients with placenta previa who might benefit from autologous transfusion requires further study. No other factor, including previous cesarean section, was significantly more common in the transfused group.

We conclude that although red blood cell transfusion associated with cesarean section delivery is frequently performed, it is difficult to predict those patients who would most benefit from autologous donation. This is primarily due to inability to (1) predict which patients will require cesarean section delivery, (2) predict which cesarean section patients will require blood transfusion, and (3) safely perform autologous donation in those patients at highest risk. As a result, the role of autologous donation and transfusion in the care of obstetric patients remains to be defined.

Discussion

DR. STEPHEN R. GOLDMAN, Atlanta, Georgia. Although many of the traditional risks of blood transfusion have been reduced by improved blood banking technology, a number of risks still remain. The recent introduction of testing for so-called hepatitis C may further decrease, but will not likely eliminate, the risk of posttransfusion hepatitis, which currently has been variously quoted between 1 and 100 and 1 in 300 for each unit transfused.[1] The risk for transfusion-acquired human immunodeficiency virus is much smaller than that for hepatitis, at 1 in 40,000 to 1 in 100,000, but mortality from the disease is presently considered 100% and donor screening by demographic risk factors may become less efficient if, as currently suggested, human immunodeficiency virus infection continues to increase in the heterosexual, non-drug-abusing population.

Under the circumstances, the use of autologous blood in obstetric patients must be investigated. Dickason and Dinsmoor's study has clearly shown the difficulty we can face when we try to prospectively identify the population at risk for transfusion, for whom autologous donation might be desirable. In this study, 6.8% of patients undergoing cesarean section required transfusion. By way of comparison and with due respect to obvious differences in respective settings, at Piedmont Hospital in Atlanta where I practice, the incidence of transfusion for patients undergoing cesarean section was 1.45% from data accumulated between 1984 and 1986 (personal communication). This almost fivefold difference raises some questions about transfusion practice in the current study. Did any of the patients receive autologous units? How many were single-unit transfusions? Were the cases of transfusion, in general, reviewed for appropriateness? If these factors were not analyzed, and had they been, it is possible that the results of the study would have been quite different.

A number of other concerns about autologous transfusions need to be addressed, beginning with whether autologous donation in pregnancy is safe. On the basis of the studies cited in this article and on one other I was able to locate,[2] it would seem that it is safe. However, the numbers of patients involved are relatively small, and all were confined to the latter portion of the third trimester.

Can autologous donation be done without fetal monitoring? That situation might be necessary if it is to be a practical modality. There is one study by McVay et al.[3] that shows no increased untoward effects in such a group.

In Dickason and Dinsmoor's study, one risk group, those with low preoperative hemoglobin values, presents a "catch 22" with respect to autologous donation. If the hemoglobin value is sufficiently low, the patient is not a candidate for donation, but if the value is marginal, it may be rendered low by the act of donation. In McVay et al.'s study, transfusion incidence was 21% for women donating within 1 week of delivery versus 9.4% for women donating earlier.

If one excludes patients with acute third-trimester hemorrhage necessitating immediate cesarean section, the remaining patients at risk for bleeding, namely, those with placenta previa, may be well served by autologous donation, provided they are not having recurrent episodes of bleeding resulting in marginal anemia contraindicating donation. However, the safety of multiple unit donations would need to be established.

The article mentions vertical incision and cesarean hysterectomy as conditions significantly associated with transfusion. The occasional situation in which either circumstance might be known in advance could well be indications for autologous donation. In the Piedmont Hospital series, 5% of patients undergoing cesarean section required vertical incision, whereas vertical incisions accounted for 10% of those transfused.

Although not identified in the current study, one other group of patients who might also benefit from autologous donation are those individuals with multiple red blood cell–associated atypical antibodies, for whom it would be highly difficult or impossible to find compatible homologous blood, especially in an emergency.

Finally, it should be duly noted that transfusion risks can also be prevented by transfusion avoidance. The 1988 report from the National Institutes of Health, among others, points out current concepts of transfusion based on clinical assessment and relegates outdated concepts of various ancillary benefits of transfusion to medical history. The role of ultrasonography in transfusion avoidance should also be explored. Placental localization before planned cesarean section may well be desirable. Antepartum localization in patients with risk factors for cesarean section or transfusion would be worth considering if studies are done that establish predictive criteria. Intrapartum localization scan just before cesarean section is an alternative to be considered, especially if predictive criteria turn out not to exist. However, the rationale for all or any of this probably depends, as much as anything else, on the overall incidence of indicated homologous transfusion in one's institution or practice.

Dr. Robert B. Hunt, Boston, Massachusetts. I am amazed at the amount of blood that patients can lose at cesarean section. As was pointed out, there are problems with autologous blood transfusions. First, a lot of the blood is not used; second, the patients who need it most usually cannot give it; third, it is often not possible to predict in advance who will lose a lot of blood. Might the solution lie with expanded use of the cell saver? We have used it quite effectively in our patients undergoing multiple myomectomy.

Dr. William Mann, Newport News, Virginia. When we look at the factors associated with blood loss, it appears that the two most likely to be controlled by the surgeon are the choice of anesthetic and the intraoperative blood loss, yet the choice of anesthetic is often dictated by the situation. I wonder then, because intraoperative blood loss is the only parameter over which the surgeon has control, if the data might be affected by the use of the stapling device in making the uterine incision. The staple might be associated with a longer operating time; therefore I wonder if operating time affected blood loss.

Dr. Leslie W. Beadling, Jacksonville, Florida. What were the criteria for blood transfusion?

Dr. Dinsmoor (Closing). I agree that our transfusion rate was somewhat high. One of the reasons we did the study was to determine this. Patients being scheduled

for elective repeat cesarean often asked what their chance of receiving a transfusion might be and until this time I had no numbers to give them. I think that there are two reasons for our relatively high transfusion rate: (1) We have a large training program and therefore we have some less experienced surgeons on some of the cases; (2) more important, we are a tertiary referral center and are referred a lot of patients who are extremely high risk and already having bleeding problems. I would note that the study by Dr. Klapholz, who reported on 30,000 patients from the Beth Israel Hospital, cited a transfusion rate in the cesarean patients of 5.2%.

We did not use any autologous units in this study. It is not our routine to do so. We are thinking about studying this in our placenta previa patients.

There was one single-unit transfusion in these 61 patients. Yes, all of our transfusions are reviewed by a blood utilization committee.

I have been informallly observing our placenta previa patients to see how many might have been candidates for autologous transfusions. Many cases are diagnosed when the patients come in bleeding and are delivered that same day. In the three patients we have had in recent months who have had the diagnosis made antepartum, one was too anemic to donate, one was too late in her pregnancy to donate, and the third was too early in her pregnancy to donate. The last patient may be our first candidate in this group.

It is my understanding that the cell saver cannot be used in obstetric patients because the blood is going to be contaminated with amniotic fluid. To infuse blood that contains amniotic fluid runs the risk of amniotic fluid embolism–type complications. With regard to the choice of anesthesia, oftentimes the emergent nature of the cesarean section determines the choice of anesthesia. I have a suspicion that our estimated intraoperative blood loss is biased in our patients who received transfusions. Many received intraoperative transfusions, and the amount of intraoperative blood loss and number of units of blood that the patient received intraoperatively might have had a significant influence on the estimation of blood loss.

We have used the stapling device for some cesarean sections, but I do not have any data on its use or on the operative times. We keep records of start time and finish time, but these data were not analyzed.

We don't have definitive criteria for blood transfusion. In the past 5 years our tendency to transfuse has decreased. In the early 1980s, anyone with a hematocrit <30% and certainly anyone with associated endometritis received transfusions. Now our criteria are much more strict. A majority of these transfusions were done intraoperatively, when there was uterine atony and a great deal of blood loss.

Amnioinfusion: An aid in the ultrasonographic evaluation of severe oligohydramnios in pregnancy

Thomas A. Quetel, MD, Andres A. Mejides, MD, Fawwaz A. Salman, MD, and Mayra M. Torres-Rodriguez, BS, RDMS

Miami, Florida

OBJECTIVE: Amnioinfusion was used in pregnancy complicated by severe oligohydramnios to enable a more comprehensive ultrasonographic evaluation of the pregnancy.

STUDY DESIGN: Thirteen patients were referred to the Division of Obstetrical and Gynecological Ultrasound at the University of Miami because of severe oligohydramnios in which a definitive diagnosis could not be made. Nine patients were in the second trimester and four were in the early third trimester. All patients underwent amnioinfusion with warm physiologic saline solution and instillation of indigo carmine. Genetic amniocentesis was performed in 11 patients.

RESULTS: After amnioinfusion a satisfactory comprehensive ultrasonographic examination could be performed on all patients. In most cases we were able to achieve a definitive diagnosis.

CONCLUSION: Amnioinfusion with the addition of indigo carmine was a satisfactory technique to enable a more comprehensive ultrasonographic evaluation of pregnancy complicated by severe oligohydramnios.

(AM J OBSTET GYNECOL 1992;167:333-6.)

Key words: Amnioinfusion, oligohydramnios, ultrasonography

Pregnancy complicated by severe oligohydramnios presents very challenging diagnostic and management problems. The diagnostic considerations include premature rupture of the membranes, genitourinary malformations, other major congenital anomalies, chromosomal abnormalities, intrauterine growth retardation (IUGR), and fetal infections. Ordinarily, targeted high-resolution ultrasonography is very helpful in answering some of these diagnostic dilemmas, often in conjunction with amniocentesis or fetal blood sampling. In the presence of severe oligohydramnios these diagnostic modalities are often inadequate or technically unable to be performed. In 1985 Romero et al.[1] reported both false-positive and false-negative diagnosis of renal agenesis in patients with severe oligohydramnios. Wladimiroff[2] in 1975 reported on the administration of furosemide to mothers with oligohydramnios. Fetal urine production was observed in those with functioning urinary systems. We have not found this

technique to be helpful in our laboratory. Amnioinfusion has been described and is being used in late pregnancy, in the intrapartum period, to prevent meconium aspiration and to eliminate variable or prolonged decelerations.[3-5] In 1988 Gembruch and Hansmann[6] reported on artificial instillation of amniotic fluid to enhance ultrasonographic identification of fetal anatomy in patients with oligohydramnios. In 1989 Nicolini et al.[7] reported two cases of severe oligohydramnios in which fetal intraperitoneal infusion of normal saline solution was used to enhance ultrasonographic evaluation.

We present 13 cases of severe oligohydramnios in which intraamniotic amnioinfusion of normal saline solution was used to enhance the ultrasonographic evaluation of pregnancy.

Material and methods

Thirteen patients were referred to our laboratory with the diagnosis of oligohydramnios so severe that a satisfactory ultrasonographic examination could not be performed. Nine patients were in the second trimester of pregnancy and four were in the third trimester. The gestational age ranged from 14 to 31 weeks. Four patients had elevated maternal serum α-fetoprotein. Two patients were diabetic. None had premature rupture of the membranes documented clinically with certainty.

Because of the severity of the oligohydramnios and the inability to perform an adequate ultrasonographic evaluation, a diagnosis was not possible. The decision was made to perform an intraamniotic infusion with warm (0.9N) physiologic saline solution. Only those patients in which the oligohydramnios was so severe as to make an adequate ultrasonographic examination impossible were subjected to amnioinfusion. A 22-gauge spinal needle was placed in the amniotic sac under direct ultrasonographic guidance. At times an electronic biopsy guide was helpful in placing the needle in a very small pocket. The volume of saline solution infused ranged from 60 to 350 ml. The volume targeted for infusion was 200 ml. This varied, however, on the basis of the volume needed to enable an adequate ultrasonographic examination. The saline solution was infused slowly over a 15- to 20-minute period in 20 ml aliquots with gentle pressure on a 20 ml syringe. To rule in or out premature rupture of the membranes, 3 ml of indigo carmine was instilled, with the same needle, into the amniotic sac after completion of the saline infusion. Because of the association of chromosomal abnormalities with severe oligohydramnios, genetic amniocentesis was performed in 11 of the 13 patients. With the infusion needle still in the amniotic cavity, a small volume of fluid was aspirated and sent for chromosomal analysis.

Results

Thirteen patients with severe oligohydramnios in pregnancy underwent amnioinfusion because of our inability to perform a satisfactory ultrasonographic examination and arrive at a diagnosis to explain the cause or association of the severe oligohydramnios.

Upon infusion of saline solution and a reaccumulation of an amniotic fluid volume, there was a dramatic increase in fetal movement that was not present before the amnioinfusion. Preinfusion ultrasonography (Fig. 1) failed to reveal a major malformation in the fetus of an insulin-dependent diabetic mother at 20 weeks' gestation; the fetus had severe oligohydramnios. The malformation became very apparent (Fig. 2) after the infusion of 220 ml of saline solution.

Of the 13 patients infused (Table I), adequate ultrasonographic evaluation was possible in 12. One patient had gross vaginal leakage of fluid during the infusion, which obviated the amniotic accumulation. With the addition of indigo carmine we could make positive diagnosis of premature rupture of membranes in six patients and eliminate the diagnosis of it in the remaining seven patients. Intrauterine growth retardation of the symmetric type was diagnosed in four of the patients.

Table I. Postamnioinfusion ultrasonographic diagnosis and pregnancy outcome in 13 patients with severe oligohydramnios

Case No.	*Maternal age (yr)*	*Gestational age (wk)*	*Ultrasonographic diagnosis*	*Pregnancy outcome*
1	32	18	Premature rupture of membranes, choroid plexus cyst	Induced abortion
2	28	31	Renal agenesis	Renal agenesis, pulmonary hypoplasia
3	32	21	Intrauterine growth retardation	Delivered at 39 wk, 1640 gm; no anomalies; discharged home
4	33	19	Premature rupture of membranes; no anomalies seen	Induced abortion
5	39	14	Renal agenesis, intrauterine growth retardation	Delivered at 39 wk; neonatal death day 1, 1.4 kg; severe oligohydramnios and Potter's facies; kidneys reported seen at autopsy
6	29	15	Renal agenesis	Chorioamnionitis; spontaneous abortion
7	39	20	Premature rupture of membranes, no anomalies seen	Chorioamnionitis; delivery at 26 wk; discharged home
8	26	23	Renal agenesis, intrauterine growth retardation	Stillborn at 38 wk; no autopsy
9	34	21	Premature rupture of membranes, gross leakage	Chorioamnionitis; spontaneous abortion 21 wk
10	29	25	Premature rupture of membranes, no anomalies seen	Chorioamnionitis; delivery 34 wk; neonatal death day 1
11	26	23	Premature rupture of membranes, no anomalies seen	Chorioamnionitis; delivery 34 wk; discharged home
12	35	20	Intrauterine growth retardation	Delivered at 30 wk, 465 gm; discharged home
13	23	20	Encephalocele, multicystic kidneys	Induced abortion; Meckel-Gruber syndrome confirmed

Table III. Summary of outcomes in 13 patients after amnioinfusion for severe oligohydramnios

	No.	*%*
Induced abortion	3	23.1
Spontaneous abortion	2	15.4
Chorioamnionitis	5	38.5
Neonatal death	4	30.8
Discharged home	4	30.8
Overall pregnancy loss	9	69.2

Five major congenital malformations were suspected. Of these, four were renal agenesis. One was confirmed by autopsy and two were suspected clinically but autopsies were not performed. The fourth case had kidneys demonstrated at postmortem examination, but there was severe oligohydramnios and the fetus was described as having Potter's facies. One fetus with encephalocele and multicystic kidneys (Meckel-Gruber syndrome) was confirmed at postmortem examination. Chromosomal studies were attempted in 11 of the 13 patients. With postinfusion aspirated fluid, eight karyotypes were obtained; two failed to grow, and one attempt was unsuccessful. Of the two patients who did not have attempts at karyotyping made, one had premature rupture of membranes with gross leakage of fluid as the saline solution was infused and the second patient had a normal karyotype established by genetic amniocentesis performed earlier in the pregnancy for maternal age and elevated maternal serum α-fetoprotein. No abnormal karyotypes were found in our patients. These findings are summarized in Tables II and III.

The overall pregnancy loss was 69.2% in this small group of patients with severe oligohydramnios. Cho-

rioamnionitis developed in five patients (38.5%). In two patients it developed within 3 days after amnioinfusion, and in three it developed more than 4 weeks after amnioinfusion. Four patients with chorioamnionitis had premature rupture of membranes demonstrated by amnioinfusion and indigo carmine. In one patient with chorioamnionitis premature rupture of membranes could not be documented.

Comment

Amnioinfusion was demonstrated to be a technically simple method to enable a comprehensive ultrasonographic examination of the pregnant patient with severe oligohydramnios. By the addition of indigo carmine the diagnosis of premature rupture of membranes could generally be made accurately and quickly by the demonstration of the passage of blue dye. It was also shown that a karyotype could be obtained in a majority of these patients by culturing the aspirated fluid. The incidences of chorioamnionitis and pregnancy loss were high in this group as could be expected in cases of severe oligohydramnios, most occurring in the second trimester of pregnancy.

Discussion

Dr. Edgar O. Horger III, Columbia, South Carolina. I have had experience with 11 early second-trimester amnioinfusions, each of which was performed for the strong suspicion of a fetal renal abnormality. Unfortunately, in two of the 11 cases we had rupture of the membranes very shortly after the amnioinfusion. I assume that we put in too much fluid and built up too much intraamniotic pressure. In your study you set out to give 200 ml of fluid but stopped short, giving anywhere between 60 and 350 ml. Did you make any effort to measure intraamniotic pressure along the way? Does this relate to the possibility of rupture of membranes? Did any of your cases have rupture of membranes shortly after you did the amnioinfusion?

Dr. Quetel. First, we did not measure the pressure either before or after the amnioinfusion. It appears that would be something that would not be very difficult to do. Second, we had six patients with premature rupture of membranes. Attempts had been made before the patients being referred to us to try to establish this diagnosis clinically, and it could not be done. With the indigo carmine, one patient, while still on the examining table, had gross leakage of blue fluid into the vagina during the amnioinfusion. Another had the blue dye passed during the first hour after the procedure. It is difficult to say whether we caused the premature rupture of membranes, but we know in our cases of premature rupture of membranes there were no other associated conditions to explain the oligohydramnios.

Dr. Mara J. Dinsmoor, Richmond, Virginia. I was curious about the five patients with chorioamnionitis. Did these patients already have ruptured membranes or did they develop chorioamnionitis after the amnioinfusion?

Dr. Quetel. This has been reported previously by another author. We found that in the six cases of chorioamnionitis five had premature rupture of the membranes and one did not.

Long-term outcome in fetal hydrops from parvovirus B19 infection

Asad U. Sheikh, MD, Joseph M. Ernest, MD, and Michael O'Shea, MD
Winston-Salem, North Carolina

Parvovirus B19 infection in the fetus is associated with anemia and hydrops and can result in fetal death. Fetal transfusion has been used in an attempt to improve outcome; however, it is associated with its own perinatal morbidity. We report two cases of fetal parvovirus B19 infection that were confirmed by polymerase chain reaction for parvovirus B19 deoxyribonucleic acid in umbilical cord blood. Ultrasonographic signs of compromise were observed at 30 and 24 weeks of gestation. Both fetuses were hydropic and one fetus was also anemic. Serial sonograms demonstrated that the hydrops resolved spontaneously over 3 to 5 weeks after diagnosis. One infant was delivered at 32 weeks of gestation as a result of idiopathic preterm labor. The other infant was delivered at term. Both infants appeared relatively normal at birth and have developed normally in the first year of life. Thus fetal hydrops in association with parvovirus B19 infection does not always lead to poor long-term outcome. A conservative approach without in utero therapy may be appropriate for the management of some of these fetuses. (Am J Obstet Gynecol 1992;167:337-41.)

Key words: Parvovirus B19, hydrops, deoxyribonucleic acid polymerase chain reaction

Human parvovirus B19 was identified in 1975[1] and has been associated with in utero fetal death since 1984.[2] Maternal symptoms are variable and do not correlate consistently with the presence or severity of fetal infection. Pregnancies at any gestational age can be affected. Infection may have no effect on the fetus or can result in aplastic anemia, nonimmunologic hydrops, and increased perinatal mortality.[3-5]

Because fetal parvovirus B19 infection can have a variety of outcomes, agreement is lacking on the management. Fetal hydrops is frequently associated with poor prognosis,[6] prompting attempts at invasive in utero treatment that may be appropriate but is not without risks. We will present two cases of in utero parvovirus B19 infection with hydrops resolving without therapeutic intervention.

Case reports

Case 1. A 26-year-old white woman, gravida 2, para 0, aborta 1, was referred at 30 weeks of gestation for fetal hydrops. Her prenatal course had been uncomplicated until the most recent examination revealed that the fundal height exceeded that expected for gestational age. She denied any rash or arthralgia but complained of a flulike illness 3 weeks before her office visit.

Ultrasonographic evaluation revealed ascites, pericardial effusion, abdominal wall edema, bilateral hydroceles, and severe polyhydramnios (Fig. 1). Gestational age by biparietal diameter and femur length was consistent with 30 weeks. No congenital anomalies were identified. The mother was blood type A-positive and had a negative indirect Coombs screen. Acute and convalescent maternal tests for toxoplasmosis, rubella, cytomegalovirus, and herpes (TORCH) titers showed no evidence of a recent infection. There was no evidence of fetomaternal transfusion by the Kleihauer-Betke test. Maternal serum was immunoglobulin (Ig) G positive and IgM negative to parvovirus B19 by enzyme immunoassay. A diagnostic cordocentesis was performed. The fetal complete blood cell count revealed hemoglobin of 14.3 gm/dl, white blood cells 2.3×10^9/L, platelets 288×10^9/L, nucleated red blood cells 8/100 white blood cells, lactate dehydrogenase 179 U/L, aspartate transaminase 19 U/L, alanine aminotransferase 3 U/L, γ-glutamyl transferase 1889 U/L, total protein 3.5 gm/dl, and albumin 2.2 gm/dl. The karyotype was 46,XY. Fetal serum was IgG positive but IgM equivocal to parvovirus B19. Deoxyribonucleic acid (DNA) of parvovirus B19 was detected in the serum by polymerase chain reaction determined by the Centers for Disease Control; however, the results were not available until 8 weeks after the procedure. Amniotic fluid was IgG positive but IgM negative to parvovirus B19 by enzyme immunoassay. The patient was advised that the prognosis was guarded. Although no specific therapy could be recommended, we suggested that she record daily fetal movement, have twice weekly nonstress fetal heart rate testing, and weekly ultrasonographic evaluations to monitor fetal status.

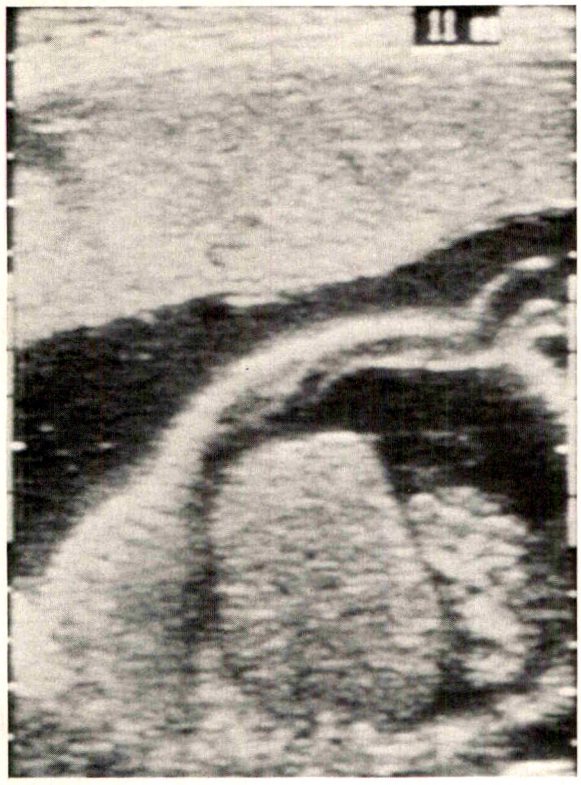

Fig. 1. Severe fetal ascites with bowel, liver, and umbilical vein readily apparent.

The ascites began decreasing by 34 weeks of gestation. By 36 weeks the hydrops had resolved and the amniotic fluid appeared only mildly increased. The amniotic fluid index was normal by 38 weeks.

Labor was induced at 41½ weeks of gestation. The patient required a cesarean section for transverse arrest in the second stage of labor. A 3550 gm male with Apgar scores of 8 and 9 at 1 and 5 minutes, respectively, and a flaccid abdominal wall was delivered. No organomegaly was demonstrated by radiography or ultrasonography. At birth, the hemoglobin was 16.3 gm/dl, white blood cell count 13.5×10^9/L, platelets 332×10^9/L, nucleated red blood cells 1/100 white blood cell count, total protein 6.4 gm/dl, albumin 3.6 gm/dl, and γ-glutamyl transferase 270 U/L.

At 3 months of age the infant was meeting appropriate developmental milestones, However, he was noted to have poor abdominal muscle tone, and both the liver and spleen were felt to be palpable 2 to 3 cm below the costal margin. An ultrasonographic examination did not demonstrate any significant organomegaly. At 9 months of age the baby appears to be normal.

Case 2. A 28-year-old white woman, gravida 4, para 2, abortus 1, was referred at 24 weeks of gestation for fetal hydrops. At 17 weeks of gestation the patient developed a nonpruritic macular rash that began on the trunk and spread to the face and extremities. The rash resolved spontaneously after 5 to 7 days and was followed by symmetric arthralgia involving feet, hands, and knees. The arthralgia also resolved spontaneously. Maternal IgG and IgM for parvovirus B19 obtained during this period were positive. Maternal blood type was O positive and indirect Coombs screen was negative. The maternal serum α-fetoprotein level (AFP) at 16 weeks of gestation was normal.

At 24 weeks an ultrasonographic examination was performed because the fundal height was larger than expected. The fetus had abdominal ascites, pericardial effusion, severe polyhydramnios, and an edematous placenta. Biparietal diameter and femur length were consistent with 23 weeks of gestation. Acute and convalescent TORCH titers first drawn at 23 weeks of gestation did not indicate an acute infection, nor was there evidence of fetomaternal transfusion by the Kleihauer-Betke test.

One week later the sonogram demonstrated a slight improvement of the ascites and polyhydramnios. The pericardial effusion was unchanged, but cardiac contractility appeared normal. Cordocentesis was performed with the intention of transfusing the fetus if it was severely anemic. Amniotic fluid (AFP) was normal (3.33 μg/ml). The karyotype was 46,XX. The fetal hemoglobin was 11.7 gm/dl, and white blood cells 2.6×10^9/L. Fetal serum was IgG positive but IgM equivocal to parvovirus B19 by enzyme immunoassay. The polymerase chain reaction was subsequently reported to be positive for parvovirus B19 DNA in the fetal serum. The patient was counseled that the prognosis was poor for hydrops fetalis resulting from a parvovirus B19 infection. She was offered weekly sonograms in addition to recording daily fetal movement.

By 26 weeks the ascites and polyhydramnios had resolved. The pericardial effusion was undetectable in all subsequent examinations.

The patient went into spontaneous premature labor at 32 weeks of gestation. A 1495 gm female was delivered with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively. Neonatal hemoglobin was 19.8 gm/dl, platelets 119×10^9/L, white blood cells 6.6×10^9/L, and nucleated red blood cells 1/100 white blood cells. Parvovirus B19 DNA was not detected in the neonate's serum obtained shortly after birth. The infant had mild respiratory distress syndrome, but the physical examination was otherwise normal. The infant was discharged 38 days after birth. Placental histologic studies showed no significant infectious changes.

At 18 months of age the child had normal abdominal tone and was meeting the appropriate developmental milestones.

Comment

In these two cases of severe hydrops fetalis resulting from fetal parvovirus B19 infection, the fetal manifestations of infection spontaneously resolved within 5 weeks of diagnosis. This observation suggests an alternate course of management instead of previously described recommendations of in utero fetal therapy.

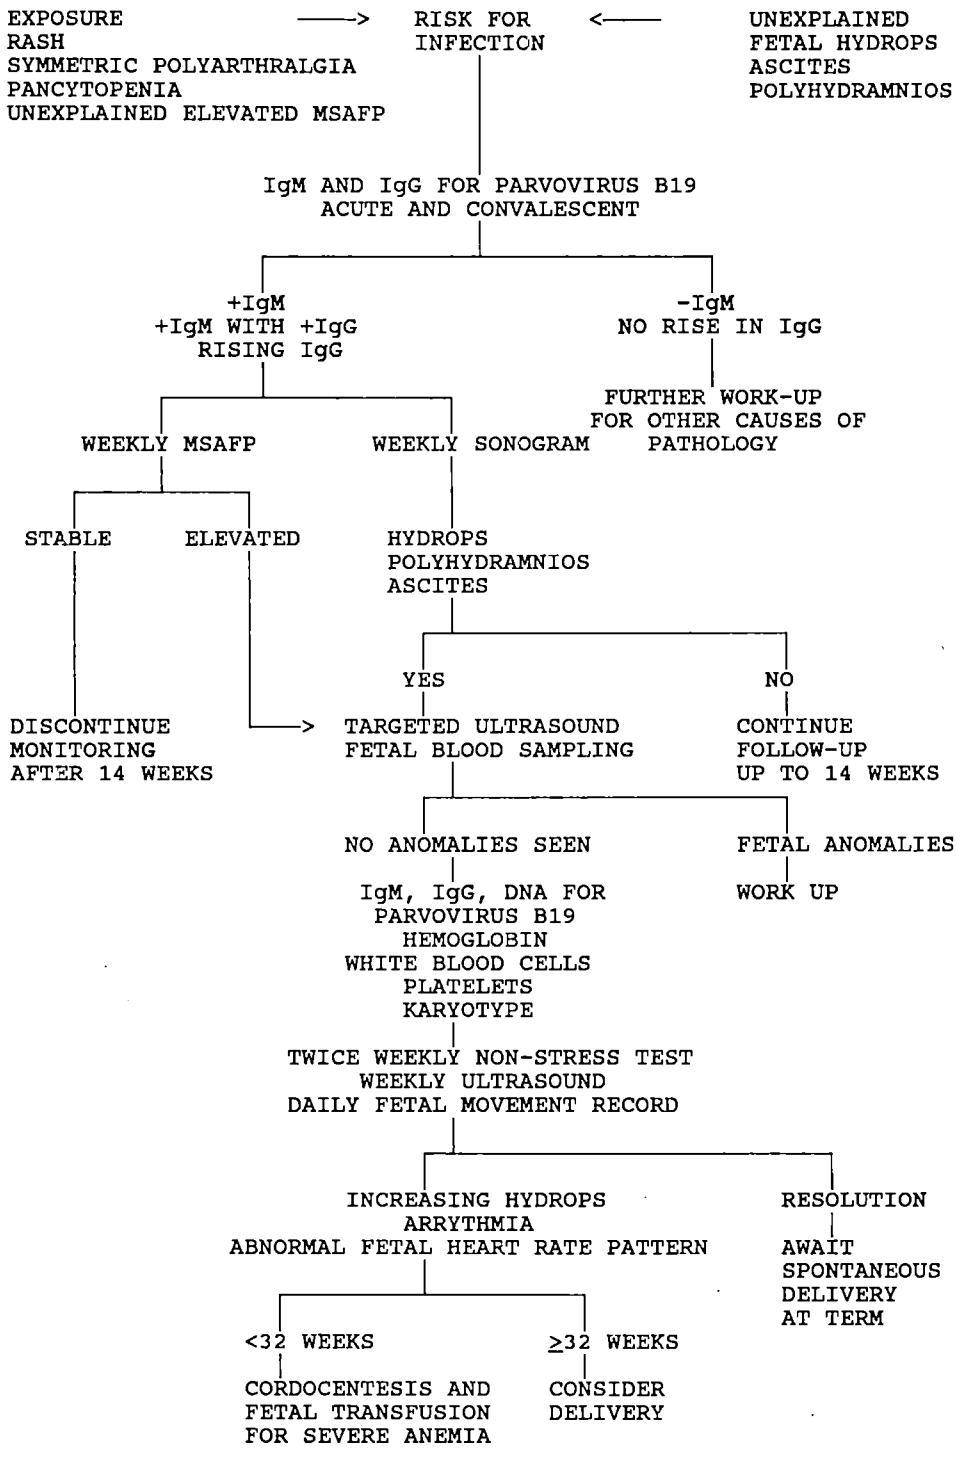

Fig. 2. Flow chart.

Approximately 35% to 50% of the general population is susceptible to parvovirus B19 infection; 20% of this group will become infected after exposure.[7] The risk for infection is highest among household contacts and in working conditions involving close contact, such as in schools.[8] The Centers for Disease Control have estimated that the risk of fetal death from infection on the basis of the risk for maternal infection and the transmission rate to the fetus ranges from <1% to 15%.[9]

Parvovirus B19 infection, or Fifth disease, should be suspected if there has been a local outbreak or if the mother has symmetric polyarthralgia or a maculopapular rash. In children, however, the "slapped cheek"

rash is a more common presentation. Ultrasonographic signs of fetal infection include ascites, effusions, skin edema, polyhydramnios, cardiomegaly, placentomegaly, and decreased fetal movement.[7] Unexplained elevated maternal serum AFP[10] may also indicate infection. The fetus may be anemic or pancytopenic, which can be confirmed by cordocentesis. Diagnosis is confirmed by counterimmunoelectrophoresis or radioimmunoassay for IgM to parvovirus B19 in the maternal serum. Electron microscopy of blood or tissue is useful only when viral particles are seen. DNA tests for parvovirus B19 have become available and are highly sensitive. However, they are only positive in blood during viremia or if the tissue is currently infected.[11, 12]

There are several mechanisms by which the pathologic changes associated with infection occur. Fetal anemia results from arrest of red blood cell maturation[13] and karyorrhexis of red blood cells.[14] Infection of the myocardium may result in direct impairment of cardiac function.[15, 16] Hepatic function may also be impaired directly by infection or by hemosiderin deposition in the hepatocytes and Kupffer cells, which results in necrosis and fibrosis.[17, 18]

Although hydrops is frequently associated with poor prognosis, attempts have been made to use maternal serum AFP or cardiac size to predict outcome. Maternal serum AFP increases 4 weeks before ultrasonographically detectable signs and 6 weeks before fetal death in infected pregnancies.[10] Normal values for maternal serum AFP have been determined through 36 weeks of gestation.[19, 20] Elevation of maternal serum AFP may be the result of hepatic or placental damage. In hydropic fetuses an increased cardiac biventricular outer diameter >95th percentile is predictive of perinatal death.[21]

Past treatments have included in utero fetal transfusion,[22] direct fetal digitalization,[15] and serial thoracentesis or paracentesis.[23] These have been combined with frequent reevaluation by ultrasonography, fetal nonstress tests, or fetal movement records.[7, 15, 23] An alternate approach is outlined in Fig. 2. If infection is suspected, specimens for maternal IgM and IgG titers are drawn immediately and measurements are repeated in 4 weeks. Patients with evidence of previous exposure and no acute rise in IgG require no further evaluation for parvovirus B19 infection. Other causes of hydramnios or hydrops should be sought in those pregnancies where parvovirus B19 infection is not identified. Serial evaluation including weekly maternal serum AFP and sonogram screening should be offered to patients with acute infection as diagnosed by the presence of IgM, IgM, and IgG, DNA, or an acute rise in IgG to parvovirus B19. This weekly screening should be performed for up to 14 weeks after the diagnosis of infection is confirmed.[3, 16]

In the presence of hydrops at or beyond 20 weeks of gestation, diagnostic cordocentesis is recommended. The testing should include karyotype, hemoglobin, platelet count, and white blood cell count in addition to DNA, IgG, and IgM for parvovirus B19. A conservative approach combining twice weekly fetal nonstress tests, serial sonograms, and recording of fetal movement may be used after 28 weeks. Biophysical profiles may not be helpful because anemic fetuses may still have adequate breathing, movement, and tone. Delivery should be considered when the fetus is at or beyond 32 weeks of gestation in cases where hydrops is increasing, arrhythmias are present, or fetal heart rate patterns show no variability or late decelerations. If severe prematurity precludes delivery, cordocentesis for reevaluation of hemoglobin should be performed. If the fetus is severely anemic (for example hemoglobin ≤5 gm/dl), packed red blood cells may be transfused.

A conservative approach without in utero treatment is reasonable in light of several reports that have shown recovery of fetal red cell production.[2, 24] One of our patients had normal hemoglobin and the other was mildly anemic. This is consistent with the recovery phase of parvovirus B19 infection. Spontaneous resolution of fetal parvovirus B19 infection may occur more frequently than previously suspected. Two previous case reports document parvovirus B19 infection with hydrops fetalis and subsequent spontaneous resolution.[23, 25] On the basis of these cases, the short-term prognosis of in utero parvovirus B19 infection resulting in hydrops fetalis may be favorable. Further, the two cases described here suggest that the long-term prognosis after resolution of hydrops is good. Conservative management without in utero fetal therapy is reasonable in selected cases.

Discussion

Dr. Edgar O. Horger III, Columbia, South Carolina. Dr. Sheikh, I feel that you and your coauthors showed remarkable restraint in the conservative management of the first case with hydrops at 30 weeks' gestation. I probably would have pushed for delivery, and retrospectively I think that I would have been making a mistake. Let me ask you a question that seems obvious: Can I get parvovirus from my dog?

Dr. Asad U. Sheikh (Closing). Canine parvovirus infection is frequently fatal. However, this organism is not transmitted to humans and does not appear to cause infections in humans.

Experience with mepivacaine paracervical block in an obstetric private practice

J. Robert Goins, MD
Hickory, North Carolina

OBJECTIVE: The objective of this study was to determine the efficacy and safety of mepivacaine paracervical block in term, low-risk obstetric patients.
STUDY DESIGN: Over a 3-year period all term, low-risk obstetric patients in the author's private practice were offered mepivacaine paracervical block anesthesia. One hundred eighty-two patients received 200 mg mepivacaine with each block. The patients who declined paracervical block were used as a control group to compare Apgar scores, subject to χ^2 analysis.
RESULTS: Initial injections were 97.3% successful. Average duration of anesthesia was 59.7 minutes with the first injection. Fetal bradycardia occurred in 13.2% with an average duration of 4.5 minutes. The slightly higher incidence of low Apgar scores at 1 and 5 minutes in the study group was not statistically significant. One neonatal death occurred secondary to group B streptococcal sepsis in the study group.
CONCLUSION: Mepivacaine paracervical block remains an anesthetic option in low-risk patients. The high success rate is limited by its short duration of action and the incidence of fetal bradycardia. (AM J OBSTET GYNECOL 1992;167:342-5.)

Key words: Mepivacaine, paracervical block

Paracervical block for obstetric anesthesia was initiated in Germany in the 1920s and became popular in the United States in the mid-1950s.[1] Even with the frequent occurrence of fetal bradycardia, paracervical block was presumed safe until serious maternal and fetal complications were reported in the 1960s. Perinatal deaths were described in both complicated and low-risk labors.[2,3] Since then paracervical block has decreased in popularity, and its use is limited to pregnancies with low risk of underlying fetal compromise. With the current use of electronic fetal monitoring some of the complications reported 30 years ago might be avoided.

The author is a member of an obstetrics-gynecology group practice that offers paracervical block as one of the anesthesia techniques available to laboring patients. It is discussed with the patient by the physicians and by nurse-instructors during childbirth preparation classes. The results of a 3-year experience are presented.

Material and methods

The patients included in this study are all the patients managed by the author between Jan. 1, 1988, and Dec. 31, 1990, who requested and received mepivacaine paracervical block during labor. During this period 197 patients received paracervical blocks; however, lidocaine was used in 15 patients. Therefore 182 patients are reported in this series. The characteristics of this group are recorded in Table I. Any patient who was preterm, after 42 weeks, hypertensive, demonstrating an abnormal fetal heart tone tracing, or exhibiting thick meconium-stained amniotic fluid was not given paracervical block. Patients with light meconium-stained fluid were allowed to receive paracervical blocks. A control group of the remainder of the patients delivered by the author during this 3-year period was used to compare the incidence of low Apgar scores. This control group consisted of 343 patients with characteristics

Table I. Characteristics of 182 patients receiving paracervical block

Characteristic	*No. of patients*
37 to 42 Weeks' gestation	182
Normal fetal heart tracing before block	182
Light meconium	11
Gestational diabetes	2
Vaginal birth after previous cesarean section	2
No prenatal care	1
Premature rupture of membranes <24 hr	1
Von Willebrand's disease	1
Congenital absence of right pulmonary artery (asymptomatic)	1

Table II. Efficiency and duration of mepivacaine paracervical block

Paracervical block No.	*Success rate*		*Average duration (min)*
	No.	*%*	
1	177/182	97.3	59.7
2	65/69	94.2	52.1
3	12/12	100	46.7

similar to the study group, but the controls underwent anesthetic techniques other than paracervical block.

The method of injecting the paracervical block involved the use of a disposable paracervical-pudendal block tray that does not allow the needletip more than 5 mm beyond the guide. The patient was placed in lithotomy position. After the vulvar area was washed with a chlorhexidine solution, the guide was placed in one of the lateral fornices of the vagina, aimed toward the pelvic sidewall and away from the fetal head. The needle was inserted through the guide to a depth of ≤5mm. After aspiration to rule out intravenous injection, 10 ml of 1% mepivacaine was injected with aspiration after every 2 to 3 ml. A similar injection was then performed in the other lateral vaginal fornix with no delay other than the time required to resposition the guide and the needle. The patient received a total of 200 mg mepivacaine with each paracervical block.

Results

The anesthetic efficiency of mepivacaine paracervical block in these 182 patients is summarized in Table II. Successful anesthesia was judged only by the patient, so a successful block was noted if the patient stated that she had experienced pain relief. The efficiency of repeat injections is also reported in Table II. Sixty-nine patients required a second block, and 12 needed a third after the anesthetic effects of earlier injections faded.

The duration of initial and repeat paracervical blocks is also recorded in Table II. Only successful blocks were used to determine average duration. The range of duration was 14 to 120 minutes. Duration of <30 minutes was always associated with delivery within 35 minutes of injection. As shown in Table II, duration of effect decreases with subsequent blocks.

Maternal side effects in this group are infrequent. Transient tinnitus or oral paresthesias occurred in only four patients (2.2%). There were no seizures, significant blood pressure changes, or hematomas in these patients.

Fetal bradycardia was the most common side effect. It was defined as a fetal heart rate drop below 100 beats/min (or 40 beats/min below previous baseline) lasting more than 30 seconds and occurring within 45 minutes of paracervical block. Early decelerations associated with pushing were not included. Incidence, injection to bradycardia interval, and duration of bradycardia are reported in Table III. Management of this complication included increasing maternal intravenous fluid infusion, maternal oxygen therapy by mask, and maternal positioning on the left side. All episodes of bradycardia responded without any further intervention. The range of duration of fetal bradycardia was 1 to 8 minutes.

Table III. Bradycardia with mepivacaine paracervical block in 182 patients

Incidence	*Average injection-bradycardia interval (min)*	*Average duration (min)*
24/182 (13.2%)	7.9	4.5

Table IV. Incidence of Apgar scores <7

Group	*1 min Apgar score <7*	*5 min Apgar score <7*
Paracervical block	19/182 (10.4%)	4/182 (2.2%)
Control	24/343 (7.0%)	4/343 (1.2%)

Data were evaluated by χ^2 statistical analysis. Differences in 1-minute Apgar scores between the paracervical block group and control group ($\chi^2 = 1.87$) and differences in 5-minute Apgar scores between the groups ($\chi^2 = 0.84$) were not statistically significant.

A comparison of low Apgar scores (<7) between the paracervical block group and the control group is presented in Table IV. There is a higher incidence of low Apgar scores at 1 and 5 minutes in the paracervical block group, but the differences are small. Of the 19 study patients with 1-minute Apgar scores <7, seven were associated with shoulder dystocia, five had experienced fetal bradycardia, three had meconium, two had a tight nuchal cord, and one had group B streptococcal infection. Of the four babies with 5-minute Apgar scores <7, two were associated with shoulder dystocia, one with tight nuchal cord, one with light meconium, and none had fetal bradycardia from paracervical block.

There was one neonatal death in the paracervical block group, but this was an effect of group B streptococcal infection rather than an anesthetic complication. The patient was a 34-year-old woman, gravida 6, para 2-0-3-2, with a benign prenatal course. At 37 weeks she was in labor, and the cervix was 3 cm dilated and 80% effaced with the vertex at −2 station and with intact membranes. Amniotomy was performed, and clear fluid was noted. She received 50 mg meperidine hydrochloride intravenously, and 2 hours later, at 7 cm dilatation, she requested paracervical block. Relief was obtained for 68 minutes; at 75 minutes after the first

paracervical block a second injection was performed at 8 cm dilatation. Outlet vacuum extraction delivery of a 2750 gm male infant occurred 31 minutes after the second block. There was no fetal bradycardia, maternal fever, or meconium. Apgar scores were 6 at 1 minute and 7 at 5 minutes. The baby was transported from the birthing room to the nursery with oxygen. The initial working diagnosis was transient tachypnea versus sepsis. Sepsis evaluation was performed and chest radiography showed pneumonia. In spite of aggressive antibiotic, respiratory, and fluid management, the condition of the infant deteriorated and he died 14 hours after birth. Blood cultures grew group B streptococci.

Comment

The success rate for mepivacaine paracervical block in this group of 182 patients was excellent. However, duration of action of only 1 hour with the first block and even less with subsequent injections requires frequent repeat procedures. This exposes the patient to higher total doses of local anesthetics with greater potential for toxicity. The 13.2% incidence of bradycardia was comparable to earlier studies. The occurrence of lower Apgar scores was also slightly higher in the paracervical group. These findings reinforce the prudence of using this anesthetic technique in low-risk patients only. Perhaps the ideal patient is one who is multiparous, at term with no evidence of fetal compromise, and experiencing a rapid labor.

The worst fetal outcome during this 3-year experience was a neonatal death associated with group B streptococcal infection. This outcome was unrelated to the patient's paracervical block.

Discussion

DR. ALLAN G. MCLEOD, Miami, Florida. In 1992 a report of 182 patients receiving mepivacaine paracervical block for labor analgesia is unusual and of special interest to me in that I have used the technique extensively in the past. In the late 1960s and 1970s, as stated by Dr. Goins, the technique engendered a reputation for serious complications, resulting in diminished popularity of the technique, especially in the hostile medicolegal climate. Second, its duration of action was relatively short, and obstetric anesthesiology services, including epidural anesthesia, were becoming increasingly available to obstetricians as the subspecialty of obstetric anesthesiology began to gain a foothold.

Patients in this study were carefully selected to exclude parturients at increased risk.

The paracervical block technique was carefully described by Dr. Goins correctly emphasizing preinjection aspiration, depth of penetration, and correct positioning of the needle to avoid intravascular injection or injection directly into the fetal scalp. These are important factors in reducing the complication rate. Personally, I tended to delay the injection in to the second fornix for a brief interval while monitoring the fetus; this appeared to minimize the incidence of bradycardia. In more advanced labor, placing the examining fingers between the fetal head and the needle insertion point in the fornix is an extra safeguard. I commend Dr. Goins also for the careful vulvar cleansing performed before the injection but had some concern regarding use of the lithotomy position for any prolonged period.

An Apgar score <7 at 5 minutes did not appear to be a complication of the block itself in Dr. Goins' study. The only death in the series was related to a β-streptococcal infection.

Dr. Goins, while reporting a high success rate, emphasizes such drawbacks as short duration of action and the need for repeat injection with resultant exposure to higher total doses of local anesthetic agents. I concur with his statement that the normal multiparous woman requiring analgesia is probably the ideal candidate for this technique. It would have been interesting to learn the extent of the discussion of the technique with couples at the childbirth preparation classes.

Fetal bradycardia occurred in 13.2% of cases in this series, which is less than the 25% to 35% reported by others. This may well be attributable to the careful technique of Dr. Goins. The injection-to-bradycardia interval averaged 7.9 minutes with an average duration of 4.5 minutes. Shnider et al.[1] noted an onset within 2 to 10 minutes and a duration of 3 to 30 minutes and emphasized that whereas the cause of the bradycardia was controversial its significance was not. Increased neonatal morbidity and >50 cases of perinatal death associated with paracervical block have been reported in the American and European literature. Shnider et al. emphasized that paracervical block should not be used in situations where the fetus is potentially or actually compromised.

Dr. Goins injected 10 ml mepivacaine on each side. I found it possible to obtain a satisfactory block with 5 to 7 ml on each side. In addition to the safeguards already mentioned, the drug dosage should be kept to a minimum.

Bupivacaine should not be used for paracervical block. Freeman and Arnold[2] suggested that chloroprocaine should be used rather than mepivacaine or lidocaine if more than one dose was likely to be required.

Dr. Goins has demonstrated that paracervical block can be used safely in an obstetric practice; however, use

of the technique demands that the user and the parturient are fully aware of the hazards associated with its use and the steps necessary to minimize their occurrence.

Most obstetric services have discontinued the use of paracervical block in favor of epidural anesthesia or other forms of analgesia, and use of the technique tends to be limited to those units with minimal obstetric anesthesiology services or small community hospitals.

I should like to congratulate Dr. Goins on his study and caution him to be ever vigilant in his selection of patients and in applying the appropriate safeguards in the use of the technique and, finally, to recognize clearly that he is "swimming against the tide" in the unfortunate event that he should experience a serious complication in the future.

DR. GOINS (Closing). As far as counseling patients is concerned, I explained how I perform the technique and that our incidence of bradycardia is about 15%. The patients are also told that should bradycardia occur, they will be placed on a side and given oxygen. They understand that in the past the bradycardia has responded to this. It is important that they know ahead of time about the possibility of bradycardia, because they are very aware of changes in the monitor, almost staring at the monitor like children in front of a television. The dosage that I currently use is based on past experience. Lower dosages failed to give an anesthetic effect of sufficient duration. The use of paracervical anesthesia is limited to low-risk patients.

I appreciate the discussion of the cause of the bradycardia that is associated with paracervical block, which I did not touch on in my article.

Dr. Hopwood's article is one that I reviewed. In the group of patients with 5-minute Apgar scores <7 none of the patients experienced fetal bradycardia. Of the 19 patients who had 1-minute Apgar scores <7, five experienced fetal bradycardia. I do not have it broken down as to the time between injection of the local anesthetic and delivery. Among the patients with low Apgar scores who were delivered within 30 minutes of the block, there was only one baby with a low Apgar score. That baby who subsequently had group B streptococci had a 1-minute Apgar score of 6 and a 5-minute Apgar score of 7.

With regard to the question about scalp pH and cord gas studies, I did not determine scalp pH in any of the patients with fetal bradycardia, and no cord gas studies were done on either the study patients or the control patients.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Refining the biophysical profile with a risk-related evaluation of test performance

Lawrence D. Devoe, MD, Alaaeldin A. Youssef, MD, Paula Gardner, RN, Cheryl Dear, RN, BSN, and Cheri Murray, RN

Augusta, Georgia

OBJECTIVE: Our objective was to determine the ability of biophysical profile variables to predict bad perinatal outcome in high-risk third-trimester pregnancy.

STUDY DESIGN: The outcomes of 1146 fetuses were correlated with abnormal single or multiple variables occurring in biophysical profile done within 72 hours of delivery. Theoretic risks of poor outcomes for different combinations of abnormal variables, calculated with Shortliffe's formula, were compared with the actual risks observed (χ^2 tests).

RESULTS: Two hundred forty-six fetuses had at least one abnormal biophysical profile variable with the risk of bad outcome, for a single abnormal variable, ranging from 8% (body movements) to 100% (tone) and increasing from 14% (any variable abnormal) to 63% (all variables abnormal). In most (57%) observed combinations of biophysical profile variables, significant differences between theoretic and actual risks of bad outcomes were found. By stepwise logistic regression the best predictive model contained all variables except fetal movement.

CONCLUSIONS: Dynamic biophysical profile variables appear to be interdependent. Not all combinations of abnormal variables occur and specific combinations improve prediction of poor outcome. Risk-related scales for biophysical profile outcomes might prove superior to more conventional scoring systems. (Am J Obstet Gynecol 1992;167:346-52.)

Key words: High-risk pregnancy, biophysical testing, fetal heart rate, fetal movement, fetal breathing, amniotic fluid volume

The fetal biophysical profile has become an increasingly popular test over the past decade.[1-3] The biophysical profile combines variables reflecting fetal status, e.g., baseline heart rate, breathing movements, and body movements, with those more suggestive of chronic status, e.g., amniotic fluid volume and neurologic tone. This testing approach assumes that the consideration of multiple variables improves diagnostic accuracy and provides a more comprehensive evaluation of fetal condition. Although previous reports have addressed these issues,[4-9] they have shared the following features: (1) test variables have not been collected simultaneously, (2) an arbitrary rating scheme for variables has been used, (3) the length of observation has been relatively short, often ≤30 minutes, (4) standardization of testing conditions has not been strictly enforced, and (5) the prevalence of poor outcomes has been relatively low. Earlier studies have suggested, on the one hand, that there is a progressive sequence in the appearance of abnormal variables,[2] and, on the one hand, that there is little prognostic difference among tests grouped by number of abnormal variables.[1-3] More recently, Manning et al.[10] have questioned the relationship of specific abnormal variables and their combinations to test accuracy. They suggest that there are prognostic differences associated with different combinations of variables and that the unequal distribution of these combinations implies an interdependence of these variables.

We undertook the present study to test the validity of these prior assumptions. First, we wished to determine if there were differences in the prognostic values of individual variables and their combinations for predicting the risk of abnormal outcomes. Next, we wished to determine if, within each grouping of abnormal variables, all combinations of abnormal variables were equally probable. Finally, we wished to determine if a model that assumed independence of variables would yield predictive values that agreed with those actually observed in the field.

Material and methods

The study population consisted of 1146 patients who received antenatal testing at the Medical College of Georgia Hospitals and Clinics for a variety of high-risk problems (Table I). All were tested between 32 and 42

weeks of gestation and delivered within 72 hours of their final test. Testing results were available to clinicians who provided obstetric care. Although antepartum management was based on a variety of clinical considerations, in general fetuses with normal biophysical profiles were retested within 7 days, those with one abnormal variable were retested within 24 to 48 hours, and those with two or more abnormal variables were evaluated for delivery.

Biophysical testing was performed in accordance with a previously published protocol.[11] Ultrasonographic observations of fetal breathing movements, body movements, amniotic fluid volume, and tone (flexion-extension movements) were acquired simultaneously with a continuous recording of fetal heart rate. These data were entered in a specially programmed microcomputer that analyzed the incidences of fetal breathing movement, body movement, flexion-extensions, accelerations and decelerations, and the baseline fetal heart rate.[11] Amniotic fluid volume was measured as the largest single pocket in vertical and horizontal dimensions. Previously published institutional standards[3] for gestational age were used as reference points. Abnormal values for any variable were considered to be those that exceeded the normal population means by >2 SD.

For the purposes of this study, only the last tests before delivery were considered in the subsequent correlations with outcomes. Perinatal end points examined were mortality, intrapartum fetal distress requiring operative intervention, 5-minute Apgar score <7, neonatal mixed or metabolic acidosis (on the basis of umbilical arterial pH <7.15 and base excess >−8.0 mEq/L). The conditional probability for the risk of bad outcomes associated with each variable was determined by its occurrence as the sole abnormal variable with all bad outcomes.[12] The theoretic risk of bad outcomes associated with combinations of more than one abnormal variable was determined by the following formula of Shortliffe and Buchanan[13]

$$BO = \sum_{a} Ra - \sum_{\substack{a=b \\ a<b}} Ra\,Rb + \sum_{\substack{a=b=c \\ a<b<c}} Ra\,Rb\,Rc \ldots$$

where BO is risk of bad outcome and Ra, Rb, Rc . . . is risk of bad outcome associated with abnormal variable (if the variable is normal, R = O).

The theoretic risks of bad outcomes and the observed rates of bad outcomes associated with each combination of abnormal biophysical profile variables were compared. For the purposes of this study, a level of disagreement >0.2 (range 0 to 1.0) was considered clinically significant. In addition, the distributions of combinations of abnormal variables and their associated positive predictive values were compared with χ^2 tests.

Table I. Indications for biophysical testing

Indications	*No.*	*%*

Poor obstetric history	44	3.8
Miscellaneous obstetric	274	24.4
Miscellaneous medical	54	4.7
TOTAL	1146	100.0

The standard for comparison within each category of abnormal variable combinations, ie, two abnormal variables, three abnormal variables . . . , was the mean positive predictive value for the entire category[10]; no combination with fewer than five cases was considered for this comparison.

Linear logistic regressions were applied to combinations of abnormal variables. A p value <0.05 was considered significant.

Results

The study population was delivered at a gestational age of 38.1 ± 2.1 (mean ± SD) weeks. The distribution of test outcomes by number of abnormal variables and associated perinatal outcomes is listed in Table II. Two hundred forty-six patients (21.5%) had at least one abnormal variable on their last biophysical profile. There was a positive correlation ($r = 0.31, p = 0.04$) between increasing numbers of abnormal variables and the occurrence of all bad outcomes. Similar trends were seen with all individual bad outcomes except for low 5-minute Apgar scores.

Table III shows that the nonreactive nonstress test (NST) was the most common abnormal variable, whereas absent tone was the least common abnormal variable. No individual variable had high sensitivity, whereas all had high specificity. Similarly, positive predictive values for all variables except fetal tone were <50%; all variables had negative predictive values >88%.

Table IV shows the frequency of tests with a single abnormal variable and associated poor outcomes. Although a nonreactive NST occurred significantly more often than the other abnormal variables, absent fetal tone was the only variable uniformly associated with abnormal outcomes. In both cases a major fetal anomaly was present (anencephaly, holoprosencephaly), and neonatal death occurred.

Combinations of two or more abnormal variables and their associated poor perinatal outcomes are shown in Tables V through VII. Six of 10 possible combinations of two abnormal variables were observed (Table V), of

Table IV. Abnormal individual biophysical variables: Frequency and associated perinatal outcomes

Variable	*Frequency*		*Abnormal outcomes*	
	No.	*%*	*No.*	*%*
NST	69	51.9	8	11.6
Fetal breathing movement	34	25.6	6	17.7
Amniotic fluid volume	16	12.0	3	18.8
Body movement	12	9.0	1	8.3
Tone	2	1.5	2	100.0
All tests	133	100.0	20	15.0

which abnormal fetal breathing movement and nonreactive NST were the most frequent. Three of these six combinations of abnormal variables were of sufficient size to allow statistical comparisons. Only the combination of abnormal NST and amniotic fluid volume had a predictive accuracy that was significantly greater than the group mean and approximately twice that calculated for independent variables. Five of 10 possible combinations of three abnormal variables were observed (Table VI), of which abnormal NST–body movement–fetal breathing movement was the most frequent. Only two combinations occurred frequently enough to allow statistical comparisons of predictive accuracy; neither differed significantly from the group mean. The predictive accuracy of the combination of abnormal NST–body movement–fetal tone differed significantly from that predicted for independent variables. Two of five possible combinations of four abnormal variables was observed (Table VII). The predictive accuracy of each combination differed significantly from that predicted for independent variables.

The predictive accuracy of five abnormal variables was 62.5%, although the formula would have yielded a 100% risk of poor outcomes. Had intrauterine growth retardation been considered as a measure of poor outcome, the predictive accuracy would have been 100% because all cases without other complications had birth weights <10th percentile for gestational age.

Sixteen perinatal deaths (three stillbirths and 13 neonatal deaths) occurred in the study group. Only one death followed a normal biophysical profile and was due to complications of prematurity. Of the three neonatal deaths associated with a single abnormal biophysical profile variable, two were in infants with major central nervous system malformations; the other death was a consequence of necrotizing enterocolitis in an otherwise normal term infant. Two stillbirths occurred in the group with two abnormal variables: one in a poorly controlled diabetic patient and the other in a fetus with hydrops caused by congenital heart block.

Table V. Combinations of abnormal variables: Frequency and associated perinatal outcomes observed and predicted

Variable	Frequency		Abnormal outcomes	
	No	*%*	*Observed (%)*	*Predicted (%)*
NST–fetal breathing movement	32	54.1	28.1	27.3
NST–body movement	10	17.0	20.0	19.1
NST–amniotic fluid volume	7	11.9	57.1	28.4
Fetal breathing movement–tone	4	6.8	25.0	59.0
NST–tone	3	5.1	0.0	56.0
Fetal breathing movement–amniotic fluid volume	3	5.1	0.0	33.3
All tests	59	100.0	17 (29.0)	

Table VI. Combinations of three abnormal variables: Frequency and associated perinatal outcomes observed and predicted

Variable	Frequency		Abnormal outcomes	
	No.	*%*	*Observed (%)*	*Predicted (%)*
NST–body movement–fetal breathing movement	8	36.4	37.5	38.0
NST–body movement–tone	6	27.3	33.3	70.0
NST–body movement–amniotic fluid volume	3	13.6	33.3	39.0
NST–fetal breathing movement–amniotic fluid volume	3	13.6	33.3	49.0
NST–fetal breathing movement–tone	2	9.1	50.0	79.0
All tests	22	100.0	8 (36.4)	

The remaining deaths associated with three or more abnormal variables were either consequences of major anomalies (two cases) or intrauterine growth retardation (eight cases).

Logistic regression analysis was applied to all test outcomes and yielded a model that was highly significant for all abnormal outcomes ($\chi^2 = 35.62$, $p < 0.00001$). This model required NST, fetal breathing movement, amniotic fluid volume, and tone for any abnormal outcome, with the highest weighting for tone (2.78) and the lowest for amniotic fluid volume (2.08). Body movements were not required for the prediction of any poor outcome.

Comment

Fetal biophysical testing has entered its second decade of clinical investigation and application. The consensus of previous studies is that the combined observation of several biophysical variables yields a test whose predictive accuracy exceeds that of the NST alone.[14, 15] The extensive data base compiled by Manning et al.[5] suggests that predictive accuracy of poor perinatal outcomes increases significantly as the number of abnormal biophysical variables increases. Vintzileos et al.[16] and Manning et al.[10] have implied that consideration of specific test variables, when abnormal, may be more important for prognosis than a raw score derived from combining unweighted variables. It has been implied further that a modified biophysical profile, focusing primarily on the NST and amniotic fluid volume evaluation, might be sufficient for most antepartum testing needs.[17] These issues are clearly important to resolve because biophysical testing is more labor intensive than the NST or amniotic fluid volume measurement.

The current study has focused on the frequency of associated abnormal biophysical profile variables and their relationship to the risk of a bad perinatal outcome. As in virtually all prior reports of biophysical testing, we have observed a positive relationship between the number of abnormal biophysical profile variables and the risk of bad perinatal outcomes. In contrast to some of the previous studies[3, 5, 6] we also found that tests with only one abnormal variable could be associated with an increased risk of perinatal compromise when compared with tests in which all variables were normal. The most significant abnormal variable, when seen in isolation, appears to be fetal tone, because this abnormality was rare but was always associated with central nervous system anomalies.

Our data tend to support some of the conclusions reached by Manning et al.[10] in a similar previous study. The frequencies of abnormal individual variables either in isolation or in combination with other abnormal variables are not equal. The most common abnormal vari-

Table VII. Combinations of four abnormal variables: Frequency and associated perinatal outcomes observed and predicted

Variable	Frequency		Abnormal outcomes	
	No.	*%*	*Observed (%)*	*Predicted (%)*
All except amniotic fluid volume	11	68.8	31.2	88.0
All except tone	5	31.2	40.0	67.0
All tests	16	100.0	7 (43.7)	

able was the nonreactive NST. This finding agrees with that of Baskett et al.[4] but differs from our previous report[3] and that of Manning et al.[10] in which fetal breathing movement and fetal tone were the most common abnormal variables, respectively. These differences may reflect sample size, gestational age of the population studied, study technique, and cutoff points used for abnormal variables. No individual variable confers sufficient predictive accuracy to be a good "stand-alone" test.

The frequency distribution of the abnormal individual variables is also of interest, because it bears on the "ontogeny" of fetal response to intrauterine compromise proposed by Vintzileos et al.[2, 8] Their model suggests an inverse relationship between the age of appearance and the central nervous systems centers in which biophysical activities develop and their sensitivity to hypoxia. This model implies that hypoxia would affect the newer centers such as those governing fetal heart rate and fetal breathing movement before those regulating body movements and tone. Although our data do not directly confirm a sequential pattern of variable abnormality before poor outcome, the relative frequency of abnormal variables follows the sequence proposed by Vintzileos et al.[2] with nonreactive NSTs being the most common and absence of tone the least common.

This study differs from most of its predecessors in the manner with which the biophysical data were collected and in the standards used for their testing. In our laboratory, both ultrasonographic and fetal heart rate data are collected simultaneously under rigorously standardized environmental conditions. They are rated according to standards that we have established for normal fetuses of similar gestational age.[3] These normative standards are more stringent for all biophysical variables than those used in the other approaches. Although this makes the analysis of the combined abnormal variables not directly comparable to those of Manning et al.,[10] it also avoids possible artifacts that occur when fetal state changes during the course of a study. The failure to observe all possible combinations of abnormal variables may be due partly to sample size but may also reflect their dependent relationship to fetal state. This latter contention is supported by the fact that in no combinations of two or three abnormal variables was decreased body movement seen without abnormal NST, and in all combinations of four abnormal variables, abnormal NST, fetal breathing movement, and body movement occurred together.

A further argument for the interdependence of the biophysical variables is supported by the discrepancies in predicted and observed risks of bad perinatal outcomes in more than half (4/7) of the test combinations sufficiently large to analyze. In most instances (3/4), the observed incidence of poor outcome was considerably lower than that predicted by a formula that assumed that the variables were independent. Our data also support the view that certain combinations of abnormal variables may have greater prognostic importance than others, e.g., the combination of nonreactive NST and abnormal amniotic fluid volume. More important, predictive accuracy for all observed combinations of three or four abnormal variables appears to be similar within their respective categories.

This study adds further support to the original thesis of Manning et al.[1] that multiple variable biophysical testing can augment prediction of outcome in high risk pregnancy. Additional variables improve the predictive accuracy of the biophysical profile; however, they do not appear to be of equal importance for establishing prognosis. The logistic regression model suggests that fetal movement data could be eliminated without reducing predictive accuracy, provided that all variables are collected simultaneously. This is most likely due to its being redundant when collected simultaneously with the NST. Conversely, fetal tone appears to be an essential component of the biophysical profile; its elimination from the logistic model effected the greatest alteration in predictive accuracy.

For practical considerations, this study has shown that when biophysical profiles contain one or two abnormal variables the nature of the specific abnormal variable becomes quite important as the risk of poor outcome shows the greatest variation in these cases. Once three or four variables are abnormal, the specific nature of the variables included in these combinations becomes less important, because predictive accuracy is quite similar for all observed combinations within these groupings. It is also clear that relatively high predictive accuracy is achieved only when all variables are abnormal. This suggests that clinical management after the

majority of abnormal biophysical profiles should rely very strongly on additional clinical data, especially fetal maturity, before intervention is undertaken.

Discussion

DR. WILLIAM F. O'BRIEN, South Florida. The manuscript details an analysis of the components of the fetal biophysical profile with respect to outcome in an attempt to establish a system for weighing or condensation of components. The authors used a data base constructed from computer-aided biophysical profiles with institutionally derived criteria obtained on over 1000 women, with only the last test being used for analysis.

The "outcome" used was a group of potential markers of fetal compromise ranging in severity from mortality to a 5-minute Apgar score <7. Analysis essentially compared the actual rate of bad outcomes, which occurred with a combination of abnormal biophysical profile components with the theoretic expectation of risk based on the observed risk when only a single component was abnormal. Finally, the components were entered into a logistic regression model.

As expected from prior reports, the incidence of abnormal fetal outcomes in general increased along with the number of abnormal biophysical profile components. The NST and fetal breathing movements were the components most often found to be abnormal either singly or in combination with other biophysical profile components.

When two component combinations were tested, the combination of abnormal NST and amniotic fluid volume components appeared to be particularly ominous, with an observed rate of bad outcomes almost twice that predicted. This result was almost certainly due to the fallacies inherent in dealing with limited numbers, because this combination had better results when either the fetal motion or fetal breathing movement component was abnormal. Most of the obvious discrepancies were related to the fetal tone component, as a result of the overprediction of risk on the basis of abnormal fetal tone. This was a single abnormal component only twice and in both cases a major central nervous system anomaly resulted in neonatal death.

These results conflict with those reported by Manning et al.[1] in a similar study. In that study the combination of abnormal NST and body movement, which was the second most common combination of two abnormalities noted in this manuscript, was not recorded in over 500 tests. Second, they found the combination of abnormal NST and fetal breathing movement to yield significantly greater morbidity than other combinations of two abnormal values, whereas as noted above Devoe et al. did not.

With regard to logistic regression, both reports agree on three of the components (fetal breathing movement, NST, amniotic fluid volume), but Manning et al. did not include fetal tone, as does the present report. Weighing of the variables is also different, moreover, because the highest weight is given to tone in this report.

The reasons for these differences are not certain, but several possibilities exist. As in all comparisons, the populations studied were not identical and, in this case, they were not even similar. The mean gestational age at delivery in the study by Manning et al. was 31 weeks, compared with 38 weeks in this study. Perhaps the relative importance of the components of the biophysical profile is gestational-age related. Alternatively, the criteria used for normalcy for the components of the bio-

physical profile are similar but not identical. As previously reported by this group, the results in terms of prediction accuracy do differ and the relative importance of the varying components may as well.

What remains, therefore, is the implied, but unstated and unfulfilled, goal of the study. Can a weighted biophysical profile yield more accurate predictions in a population not used to derive the model? I assume this question will be the basis of Dr. Devoe's next study.

DR. RONALD V. WADE, Charlotte, North Carolina. Dr. Devoe, in view of the data you have presented, would you comment on the common practice of eliminating the NST if all other parameters are normal?

DR. DEVOE (Closing). Our experience and that reported by the Manning group[1] would suggest that elimination of the NST is unwarranted. The reason is that the NST supplies information that is not really replicated by any of the other components of the biophysical test. In addition, Manning's own experience in eliminating the NST resulted in reports of stillbirths with otherwise normal biophysical profiles within a week of their last test.[1] In cases in which the NST was included, in his particular series, the rate of stillbirths was extremely low unless anomalies were detected. I think that our data support the importance of the NST as a pivotal member of all the variables grouped together in the biophysical profile. It certainly weighed very heavily in all of the abnormal test combinations and was the most frequently observed single abnormal variable. Therefore our data would support maintaining the NST as an integral component of the biophysical profile.

I would like to turn to the comments that Dr. O'Brien made because I think that he has brought out a couple of significant points. First and foremost is the influence of gestational age on the outcome of testing and the outcome of pregnancy in general. There is little question that our study differs significantly from that reported by the Manning group[2] in terms of gestational age at birth and that a number of criteria used to grade morbidity in his population almost certainly reflect the impact of delivery at a lower gestational age in a high-risk population. A second major difference that exists between our study and that previously cited is the fact that we performed the collection of all of our variables in the same time frame. Manning's approach, which has been used by many others, has been to do sequential NST or ultrasonographic evaluation so that it is quite conceivable, in that time frame, that the fetal state would change and a discrepancy between the association of variables could be accounted for.

I think that the challenge that Dr. O'Brien has put forth of doing a prospective study is certainly one that is important and it is in progress at our institution.

Excessive maternal weight and pregnancy outcome

John W.C. Johnson, MD, Jeffrey A. Longmate, PhD, and Barbara Frentzen, RN, MSN
Gainesville, Florida

OBJECTIVES: This study was undertaken to determine the influences of increased maternal prepregnancy weight and increased gestational weight gain on pregnancy outcome.
STUDY DESIGN: This was a longitudinal retrospective study of 7407 term pregnancies delivered from 1987 through 1989. After excluding cases with multiple fetuses, stillbirths, fetal anomalies, no prenatal care, selected medical and surgical complications, and those with incomplete medical records, 3191 cases remained for analyses by determination of odds ratios for obstetric outcomes, by χ^2 tests for significant differences and by adjustment for risk factors with stepwise logistic regression.
RESULTS: Both increased maternal prepregnancy weight (body mass index) and increased maternal gestational weight gain were associated with increased risks of fetal macrosomia ($p < 0.0001$), labor abnormalities ($p < 0.0001$), postdatism ($p = 0.002$), meconium staining ($p < 0.001$), and unscheduled cesarean sections ($p < 0.0001$). They were also associated with decreased frequencies of low birth weight ($p < 0.001$). The magnitude of the last was less than that of the other outcomes.
CONCLUSIONS: Increased maternal weight gain in pregnancy results in higher frequencies of fetal macrosomia, which in turn lead to increased rates of cesarean section and other major maternal and fetal complications. Because these costs of increased maternal weight gain appear to outweigh benefits, weight gain recommendations for pregnancy warrant careful review. (Am J Obstet Gynecol 1992;167:353-72.)

Key words: Pregnancy, body mass index, weight gain, cesarean section

In recent years there has been much interest in the association between poor maternal weight gain and low birth weight (LBW).[1-4] Because of these observations, recommendations have recently been made by the National Academy of Science to advise further weight gain increases during pregnancy.[5] These recommendations have been made on the basis of several assumptions: (1) The morbidity and mortality associated with LBW is due in part to poor maternal nutrition, as reflected by low gestational weight gain. (2) Through nutritional counseling and support, maternal gestational weight gain can be increased. (3) Increasing gestational weight gain will eliminate or reduce the frequency of LBW complications.

Unfortunately, these assumptions have not been evaluated by carefully designed, recent studies in a United States sample. However, on the basis of these assumptions there have been frequent articles in the lay press encouraging pregnant patients to eat "to appetite."[6, 7] Publications dealing with prepregnancy counseling and preparation for pregnancy give limited attention to the potential complications of excessive maternal prepregnancy weight and excessive gain during pregnancy.

These considerations are of great interest to clinicians, because of an increasing percentage of obesity among pregnant patients[5] and because of the greater cesarean section and complication rates observed among such patients. Accordingly, this study was undertaken to assess the adverse effects of excessive maternal weight on pregnancy outcome. There have been a number of other studies addressing these issues.[8-13] This analysis is different in that it focuses on a recently delivered population of women, the majority of whom received nutrition counseling and the benefits of modern obstetric, anesthetic, and pediatric care. It therefore reflects current improvements in care. It also explores the influence of prepregnancy status (body mass index) as defined and categorized in the recent National Academy of Sciences publication[5] and weight gain during pregnancy, in conjunction with other important risk factors.

Methods

With a computerized data system for all deliveries at our institution from Jan. 1, 1987, through Dec. 31, 1989, we identified a total of 7407 patients delivered at or beyond 38 weeks of gestation. The study group consisted predominantly of patients who received care from the prenatal clinics of the University of Florida, Departments of Obstetrics and Gynecology. These clinics serve a twelve-county section of North Central Florida that includes a college town but is otherwise predominantly rural. Three to four percent were private patients. The majority of the remaining patients were

of low-income status (≤150% of federal poverty level). All patients were counseled by a nutritionist and encouraged to gain ≥24 pounds. No limit was placed on maximum weight gain. Glucose screening was routinely done for diabetes mellitus on all patients at 24 to 28 weeks' gestation.

Information on each patient was entered on standardized forms at the first antepartal visit, at delivery, and at discharge from the hospital. After verification for accuracy, the nearly 200 variables were computerized. All singleton pregnancies delivered at ≥38 weeks that received prenatal care and were delivered of live infants in Shands Hospital were included in this study, provided they were not diagnosed with fetal abnormalities, oligohydramnios, or polyhydramnios. There were 6634 patients meeting these criteria. Another 1463 patients with identified relevant medical or surgical complications (gastrointestinal disorders, sickle cell hemoglobinopathy, hepatitis, hematologic disorders, malignant disease, renal disease, neurologic disease, pulmonary disease, psychiatric disorders, tuberculosis) were excluded. Patients with appendicitis, nonhemoglobinopathic anemia (hematocrit <30%), bone or joint disease, urinary tract infections, and asthma were retained because their exclusion would have significantly reduced the total numbers and because these complications did not appear to influence the outcomes of interest. For purposes of this study, we grouped all patients together who voluntarily admitted to tobacco, alcohol, or illicit drug use as patients admitting to substance abuse. Patients with the diagnoses of diabetes, preeclampsia, and chronic hypertension were included for special studies as noted. Seven hundred four cases were excluded because of incomplete risk variable data; an additional 1276 cases were excluded because of incomplete outcome variable information. The final number of deliveries left for analyses was 3191. The mean sociodemographic characteristics (maternal age, parity, level of education, ethnic group proportions, percentage receiving private medical care, number of prenatal visits, and gestational age) and the mean anthropometric features (maternal height, body mass index, gestational weight gain, net weight gain, and infant birth weights) for the entire sample were not significantly different from the study sample ($p > 0.05$). Pregravid weight was determined on the basis of maternal reporting. The weight recorded at the last prenatal visit was designated as the maternal weight at delivery. The mean length of time between last prenatal visit and delivery was 6.1 ± 6 days. Weight gain during pregnancy was calculated by subtracting the self-reported prepregnancy weight from the maternal weight last recorded before delivery. Height was measured and recorded on registration. Birth weight was measured and recorded at delivery.

Gestational age was assigned by the physician delivering the patient on the basis of the best estimate from menstrual data, physical examination, and ultrasonographic studies. Race, marital status, private or nonprivate care, educational level, and parity were all obtained from the prenatal history. Information concerning drug abuse was voluntarily provided by the patients during routine questioning, usually on the first prenatal visit. Intrapartum complications were recorded by the physicians delivering the patients, including the presence or absence of fetal heart rate (FHR) abnormalities, labor abnormalities, and meconium staining. Fetal gender, birth weight, Apgar scores, and the presence or absence of neonatal resuscitation were derived from delivery room data.

We chose to evaluate the relationships between certain outcomes and the following risk factors: (1) prepregnancy weight stratified into quartiles; (2) height (<62 inches, 62 to 65 inches, and >65 inches); (3) body mass index stratified into the four groupings recommended by the National Academy of Sciences[5]; (4) maternal gestational weight gain stratified into quartiles for this patient population, into quartiles of net gestational weight gain (total maternal weight gain minus baby's birth weight), or according to National Academy of Science recommendations for body mass index, as being below, within, or above the recommended range[5] (patients with obese body mass indexes were assigned a recommended range of 15 to 25 pounds); (5) ethnic groups (white, black, and other); (6) gestational age 38 to 42 and >42 weeks; (7) married or single; (8) private physician care or not; (9) education (less than high school graduate, high school graduate, and any beyond high school graduation); (10) parous or not; (11) maternal age (<20, 20 to 26, and >26 years); (12) admitted smoking, alcohol, or illicit drug use; (13) fetal gender; (14) birth weight categorized into <2500 gm, 2500 to 4000 gm, and ≥4000 gm; (15) maternal diabetes (pregestational and gestational) or not; and (16) hypertensive or not.

Outcome variables studied included (1) fetal macrosomia (≥4000 gm) and (2) low birth weight (<2500 gm) where the risk factor birth weight (<2500 gm, 2500 to 4000 gm, and >4000 gm) was excluded. The risk factor of birth weight was included in assessing the following outcomes: (3) meconium staining, (4) 1-minute Apgar scores, (5) 5-minute Apgar scores, (6) unscheduled cesarean sections, (7) oxytocin induction, (8) oxytocin augmentation, (9) labor abnormality (prolonged latent phase, protracted active phase, secondary arrest of dilation, arrest of descent, prolonged second stage), (10) FHR abnormality (decreased variability, bradycardia, or tachycardia for >10 minutes, multiple variables, or late decelerations), (11) cord umbilical artery pH <7.12, (12) newborn resuscitation (artificial ventilation

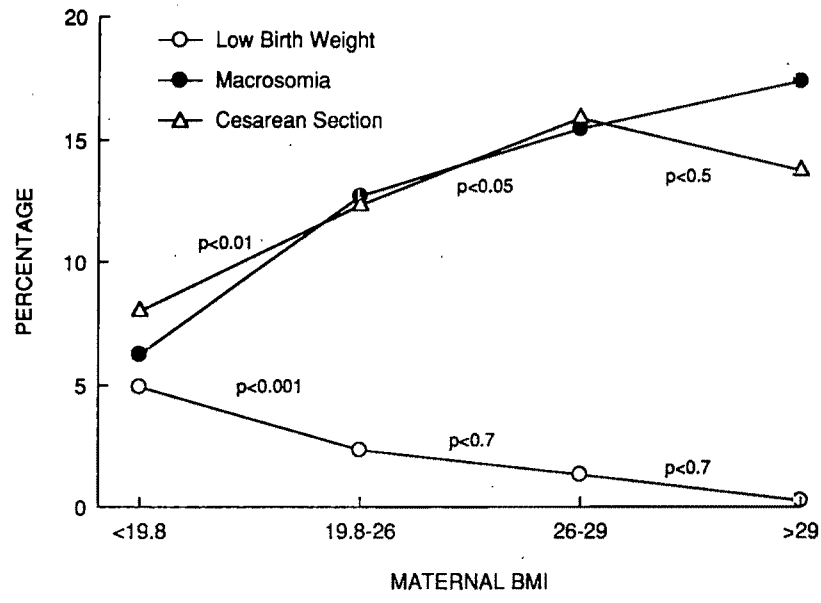

Fig. 1. This graph of unadjusted data shows the relationship between increasing maternal body mass index *(BMI)* and frequencies of macrosomia, cesarean section, and LBW. There is a very similar rise in both macrosomia and cesarean section rates with increasing maternal body mass index. *p* Values represent statistical significance between successive rates of cesarean section. Decrease in percentage of LBW (of lesser magnitude) is also noted with increasing maternal body mass index.

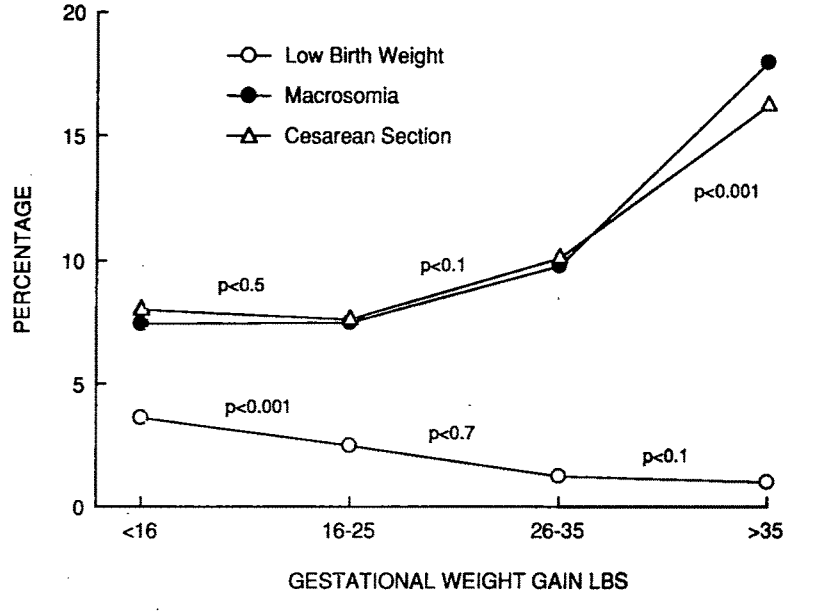

Fig. 2. This graph illustrates unadjusted relationships between increasing maternal gestational weight gain and frequencies of macrosomia, cesarean section, and LBW. As in Fig. 1, there is almost identical alteration in frequencies of macrosomia and cesarean section with increasing gestational weight gain. *p* Values represent statistical significance for differences between successive rates of cesarean section. There is corresponding decrease in LBW of lesser magnitude, also noted with rising gestational weight gain.

and endotracheal intubation), (13) shoulder dystocia, and (14) postdates (gestational age excluded as a risk factor). Patients with the diagnosis of preeclampsia (including pregnancy-induced hypertension, preeclampsia mild or severe, and eclampsia) and chronic hypertension (with or without superimposed preeclampsia) were included in assessing the associations between risk factors and the occurrence of these specific complications.

For the statistical evaluations, all risk factors were

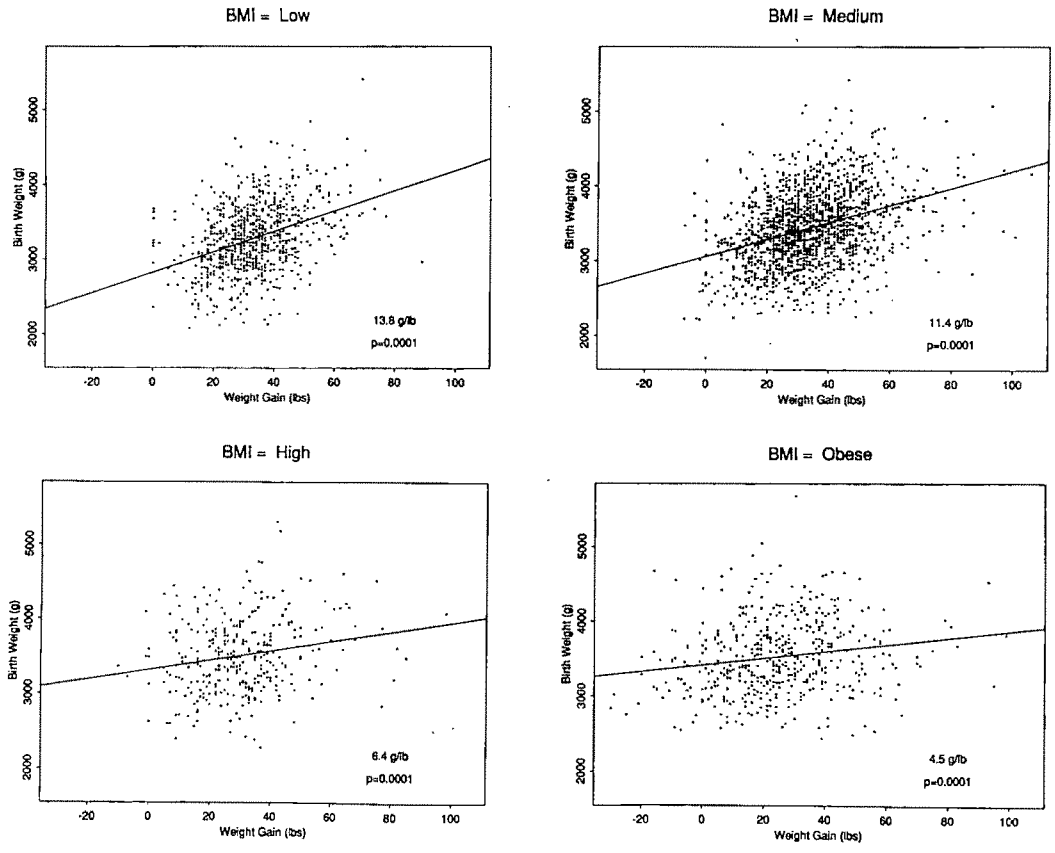

Fig. 3. This scattergram graph depicts unadjusted relationship between weight gain and birth weight in the four body mass index *(BMI)* categories. Substantial variation in birth weight is readily seen. There is significant reduction in association of weight gain to birth weight as body mass index increases, but association even among obese patients is statistically significant ($p < 0.0001$).

divided into intervals as described above, with odds ratios used to describe the effect of each level of a risk factor, relative to a reference group. The significance of each unadjusted odds ratio was assessed with a χ^2 test. Stepwise logistic regression was used to select an adjustment model, and the adjusted odds ratios were derived from the anti-logs of parameters estimated by logistic regression. The Wald χ^2 statistic provided a significance level for each adjusted odds ratio, and confidence intervals for odds ratios were formed by transforming the estimates, give or take two standard errors, from the log odds scale. Weight gain, prepregnancy weight, and height were included in each adjustment model, regardless of statistical significance.

In the trend analyses all risk factors were examined, but only those selected by a stepwise procedure at the 0.01 level of significance were included in the model. Net weight gain was used when examining birth weight and the incidences of macrosomia and low birth weight. The magnitudes of the trends in risk of an outcome were expressed as odds ratio for either a 10 pound difference in weight gain, or a five unit difference in body mass index, because these were round numbers near the average width of the intervals used in the National Academy of Science categories and recommendations.

This research project was approved by the University of Florida Health Center Institutional Review Board.

Results

The characteristics of our study population are tabulated in Table I. There were 3191 total patients in the study, including 171 with the diagnosis of hypertension (including preeclampsia) and 98 with the diagnosis of diabetes. According to body mass index category, 24% were below normal, 51% were within normal range, 10% were above average, and 15% were obese. About 58% of the patients were white, 40% were black, and 1.7% were Hispanic or Oriental. Overall, 55% were unmarried and 42% were nulliparous. High school graduation or education beyond high school may be used as a measure of moderate to high socioeconomic status. About 55% achieved these levels of education. Private physician care was used by 3.7% of all patients. The prevalence of admitted substance abuse (smoking, alcohol, or illicit drugs) was 35%.

NS, Not significant. Overall incidence 12.2%.

*Reference group.

In this population the frequencies of fetal macrosomia and unscheduled cesarean section appear to rise almost simultaneously in relationship to increasing maternal body mass index (Fig. 1) and to increasing gestational weight gain (Fig. 2).

As both body mass index and gestational weight gain rise, the incidences of macrosomia and cesarean section increase to involve one of six patients (8.9% to 14% or 15%, $p < 0.001$), whereas the LBW rate declines (4% to 1%, $p < 0.001$).

Birth weight. The unadjusted data displayed a strong association between gestational weight gain and birth weight within the four body mass index groups (Fig. 3). This association was less among women with higher body mass index but still very significant ($p = 0.0001$). A multiple regression of birth weight on net weight gain, body mass index, and seven covariables selected by stepwise fitting revealed an increase of 15.4 ± 2.2 gm birth weight per pound gained by the mother ($p < 0.0001$) and an increase of 66.9 ± 95 gm

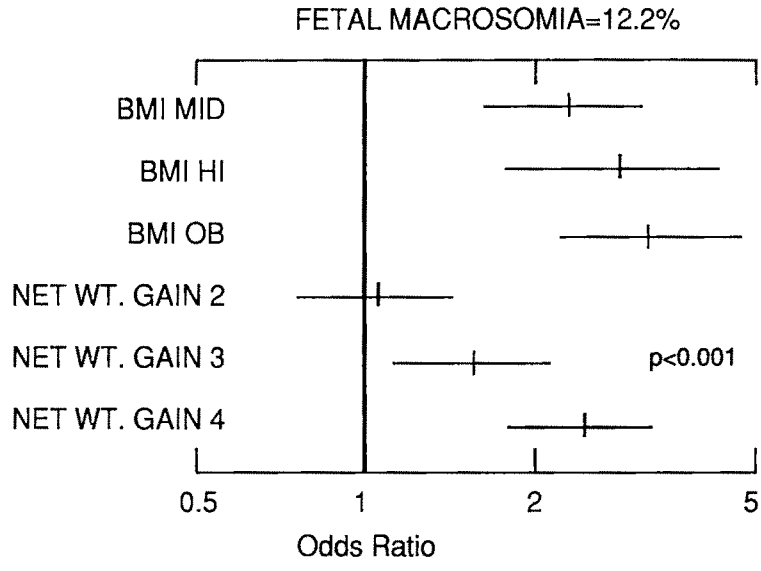

Fig. 4. This graph depicts stepwise increase in unadjusted odds ratios for fetal macrosomia with increasing maternal body mass index and increasing net gestational weight gain. Adjusted trends test was significant at $p < 0.001$. *BMI*, Body mass index; *OB*, obese.

per unit body mass index ($p < 0.0001$). Height, race (black vs white), postdate delivery, substance abuse, fetal gender, parity, and diabetes were all associated with birth weight change ($p < 0.0006$). The effect of body mass index appeared to be nonlinear, leveling off at higher values, but no curvature was detectable in the association with weight gain, adjusting for covariables. Age, education, marital status, private physician, and hypertension did not appear related to birth weight ($p \geq 0.01$).

Macrosomia and low birth weight. The overall incidence of fetal macrosomia, defined as a birth weight of ≥4000 gm, was 12.2% for this study population (Table II). The frequency of macrosomia increased in association with increasing prepregnancy weight, maternal height, maternal body mass index, and net gestational weight gain. Both body mass index and net weight gain demonstrated significant odds ratios for macrosomia (Fig. 4).

After adjusting for risk factors by stepwise logistic regression, the model still exhibited significantly increased ratios for the highest prepregnancy weight group, the medium body mass index group, and increasing net weight gain. The lack of a statistically significant adjusted odds ratio for high or obese body mass index categories may be due to the smaller numbers in these categories and associations with confounding risk factors. The adjusted odds ratios also were significantly elevated for postdatism, parous patients, patients with higher education, those delivering male infants, and diabetics. Patients admitting to substance abuse and black patients were at reduced risk. After adjusting maternal height and age, marital status, and hypertension did not exhibit significantly altered odds ratios for macrosomia (Fig. 5).

The trends analysis done by stepwise logistic regression revealed increasing risk of macrosomia with both increasing weight gain (odds ratio 1.3 for a 10-pound difference, $p = 0.0001$) and with increasing body mass index (odds ratio 1.5 for a 5-unit difference, $p = 0.0001$), adjusting for height, race, education, substance abuse, fetal gender, parity, and postdate delivery. (No interactions or nonlinearity involving weight gain and body mass index were detected.)

The frequency of diagnosed shoulder dystocia was 1.8%. There was a trend to increasing odds ratio noted with increasing maternal gestational weight gain, but after adjusting for the listed risk factors only macrosomia was significantly associated with an increased odds ratio: 5.3 (3.0-9.3; $p < 0.0001$) compared with infants weighing 2500 to 4000 gm.

Defining LBW as <2500 gm, we noted an overall incidence of 2.3% in this term population (Table III). Maternal prepregnancy weight, maternal body mass index, and net gestational weight gain related inversely to the risk of LBW (Fig. 6). Male fetuses had a significantly lower odds ratio for LBW. Patients admitting to substance abuse had a higher risk of LBW. After adjusting for these risk factors, high maternal prepregnancy weight, higher net weight gain, multiparity, and delivering a male infant were associated with low odds ratios for LBW. Patients admitting to drug abuse and black patients demonstrated increased odds ratios.

The trends analysis of LBW demonstrated an estimated odds ratio of 1.4 ($p = 0.0007$) associated with a

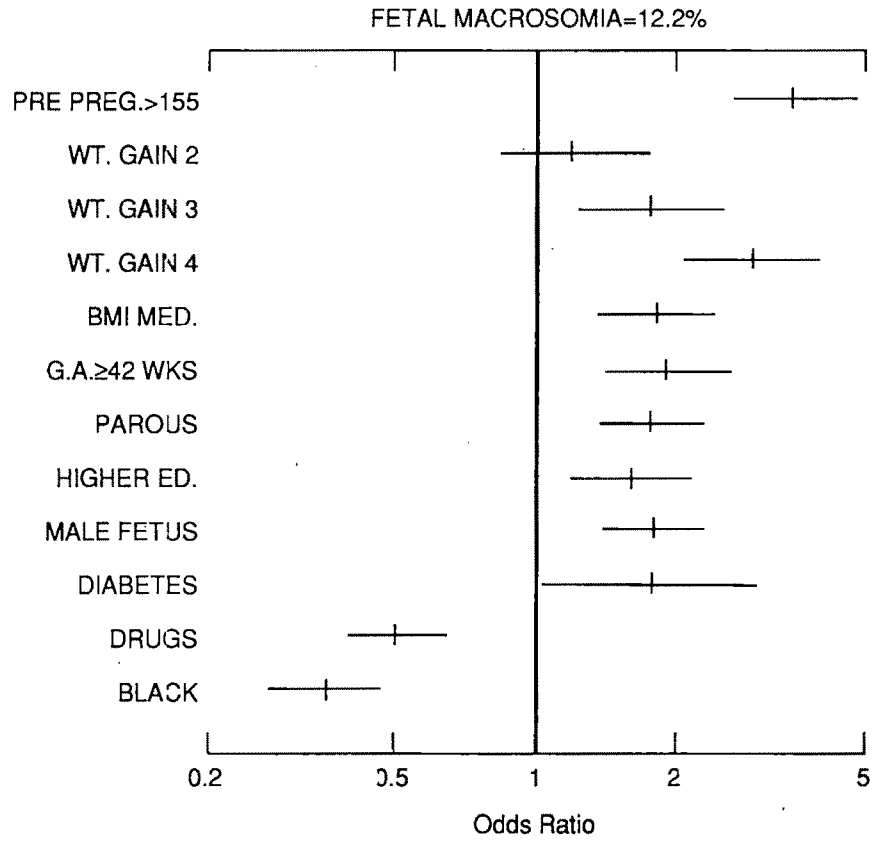

Fig. 5. This graph illustrates odds ratios and 95% confidence intervals for fetal macrosomia for variety of risk factors, after adjustment by stepwise logistic regression. Number of obstetric and demographic characteristics were associated with increased fetal macrosomia. Black patients and patients admitting to substance abuse (drugs) were noted to have significantly reduced frequencies of fetal macrosomia. *BMI*, Body mass index.

10-pound difference in weight gain, and an odds ratio of almost 3 ($p = 0.0001$) associated with a 5-unit difference in body mass index.

Unscheduled cesarean section. In analyzing the frequency of cesarean section, we chose to exclude all electively scheduled cesarean sections and analyzed only those occurring because of complications during labor. The overall incidence for this study population was 11.9% (Table IV). A significant increase in the odds ratio for cesarean section was noted with the higher body mass index categories, the higher prepregnancy weight categories, and the greater gestational weight gain categories. Macrosomia, nulliparity, higher education, diabetes, hypertension, and private care were also associated with increased odds ratios for cesarean section. Adjusting for risk factors yielded significantly increased odds ratios for the highest gestational weight gain group, private care, nulliparity, and fetal macrosomia. Being a teenager and being tall were both associated with reduced odds ratios for unscheduled cesarean section (Fig. 7). Maternal race, substance abuse, and fetal gender did not appear to influence this rate. The trends analysis done by stepwise logistic regression demonstrated an increased risk of unscheduled cesarean section associated with increasing birth weight ($p < 0.0001$), maternal gestational weight gain ($p < 0.0001$), and body mass index ($p < 0.0001$).

Postdates. The overall frequency for postdate pregnancies in this study population was 9.8% (Table V). Increased odds ratios were noted with higher maternal prepregnancy weight, higher gestational weight gain, white patients, fetal macrosomia, and admitted substance abuse. After adjusting for these various risk factors, the odds ratios were significantly elevated only for higher prepregnancy weight, patients admitting to substance abuse, and patients with fetal macrosomia. Older patients and black patients had reduced odds ratios. There was evidence on trends analysis that risk increased with weight gain (odds ratio 1.13 for a 10-lb difference, $p = 0.0014$) and with body mass index (odds ratio 1.2 for a 5-unit difference, $p = 0.0003$).

abnormalities was 7.8% (Table VI). There was a significant increase in odds ratio for labor abnormalities noted with the larger body mass index categories, the greatest gestational weight gain group, private patients, nulliparous patients, patients delivering male infants, patients with hypertension, and fetal macrosomia. After adjusting for these multiple factors, labor abnormalities had significantly higher odds ratios in private patients, blacks, nulliparous patients, and patients with a macrosomic fetus but reduced odds ratio in the tallest patient group. The risk of labor abnormalities did not seem to be significantly influenced by maternal age, education attainment, admitted substance abuse, pregnancy duration, nor marital status. There were significant trends in both weight gain and body mass index. A difference in weight gain of 10 pounds corresponds to an odds ratio of 2 ($p < 0.0001$) and a difference of 5 body mass index units corresponded to an odds ratio of about 1.65 ($p < 0.0001$). Labor abnormality was cited as the most frequent indication for unscheduled cesarean section and accounted for 40% of these operations in this study.

The overall incidence of oxytocin induction was 13.7%. There was a significant twofold increase in the odds ratio for induction observed in the highest body mass index quartile and a 1.5-fold increase in the highest weight gain category. Significantly higher odds ratios were noted in postdates patients, hypertensive patients, diabetics, and married patients. Oxytocin induction was less frequent in blacks. After adjusting for these various risk factors, only the higher body mass index groups, the postdates patients, the diabetics, the hypertensives, and the LBW cases had significantly increased risks for induction. Black patients had a decreased risk.

Oxytocin augmentation was used in 16.1% of patients. The odds ratio was significantly increased in the higher weight gain group and the hypertensive patients, with trends noted in association with increasing body mass index, prepregnancy weight, decreasing ma-

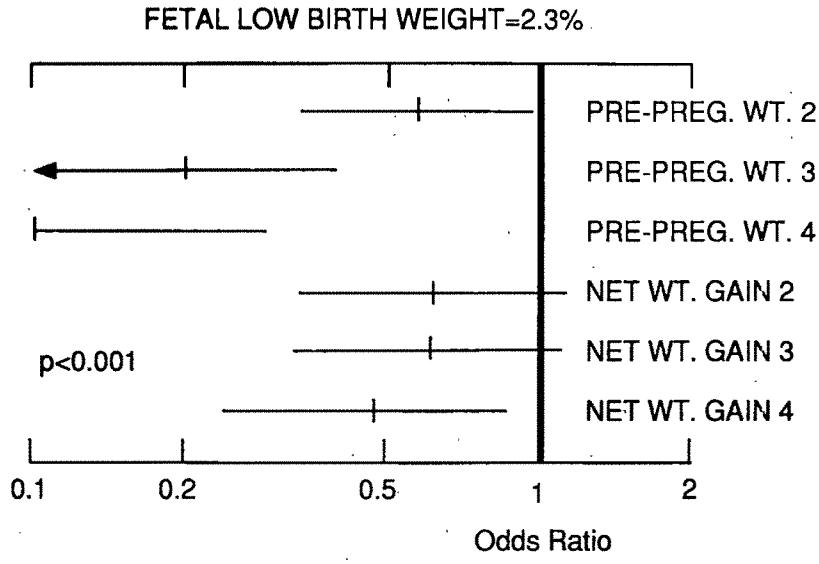

Fig. 6. This graph illustrates prepregnancy weight and net weight gain unadjusted odds ratios and 95% confidence intervals for LBW. There was stepwise reduction in risk of fetal LBW noted with rising prepregnancy weight. Net gestational weight did not demonstrate significant decrease in odds ratio except for those patients gaining >33 pounds. Adjusted trends tests were significant at $p < 0.001$.

ternal height, and the male fetus. The risk was significantly less in the parous patient. After adjusting, only nulliparity was associated with an increased risk of oxytocin augmentation. Teenagers were less likely to receive oxytocin augmentation.

FHR abnormalities. The overall incidence of intrapartum FHR abnormalities was 27% (Table VII). The odds ratio was significantly increased for the highest body mass index category, although maternal prepregnancy weight, maternal height, and maternal gestational weight gain were not associated with increased odds ratios. After adjusting for appropriate covariables, we noted statistically significant odds ratios for body mass index, nulliparity, postdatism, macrosomia, black patients, fetal male gender, and older maternal age. The trends analysis showed no significant association with weight gain and only weak evidence of an association with body mass index ($p = 0.018$). FHR abnormalities were cited as the major cause for cesarean section in about 25% of the unscheduled cesarean sections in this study.

Meconium staining. The overall frequency of meconium staining in the study population was 21.5% (Table VIII). There was a significant increase in the odds ratio noted with the larger body mass index categories, the larger prepregnancy weight quartiles, black patients, unmarried patients, and nulliparous patients. After adjusting for these risk factors, increased risks for meconium staining were found with high prepregnancy weight, short maternal stature, high gestational weight gain, blacks, nulliparous patients, and admitted substance abusers. The trends test indicated an increased risk with weight gain (odds ratio 1.1 for 10 lbs, $p = 0.0003$) and with body mass index (odds ratio 1.22 for 5 units, $p = 0.0001$). Curiously, postdatism and LBW were not associated with significantly increased odds ratios for meconium staining in this study.

Apgar scores and umbilical artery pH. The overall frequency of 1-minute Apgar score ≤7 was 18.3%. Increased odds ratios were noted for increased gestational weight gain, nulliparous patients, and patients with hypertension. These same relationships pertained after adjusting. Black patients were also at greater risk. We found no associations for maternal prepregnancy weight, height, and body mass index. The overall frequency of 5-minute Apgar score ≤7 was 2.5%. There was a significant odds ratio increase in nulliparous patients, teenagers, and patients with hypertension. After adjusting, only nulliparity was associated with an increased risk.

The mean umbilical artery pH −2 SD is 7.12 for this patient population. The overall incidence of a pH <7.12 was 1.5%. No significant associations were noted with body mass index categories, prepregnancy weight, maternal height, or gestational weight gain. A significant association was noted for teenage and nulliparous patients. Adjusting for these findings revealed a significant association only for nulliparous patients.

Resuscitation. Resuscitation, including assisted res-

piration with a mask and oxygen or intubation, was reported with a frequency of 24.5% in this obstetric population. In mothers with a high body mass index and high gestational weight gain, the odds ratios were significantly increased 1.5-fold. Increases were also noted in delivery of the first child and in the case of fetal macrosomia. Neither prepregnancy weight or maternal height were associated with increased risk of resuscitation. Adjusting for these risk factors failed to demonstrate any statistically significant associations between resuscitation and prepregnancy weight, maternal height, or weight gain during pregnancy.

Comment

This is one of the first studies evaluating pregnancy outcome in regard to the body mass index categories recommended by the National Academy of Sciences.[5] This study addresses a number of the research recommendations made in that publication. It identifies certain effects of overall gestational weight gain within specific ethnic groups and among women of different ages. It examines the effects of weight gain on maternal and perinatal outcomes in markedly and moderately obese women, and it tests the ranges of recommended weight gain against outcomes.

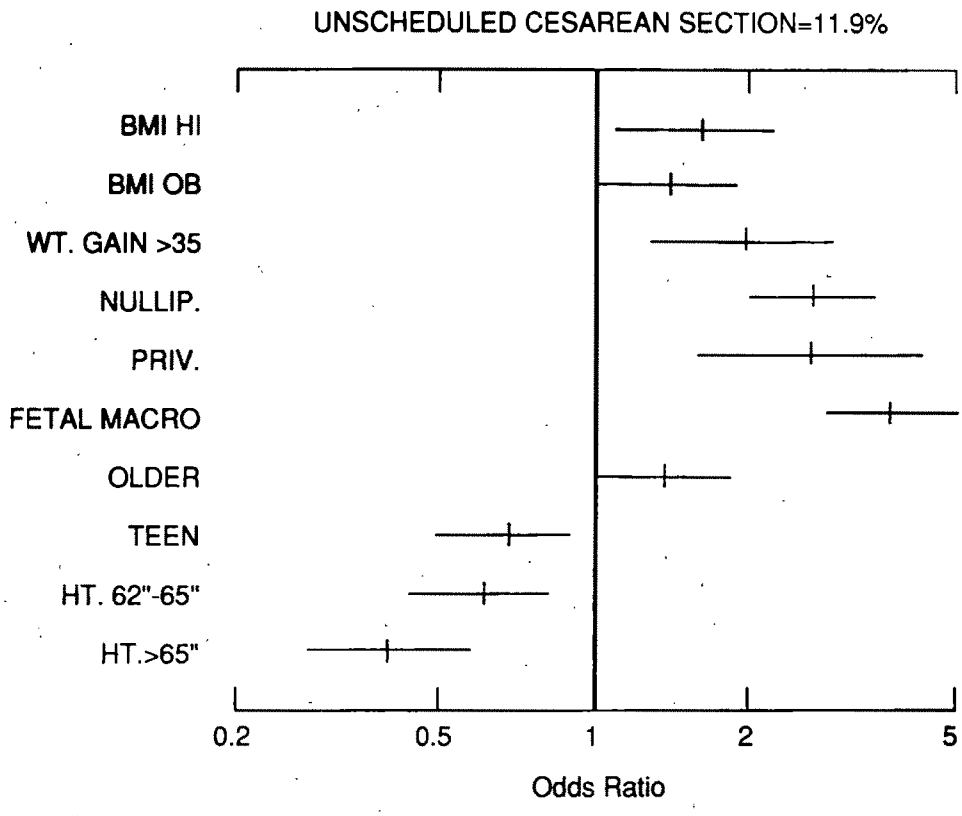

Fig. 7. This graph illustrates odds ratios and 95% confidence intervals for cesarean section, observed for number of demographic, morphologic, and obstetric characteristics after adjustment by stepwise logistic regression. Patients with high body mass index *(BMI)* and high gestational weight gain were noted to have elevated odds ratios. Nulliparous patients, private patients, and older patients, were at increased risk. Patients delivering macrosomic infants appeared to be at greatest risk. Taller patients and teenagers had reduced odds ratios. Adjusted trends tests demonstrated significant risk for unscheduled cesarean section associated with increasing body mass index, maternal weight gain, and birth weight ($p < 0.0001$).

Although this is a longitudinal retrospective study with some of the attendant disadvantages, it would be very difficult to execute a randomized study to assess the effects of maternal weight gain. Relying on patient recall for prepregnancy weight may be considered a limitation of this study, but Susser[14] observed that "patient reported weight has been shown to be reliable within a standard deviation of about 1.5 kg." In comparison with previous studies, the present investigation may be more accurate in that the duration of the pregnancy, and the outcome variables were either determined by measurement or ascertained by attending obstetric staff. Patients with selected medical and surgical illnesses were excluded. Also, this study has the advantage of reflecting recent improvements in obstetric, anesthetic, and pediatric care.

The question of what is the optimal weight gain in pregnancy is clearly a very complex issue. In this study we found that both increasing prepregnancy weight and increasing gestational weight gain were associated with increased frequencies of fetal macrosomia, labor abnormalities, postdatism, meconium staining, and unscheduled cesarean section and with a decreased frequency of LBW. We have elected to focus the discussion mostly on the association of maternal weight gain to birth weight and unscheduled cesarean section rate.

In assessing the clinical implications of the body mass index, it may be important to evaluate maternal weight and height individually because there may be marked variations in these characteristics for women of similar body mass index. For example, in the National Academy of Sciences medium body mass index category, maternal weight could vary from 88 to 202 pounds (229% increase) whereas height could vary from 55.9 inches to 74 inches (132% increase).[5] In the present study, in the adjusted analyses of unscheduled cesarean section, height exhibited a more significant effect than body mass index or prepregnancy weight. Maternal

height probably serves as a better reflection of pelvic size when analyzed alone than when expressed in the ratio that defines body mass index.

A marked increase in fetal macrosomia was noted with increasing maternal body mass index. The adjusted odds ratios for maternal weight gain and prepregnancy weight were both markedly elevated. The model used for adjustments assumed that these characteristics are additive, because no interactions were detected. If these associations were additive, women with a body mass index >29 who gain >30 pounds during pregnancy would be predicted to have a fourfold to fivefold increase in the odds ratio for macrosomia in comparison with the reference population. These preliminary findings suggest that it might be advisable to limit weight gain in obese pregnant women. These results are at variance with previous studies reporting that in obese women weight gain did not influence birth weight. However, several of these studies did not adjust for medical-surgical illnesses and were characterized by smaller numbers.[6, 11] Their results might have been influenced by type II statistical error.

The increased risks associated with high prepregnancy weight and high weight gain during pregnancy observed in this study have been amply demonstrated in many previous studies.[3, 9, 10, 13] Yet the recent National Academy of Science recommendations advocate increasing maternal weight gain during pregnancy. These recommendations appear to be based primarily on earlier observations that (1) LBW is associated with increased perinatal mortality and infant morbidity and (2) increased maternal weight gain is associated with lower rates of LBW. The inference has been drawn that increasing maternal weight gain will reduce the frequency of LBW and thereby reduce perinatal mortality and morbidity.[5] These assumptions may be dangerous and costly oversimplifications.

The causes of LBW are myriad and some are more hazardous than others.[15, 16] Prematurity accounts for a significant portion of LBW babies. A major portion of LBW term infants have no underlying fetal or maternal abnormalities. These infants are born small for familial

or constitutional reasons. In the absence of asphyxial insults, which are mostly preventable, these babies have excellent outcomes.[15, 17] An increase in maternal weight gain may reduce the frequency of this type of LBW infant, but there is little if any evidence of an associated improvement in perinatal mortality or morbidity.

Intrinsic abnormalities in the fetus (congenital anomalies, infections, chromosomal abnormalities, etc.) account for a small percentage of LBW infants but contribute significantly to poor outcomes, including death and morbidity. Maternal illnesses account for another portion of LBW infants, and asphyxial complications are primarily responsible for the poorer outcome noted in these cases. Unfortunately, in prior studies of the mortality and morbidity associated with LBW, the consequences of prematurity, intrinsic fetal abnormalities, and asphyxial events were not taken into consideration. There is little experimental or clinical evidence that increased maternal weight gain in pregnancy will reduce the wastage associated with these forms of LBW.

In fact, Kleinman[18] in a study of 3946 cases of white non-Hispanic women found that total maternal weight gain tended to overstate the association between maternal weight gain and fetal growth. He recommended the use of net weight gain rate (total maternal weight gain minus baby's birth weight divided by weeks of gestation) to assess these interrelationships. With this measure of maternal weight gain he found that an increased net weight gain was linked to a significant decrease in the frequency of term LBW infants only in women of moderate body mass index (19.8 to 26.0). In obese patients (body mass index >26.0), an increased net weight gain tended to increase the frequency of term LBW infants. Increases in net weight gain appeared to have little impact on the frequency of preterm LBW, regardless of the mother's body mass index.

In the present study we attempted to estimate the public health implications of our findings by predicting the national costs, in terms of rates of unscheduled cesarean section and low birth weight relative to differences in maternal weight gain. The recent National Academy of Science recommendations for weight gain in pregnancy[5] specify 28 to 40 pounds for a body mass index <19.8, 25 to 35 pounds for a body mass index

of 19.8 to 26, 15 to 25 pounds for a body mass index of 27 to 29, and at least 15 pounds for a body mass index >26 to 29. With these ranges (and 15 to 25 pound range for a body mass index >29) we calculated the cesarean section rates for patients according to whether their weight gain was below, within range, or above the National Academy of Science recommendations. The unscheduled cesarean section rates were 7.7%, 9.6%, and 16.6%, respectively, for these three groups. With multiple logistic regression we found that if weight gain was limited in all cases to the maximum National Academy of Science recommendation, the predicted unscheduled section rate was 9.7% (Table IX). If all weight gain was limited to the lowest NAS recommendation, the predicted unscheduled section rate was 8.1%. Assuming our statistical model is correct and that our patient population reflects the national situation, a decrease in cesarean section rate from 11.9% to 8.1% nationally could result in annual savings of $253 to $436 million dollars.[19]

A theoretic reduction in body mass index values to a maximum of 29 or even 26 would be expected to reduce the unscheduled cesarean section rate by only 0.4% to 0.9% (Table IX). The greater effect of limiting gestational weight gain is due to the higher prevalence of excessive gestational weight gain compared with high body mass index in this population.

These theoretic reductions in maternal weight would be predicted to also increase the frequencies of LBW. The LBW rates associated with maternal weight gain below, within range, or above National Academy of Science recommendations were 4.7%, 1.8%, and 1.1%, respectively. Again with multiple logistic regression, we found that limiting all weight gain to the maximum National Academy of Science recommendations yielded a predicted LBW rate of 2.5% (Table X). If all weight gain was limited to the lowest National Academy of Science recommendation, the predicted LBW frequency was 3.0%. Again, the predicted influence of reduced body mass index is a lesser increase in LBW frequency. Limiting body mass index to a maximum of 29 or 26 results in a predicted increase in LBW rate of only 0.1% to 0.2% (Table X).

Assuming our statistical model is correct and that this study population reflects the national experience with LBW, we estimate that an increase in the national frequency of this type of low birth weight from 2.3% to 3.3% would result in additional hospital expenses of about $1 to $2 million dollars per annum. Recent studies have shown no increase in long-term morbidity.[17, 20, 21] The net effect appears to argue strongly for limiting weight gain in pregnancy.

In summary, the results of this study indicate that either high prepregnancy weight or high weight gain during pregnancy lead to increased cesarean sections and other complications. These complications seem to outweigh any purported medical benefits. Furthermore, the additional expenses required to deal with these consequences on a national basis could be substantial. Recent recommendations advising additional weight gain in pregnancy need further evaluation before implementation.

Discussion

Dr. Barry Gross, Newport News, Virginia. Johnson et al. examine carefully the emphasis placed in recent years on the notion that "more is better" when referring to weight gain in pregnancy. It has been widely held that this emphasis on maximizing pregnancy weight gain reached its pinnacle in 1989 with the publication of results from the National Natality Study by the National Center for Health Statistics.[1] It was noted in that publication that LBW was 2.3 times more likely, and fetal death 1.5 times more likely, in women who gained <20 pounds during pregnancy when compared with those who gained >20 pounds. In addition, it was noted that 20% of all black mothers in 1980 gained <16 pounds during pregnancy and had the poorest pregnancy outcomes. These results might lead one to believe that there is a direct correlation between the amount of weight gained in pregnancy and the health of the baby delivered and that increasing the amount of weight gained in pregnancy will reduce the incidence of LBW infants. Johnson et al. have demonstrated that while this may indeed be true in women who start pregnancy at lower body weights, it does not translate with the same validity to those women who begin pregnancy overweight.

The first published study of diet and pregnancy was by Prochownick[2] in 1901. This work demonstrated that restricted food intake throughout pregnancy reduced the birth weights of males by approximately 400 gm and those of females by 500 gm. Indeed, over the past century there have been many varying changes in recommendations regarding weight gain in pregnancy. Over most of this time the recurrent theme was restriction of caloric intake, because it was felt that this restriction could prevent large babies and associated difficult labors and deliveries.[3, 4] This approach is entirely understandable because maternal mortality was very high and delivery by cesarean section was often an act of desperation. Later in the century controlling weight gain during pregnancy was advocated to prevent toxemia.[5]

Studies published in the 1950s, 1960s, and early 1970s generally indicated that an average weight gain of 12.5 kg (27.5 lb) was considered normal. In 1970 the Food and Nutrition Board's Committee on Maternal Nutrition and, a few years later, the American College of Obstetricians and Gynecologists published the average desirable weight gain as 24 pounds.[6, 7] In fact, the recommended gestational weight gains have essentially doubled between 1930 and 1990, from 15 pounds in 1930 to 30 pounds in the late 1980s.

Before publication of the National Natality Study,[8] generally recommended weight gain was on the order of 10 to 12 kg (22 to 27 pounds) during pregnancy. Mirroring the findings of that study, most publications in obstetrics at that time, including Standards of the American College of Obstetricians and Gynecologists, generally noted that regardless of how much women weigh before they become pregnant, the gaining of between 26 and 30 pounds during pregnancy could improve the outcome of pregnancy and reduce their chances for having the pregnancy end with fetal morbidity.[9]

There is little doubt that the plight of the LBW infant has deserved the highest order of attention by our specialty. A large body of evidence indicates that the amount of gestational weight gain is a determinant of fetal growth.[10] Lower total weight gains are associated with an increased risk of LBW babies with higher perinatal mortality. In this paper, Johnson et al., have refocused our attention to the opposite end of the continuum, excessive maternal weight gain and its outcome. Both increasing maternal prepregnancy weight and increasing maternal gestational weight gain were found to be associated with increased frequencies of fetal macrosomia, labor abnormalities, FHR abnormalities, postdatism, meconium staining, and unscheduled cesarean section.

Indeed, most studies have demonstrated an increased risk of hypertension, preeclampsia, and gestational diabetes in patients manifesting excessive maternal weight gain. Babies are bigger, and cesarean section rates are higher. Higher birth weights are associated with prolonged labor, shoulder dystocia, birth trauma, and asphyxia. Many believe that postpartum hemorrhage, puerperal infection, and venous thrombosis are more common. Surgical morbidity and mortality rises, because patients are more difficult to administer anesthesia to, have more postanesthesia complications, and have more wound complications.

Although the encouraging of weight gain has been seen as a means by which we might lower the number of LBW babies, it is clear that the weight that is gained is not always either nutritionally adequate or appropriate. Weight gain is often not a reflection of a nutritionally balanced diet.[10]

Johnson et al. used both actual maternal weight gain and body mass index as tools in this evaluation. Of interest is body mass index, which is defined as prepregnancy weight in kilograms divided by height in meters squared (or "weight for height") and has been endorsed by the National Academy of Science, in their 1990 publication *Nutrition During Pregnancy*, as a tool for patient evaluation. Johnson et al.'s data appear to demonstrate what others have noted, e.g., that in the initial risk assessment of outcomes related to maternal weight, the calculation of maternal body mass index offers no advantage over simply weighing the patient.[11]

It is well known that the effect of gestational weight gain on fetal growth is modified by the mother's prepregnancy weight for height. Multiple studies have demonstrated that the effect of a given weight gain (or rate of weight gain) on fetal growth is greatest in thin women and least in overweight women.[12, 13] Prepregnancy weight for height, or body mass index, can be a determinant of fetal growth independent of the effect of gestational weight gain. Studies show that women who are thinner before pregnancy tend to have babies that are smaller than those of their heavier counterparts with the same gestational weight gain. A desirable pregnancy weight gain seems to be, in general, inversely proportional to the body mass index of the patient.[12] Studies also suggest that increases in maternal fat, lean tissue, and body water may each be associated with increased fetal growth. Problems associated with this increased fetal growth, as demonstrated by Johnson et al., appear to be more pronounced in short women (high body mass index).

The data presented by the authors clearly suggests that there are many good reasons to suggest limitations on weight gain in selected pregnancies. Although this principle is at variance with many of the nutritional guidelines published in the mid 1980s, it does agree with the most recent (1990) suggestions by the National Academy of Science. The Academy has divided all pregnancies into four groups by determining prepregnancy weights-for-heights. As one might expect, as the individual groups' body mass index increased, its suggested weight gain decreased. Individualization of weight gain and appropriate dietary instruction therefore would seem to be the prescribed manner to approach the topic of appropriate pregnancy weight gain.

Although the degree of weight gain restriction in the overweight pregnant woman may be debated (as it has over the past 91 years), it is clear from this study by Johnson et al. that only by aggressively managing the weight gain of patients from both ends of the prepregnancy weight spectrum and pregnancy weight gain spectrum will we be able to reduce significantly maternal and neonatal morbidity and mortality and the associated physical and financial resources that those morbidities exhaust.

Dr. Herbert G. Hopwood, Jr., Arlington, Virginia. I would like to ask Dr. Johnson if he had an increase in shoulder dystocia in his patients compared with his controls?

Dr. Gene Burkett, Miami, Florida. The bottom line is what is the ideal pregnancy weight gain? Have you looked at the prepregnancy weight differences with the postpartum weight and related that to outcome as a means of trying to devise in your four groups what the ideal prepregnancy weight gain for each group might be?

Dr. John F. Huddleston, Atlanta, Georgia. Many of the studies associated with weight gain in pregnancy seem to take the extremes in weight gain rather than

looking at the time course of weight gain. I think from a clinical point of view many of us are more concerned with the abrupt weight gain than the steady weight gain. I wonder if the time course was considered in this study.

DR. JOHN J. BRITTON, Sumpter, South Carolina. Obviously, with increasing postdatism we get more fetal macrosomia and meconium staining of the amniotic fluid, but the data seem to indicate that excessive maternal weight gain during pregnancy or the obese patient who was obese before pregnancy tends to increase postdatism. Why does this group appear to have an increase in postdatism?

DR. JOHNSON (Closing). The question of what is the optimal weight gain in pregnancy is an emotional and controversial issue; and it has been for a very long time, probably because of its complexity.

We found the incidence of shoulder dystocia to be significantly increased if there was macrosomia. That seemed to be the major determinant as to whether shoulder dystocia was diagnosed. We do not have analyses that would lead us to conclude what is the optimal prepregnancy weight. I think that the National Academy of Science has chosen ideal body weight, the basis of the Metropolitan Life Insurance data of 1959, to be a body mass index of 19 to 26, that is, 90% to 110% of ideal body weight.

Dr. Huddleston raised an interesting point about the time course of weight gain during pregnancy. We did not look at that in our population. That would be a difficult and time-consuming task because we cannot retrieve that information from our computerized data bank. Dr. Kleinman looked at the rate of weight gain during pregnancy and did not report any birth weight differences from those that we have reported here.[1]

Why an increase in postdatism occurs is a very good question. We have tried to analyze this from our data. It does occur if the mother enters pregnancy above ideal weight or if she gains excessive weight during the course of the pregnancy. The increase in postdatism persists even after adjusting for macrosomia. We do not have a ready explanation other than it appears that excessive weight leads to prolonged pregnancy, rather than the converse.

A prospective randomized clinical trial comparing two oxytocin induction protocols

Peter R. Muller, MD, Thomas M. Stubbs, MD, and Sherry L. Laurent, PhD
Charlotte, North Carolina

OBJECTIVE: Our objective was to compare the safety and efficacy of two accepted oxytocin induction protocols that differ in oxytocin dose increments.
STUDY DESIGN: At the Carolinas Medical Center in Charlotte, North Carolina, 151 women with indications for induction of labor were prospectively randomized into one of two oxytocin induction protocols. Safety and efficacy of the two protocols were analyzed with two-tailed *t* tests and χ^2.
RESULTS: Time from induction to establishment of a regular labor pattern was significantly shorter in the experimental group compared with the traditional group ($p = 0.03$). However, no significant difference was seen from onset of induction to time of delivery. Incidences of hyperstimulation were not significantly different between the two protocols, but there was a trend toward a higher incidence of fetal heart rate changes in the experimental group ($p = 0.08$).
CONCLUSION: These data suggest that induction with larger dose increments will shorten time to adequate labor without an associated increase in uterine hyperstimulation or poor neonatal outcome. The differences in heart rate changes are concerning and merit further investigation. If confirmed by further studies, an increased risk of cord compression could outweigh the benefit of a faster onset of contractions.
(Am J Obstet Gynecol 1992;167:373-81.)

Key words: Oxytocin, labor

Since Theobald et al.[1] first described the use of continuous intravenous oxytocin in 1948, multiple protocols have been advocated by various authors for the use of oxytocin in the induction of labor. These oxytocin induction protocols vary in the initial dose, the time interval between dose increases, and the size of the dose increase.

Seitchik et al.[2] demonstrated in vivo that oxytocin concentrations reach steady state after 30 to 40 minutes. This finding has led to the formation of oxytocin induction protocols with interval increases of ≥30 minutes,[3-5] including the protocol listed by The American College of Obstetricians and Gynecologists (ACOG) Technical Bulletin No. 110.[6] The University of Texas Health Science Center in San Antonio presented a similar time interval between increases of continuous oxytocin, but it varied from the ACOG protocol by its larger rate increments.[7] The question arises as to whether these larger rate increments, which obtain higher oxytocin dosages sooner, may shorten the time from induction to labor and delivery without increasing the risk to the fetus.

The purpose of our study was to compare two oxytocin induction protocols: the one listed by ACOG and one similar to that presented by the University of Texas Health Science Center in San Antonio. Safety and efficacy were assessed for each protocol by comparing hyperstimulation, fetal distress, time from induction to labor, and time from induction to delivery.

Material and methods

This randomized, prospective study was performed at the Carolinas Medical Center after the approval of the Institutional Review Board of the medical center. A total of 151 patients with indication for induction of labor consented to participate in the study and were randomized to one of the two induction protocols described below. Randomization was performed only after the patient agreed to be in this clinical trial and was by computer-generated random assignment with sealed, opaque envelopes. Clinical management was by house officers with immediate inhouse consultation available at all times.

Inclusion criteria were a gestational age of 37 to 42 weeks, cephalic presentation, an adequate pelvis by clinical pelvimetry, no more than one prior lower segment cesarean section, and premature rupture of membranes with patient not in labor. Patients not in labor who received prostaglandin gels for cervical ripening

were randomized after receiving the gels. Labor was defined as regular contractions with evidence of cervical change (dilatation or effacement).[8] Excluded from the study were women with an abnormal presentation, abruptio placentae, placenta previa, previous vertical cesarean section, unknown uterine scar, previous myotomy, twins, polyhydramnios, active genital herpes, magnesium sulfate therapy, estimated fetal weight ≥4500 gm, nonreassuring fetal testing results, and regular uterine contractions (patients already contracting were considered augmentation of labor).

A total of 76 patients were randomized to the traditional protocol, which was modeled after ACOG Technical Bulletin No. 110[6] and which is currently used at our center. This will be referred to as the traditional protocol. Oxytocin was started at 1 to 2 mU/min and was gradually increased in dose increments of 1 to 2 mU/min at 30-minute intervals as needed. The rate was increased as needed according to the judgment of the nurses and physicians at the bedside. A total of 75 patients were randomized to the experimental protocol, a protocol similar to that described by Blanco and Finley.[7] This will be referred to as the experimental protocol. Oxytocin was started at 1 to 2 mU/min, and each new oxytocin rate was doubled from the preexisting rate (for example, 1, 2, 4, 8, 16 mU/min). An interval of 40 minutes between increases was used. After a level of 8 mU/min was reached, less than doubling the rate was acceptable if progression to hyperstimulation was feared (for example, 8, 10, 12 mU/min).

For both protocols 20 IU of synthetic oxytocin (Lyphomed, Fujisawa USA, Deerfield, Ill.) was mixed in 1 L 5% dextrose in lactated Ringers' solution and delivered by a secondary intravenous line. Oxytocin infusion rate was controlled by continuous electronic infusion pump. Continuous electronic fetal heart rate (FHR) and contraction monitoring were performed in all patients. Amniotomy was performed and an intrauterine pressure catheter was placed by the supervising physician when clinically indicated. Oxytocin was decreased for hyperstimulation, defined as five or more contractions in 10 minutes, contraction duration >90 seconds, or baseline uterine tone of 25 mm Hg. Oxytocin was temporarily discontinued for nonreassuring fetal heart rate changes, which included severe variable decelerations, recurrent late decelerations, prolonged decelerations, or loss of beat-to-beat variability. After 8 to 10 hours of oxytocin, if the membranes were intact and the cervix was still unfavorable, oxytocin was discontinued and the patient was scheduled for a second or third day of induction to be performed the following day. A Bishop score was documented at the beginning of each induction day.[9]

Epidural anesthesia was not withheld from patients participating in this study. The same group of house officers used the same continuous-infusion, lumbar epidural technique for patients in both protocols. Assisted vaginal deliveries were done only for clinical indication.

Patient demographics, such as age, race, gravidity, parity, and gestational age and clinical criteria (indication for induction, Bishop score, membrane status, cervical dilatation, prostaglandin gels application) were obtained from each patient on admission to the study. Obstetric outcome (number of days for induction, method of delivery, complications associated with delivery) and neonatal outcome (Apgar scores and cord pH) were recorded at completion of induction. Type and frequency of hyperstimulation episodes and FHR patterns were noted by reviewing each fetal monitor strip. Temporal data on each patient included onset of induction to time of delivery and to time of labor. Labor was defined as >150 Montevideo units as measured by an intrauterine pressure catheter. When technical consideration prevented the use of an intrauterine pressure catheter, labor was defined as three palpably strong contractions each lasting 60 seconds during a 10-minute interval. Timing of rupture of membranes and placement of epidural anesthesia were recorded. For analysis the timing of epidural placement was categorized according to placement before or after a regular labor pattern was established. If patients required more than 1 day of induction, then time to labor and time to delivery were calculated with data from the last day of induction only.

Sample size determination was based on the detection of a 2-hour difference in total length of labor between the two groups. Assuming a standard deviation of 4 hours in total length of labor, an 80% power, and an alpha level of 0.05, a total of 63 women in each group was needed.[10] A 10% failure rate was assumed, which necessitated increasing the enrollment to a minimum of 70 women in each group for a total sample size of 140.

Two-tailed t tests were used to determine significant differences between the two treatment groups for all continuous variables. Significant associations between categoric variables was determined with χ^2 analysis. Once significant univariate associations were determined, then stepwise multiple regression was used to examine temporal outcomes multivariately. Stepwise logistic regression was used to examine the outcomes of hyperstimulation and abnormal FHR patterns. Throughout all analysis a p value of 0.05 was used for the level of significance.

Results

A total of 151 patients were randomized according to the protocol, but there were 13 patients who had to be deleted from the study because of patient withdrawal, placement on regimen of intravenous magne-

sium sulfate for worsening preeclampsia, or failure to meet the inclusion criteria. Of the deleted individuals eight had been assigned to the traditional protocol and five to the experimental protocol. A total of 138 patients met the inclusion criteria for the study, with 68 assigned to the traditional protocol and 70 assigned to the experimental protocol.

Patient demographics shown in Table I indicate that there were no significant differences between the two study groups with respect to age, estimated gestational age, race, parity, or vaginal birth after cesarean delivery. The indications for induction of labor are listed in Table II. The most frequent indications in both groups were postdates and premature rupture of membranes, whereas gestational diabetes was more frequent in the traditional protocol group compared with the experimental group.

The clinical characteristics presented in Table III demonstrate no significant differences between the two groups with relation to the Bishop score at the time of enrollment in the study, the Bishop score at the time of induction on the day of delivery, the cervical dilatation at onset of induction, or the status of the membranes on entry to the study. The use of epidural anesthesia, prostaglandin gels for cervical ripening, and intrauterine pressure catheters was similar between the two groups.

The obstetric outcomes outlined in Table IV show that the groups were similar in terms of mean infant birth weight, cord pH, and Apgar scores. There were no 5-minute Apgar scores <8 in either of the two groups. Seventy-five percent of the patients in each group delivered on the first day of induction, with the remainder delivered on the second and third days of induction. The number of second- and third-day inductions were similar between the two protocol groups (Table IV). Examination of the 1-day inductions as compared with the 2- and 3-day inductions indicated that the 1-day inductions achieved adequate labor and delivery sooner, and required significantly less oxytocin. There was no difference, however, in FHR changes or cases of hyperstimulation (not shown).

There was a significant difference between the two study groups in the method of delivery (Table IV). Although the cesarean section rates were similar with the two protocols, there was an increased incidence of assisted vaginal deliveries in the experimental group. In reviewing the labor data on the 24 patients who had assisted vaginal deliveries, 11 patients (one in the traditional group and 10 in the experimental group) underwent assisted deliveries for second stage FHR changes (i.e., severe variables or persistent bradycardia). There were 11 patients (four in the traditional group and seven in the experimental group) who underwent assisted deliveries for maternal exhaustion and two patients in the traditional group who had assisted deliveries for persistent occipitoposterior presentation. Neonatal outcome was not significantly different between the two protocols in the assisted and spontaneous vaginal deliveries with respect to cord pH, birth weight or 5-minute Apgar scores (not shown).

The most frequent indication for cesarean section in both groups was secondary arrest of dilatation or arrest of descent, although fetal distress occurred in five patients and face presentations in five patients (Table IV). Complications were similar between the protocols, and there were a total of five patients who had failed inductions in the study. Three of these patients delivered vaginally 7 to 10 days later (two in the traditional protocol and one in the experimental protocol), and the remaining two required cesarean sections at the time of the failed induction (one in each protocol).

Mild shoulder dystocia occurred in four patients, with three of the four occurring in the experimental group. There were no adverse neonatal outcomes from these four deliveries. Meconium staining and nuchal

cord were the most frequent complicating events; these occurred equally in the two groups.

According to the stringent definition of uterine hyperstimulation used in this study, there were 38 (60.3%) women in the traditional protocol and 43 (62.9%) in the experimental protocol who were classified as having hyperstimulation (Table V). The types of hyperstimulation are shown in Table VI, with five or more contractions occurring in 10 minutes being the most frequent hyperstimulation pattern. A description of FHR patterns is included in Table VI, with the most commonly occurring FHR change being variable deceleration. Normal FHR patterns throughout labor induction were seen in 41.2% of the women in the traditional protocol group and in 27.1% of the experimental group, with a trend toward significance ($p = 0.08$) (not shown). Although the incidence of uterine hyperstimulation was greater than expected, it was associated with changes in FHR patterns in only 10 of the 40 patients in the traditional group and 15 of the 43 patients in the experimental group (Table V).

Table VII shows that the mean maximum dose of oxytocin in the two groups differed but was not statistically significant ($p = 0.07$). The oxytocin dose at the time labor was attained was similar in the two protocols.

The number of patients who had the oxytocin dosage modified by either decreasing or temporarily discontinuing the infusion due to perceived hyperstimulation or FHR changes did not significantly differ according to oxytocin protocol. If the oxytocin was discontinued temporarily, the average length of time it was off was 1.8 hours in the traditional protocol group and 1.7 hours in the experimental group (not shown). If the oxytocin was temporarily turned off, the mean number of times this occurred during the induction was 1.9 times in each group.

The temporal intervals of labor are presented in Table VIII. These data are only from patients who were delivered vaginally. Excluded were patients who were delivered by cesarean section (13 in the traditional protocol group and 16 in the experimental protocol group) and those three patients with failed inductions who were delivered vaginally at a later date. This part of the analysis used a total of 106 patients with 53 women in each group.

The time from induction to labor was significantly different between the two groups ($p = 0.03$). However, the time from onset of induction to delivery time was not significantly different ($p = 0.33$). There was not a significant difference between the two groups in comparing the timing of epidural anesthesia or rupture of membranes with time of delivery.

On examination of potential confounders it was determined that the time required to establish a regular labor pattern was significantly decreased for women with ruptured membranes but was not significantly affected by epidural anesthesia, the timing of epidural placement, parity, use of prostaglandin gels, or Bishop score. The total length of labor from induction to delivery was significantly decreased for women who were multiparous, had ruptured membranes, did not have epidural anesthesia, or did not have prostaglandin gels placed (not shown). Bishop scores at time of induction and use of epidural anesthesia did not affect the total length of labor.

In the multivariate analysis higher oxytocin dosages at the time of labor, ruptured membranes, timing of the epidural placement, and being assigned to the experimental protocol were all associated with a significantly reduced time for establishment of a regular labor pattern. The total oxytocin dose for the study, use of epidural anesthesia, use of prostaglandin gels, presence of hyperstimulation, and parity were not significantly associated with the time required to achieve a regular

labor pattern. The only variables that contributed significantly toward the reduction in total length of labor were higher total oxytocin doses for the study, ruptured membranes, and parity. Epidural placement and use of prostaglandin gel did not significantly affect the total length of labor in the adjusted analysis.

Multiple logistic regression was used to adjust for potential confounders while assessing the relationship between oxytocin protocols and the outcomes of hyperstimulation and FHR patterns. In a stepwise procedure the likelihood ratio test indicated that none of the independent variables contributed significantly to the incidence of hyperstimulation. The placement of an epidural anesthetic was the only variable that contributed significantly to FHR changes.

Comment

The yearly oxytocin induction rate of 5.3% (239/4552) in this center suggests that each year approximately 200,000 American women undergo oxytocin induction of labor. An additional large number of patients undergoes oxytocin augmentation of labor each year. Considering the large number of patients involved, surprisingly few papers have reported clinical trials comparing the several options in technique. Part of the explanation may be that several of the options have proved acceptably safe and effective during extensive clinical usage in particular centers. Nonetheless, in our view there is no reason why these protocols should necessarily be equivalent in any way, and a multiplicity of techniques suggests a need for comparisons to determine which is best. Considering the relative paucity of data comparing several widely used protocols, in our opinion the recent revision of ACOG Technical Bulletin No.157[11] (1991, revised from no.110,1987) appropriately expanded its list of proffered techniques. Even so, that Technical Bulletin does not list all protocols that have seen extensive and satisfactory clinical application.

Among the various options in oxytocin induction administration, the time interval between increases can be varied, and also the rate at which the dosage is increased can be varied independently of whatever time interval is chosen. Several recent reports have compared shorter versus longer time intervals between dosage increases.[3-5] In contrast, we have sought to compare slower versus faster rates of dosage increase for labor induction, with the time intervals approximately the same. Both of our study arms had "longer" intervals between doses, as suggested by Seitchik,[12] because of the time necessary for a given dose to reach its maximum effect. We are unaware of any previous randomized trials making such a comparison.

There are several points to be made concerning the

methods. First, the randomization worked quite well, with patient demographics and clinical characteristics similar between the two groups. Second, this study concerned induction of labor, and all patients with indications for induction were evaluated for inclusion into the study. Because there are a multitude of indications, we felt this would be more clinically valuable to the clinician than evaluating only one indication (i.e, postdate pregnancy). Finally, in evaluating temporal data we purposely deleted the failed inductions and cesarean patients. The three patients with failed inductions who were delivered 3 to 10 days later could not plausibly be included in the analysis of temporal data. If all cesarean section patients were included in the data for the induction to regular labor interval, the conclusions would remain the same, with the experimental group attaining labor in a shorter time interval. The inclusion of cesarean section patients in the induction to delivery analysis was not calculated because it would not provide meaningful information to the clinician. The timing of the cesarean delivery was not based on cervical status at the time of the operative procedure and would therefore not be reflective of the actual stage of labor or progression.

Five of our findings are of particular interest. First, patients in the experimental protocol reached a predetermined milestone of uterine activity 1 hour 25 minutes faster than patients in the traditional protocol ($p = 0.03$). It is quite common for patients to require >8 mU/min oxytocin for induction. Hauth et al.[13] demonstrated that 82% of patients required ≥10 mU/min oxytocin to achieve adequate labor. Indeed, in this study the dosage of oxytocin at the time of adequate labor approached 9 mU/min in both groups.

Second, although the experimental group had an induction-delivery interval of 1 hour 6 minutes (1.1 hours) shorter than that of the traditional group (slower increase), this difference did not reach statistical significance. A parallel and perhaps equally important finding is that there is so much variation in the length of labor in both groups in this study that demonstrating a difference would require a randomized trial larger in size than most that have been reported in this field of investigation. Indeed, this trial is larger than most, but because of the large standard deviation of the induction-delivery interval, this group of 138 patients would only be able to detect a difference of 2.5 hours in the induction-delivery interval, with a power of 80%. Without a difference in hyperstimulation risk and with only a small difference in absolute oxytocin dosage between protocols, the more rapid onset of uterine activity in the experimental group tilts these data in favor of that protocol, pending a more definitive answer to this question. It seems plausible to us that once adequate labor is established, so long as hyperstimulation and other problems do not ocur, it doesn't matter which protocol is used.

Third, safety issues are primarily related to hyperstimulation, which was equivalent with these protocols in our hands. Although our rates of hyperstimulation have precedent,[14] our definition was particularly strict because of our desire to determine if one protocol was harder to control than the other. Also, although there

Induction to delivery (hr, mean ± SD)	10.04 ± 5.50	8.98 ± 5.60	0.33
Rupture of membranes to delivery (hr, mean ± SD)	11.59 ± 9.01	11.36 ± 8.32	0.89
Epidural anesthesia to delivery (hr, mean ± SD)	5.69 ± 4.00	6.80 ± 5.68	0.38

was an increase in the maximum oxytocin dose in the experimental group, we do not believe this very small increase is clinically significant.

Fourth, FHR alterations versus normal heart rate patterns were noted to have occurred more frequently in the experimental group, although this was not statistically significant. This can be concerning. Variable decelerations occurred frequently and more often in the experimental group. Late decelerations occurred infrequently in both groups, although there was a small increased incidence in the experimental group. In analyzing these results, we found that the two groups did not differ in the incidence of uterine hyperstimulation resulting in FHR alterations (Table V). The data do not support that the variable or late decelerations were related to hyperstimulation and thus the oxytocin protocol. Therefore it is not clear that the safety of induction was altered by the oxytocin protocol. Of importance, the perinatal outcome was similar between the two groups. Nonetheless, the alteration in FHR, if affiliated with the oxytocin protocol, may outweigh any benefits an early labor pattern may bring.

Finally, there were more operative vaginal deliveries in the experimental group. This was initially a surprise finding. Akoury et al.,[15] however, have also suggested a higher incidence of operative vaginal deliveries in an aggressive oxytocin protocol. On review of our fetal monitor strips, none of these patients had operative vaginal deliveries secondary to hyperstimulation-related FHR changes. An explanation for this finding, if not related to hyperstimulation or to chance, is not straightforward. Possibly an intrinsic factor pertaining to the oxytocin protocol allows for more episodes of second-stage cord compression and thus more operative vaginal deliveries. This factor could be of concern, and obviously more study is required before a full explanation is found.

Several recent additions to the oxytocin literature have advanced our knowledge and understanding of this drug, which is so uniquely identified with obstetric practice. Mercer et al.[5] reported a randomized trial of 123 patients in two study arms, both of which used dosage increments similar to our experimental group. A longer time interval group (≥60 minutes) has less hyperstimulation and fewer cesarean sections for fetal distress than did a 20-minute time increment group. Their data suggest that longer time intervals produce less hyperstimulation, consistent with Seitchik's and Castillo's[14] finding that a longer time interval between dose increases was associated with less hyperstimulation.

Unlike Mercer et al., we found no difference in hyperstimulation between our study arms, perhaps because of a longer time interval in both of our groups. Interestingly, Mercer et al. had induction-to-delivery standard deviations even larger than ours. Their standard deviations for this interval of 8 hours (SEM 1.1 with 53 patients) and 7.8 hours (SEM 1.2 with 43 patients) were similar to ours.

Blakemore et al.[4] randomized 52 patients into 15-minute and 60-minute arms with mixed types of dosage increases. The hourly group received less oxytocin, but

overall effectiveness of the regimens was uncertain, with standard deviations of 7.85 and 7.4 hours in the two groups and a power of 0.8 to detect a 55% difference in the length of labor.

In conclusion, several authors have supported the concept that slow rate of increase of oxytocin administration may be advantageous in the induction of labor. Our study demonstrates that larger increments in association with slow intervals may improve efficacy by obtaining labor sooner without altering incidence of hyperstimulation or perinatal outcome. However, the difference in FHR changes and operative vaginal deliveries suggest caution in concluding that the large incremental protocol is clinically preferable until more data are available.

Discussion

DR. TERRY B. LEVENSON, Conway, South Carolina. In 1906 Dale demonstrated that myometrial tissue would contract when exposed to posterior pituitary extracts in vitro. By 1913 Watson had begun to use such extracts for the induction of labor. Complications such as uterine rupture and its attendant morbidity and mortality discouraged this practice until Theobald et al. described the administration of drip oxytocin in 1948. In 1949 DuVigneaud demonstrated the structure of the octapeptide oxytocin, work for which he was later awarded the Nobel Prize in Chemistry. Synthetic production of oxytocin soon followed.[1]

Possession of this powerful mediator of uterine contractility begs the question what is the safest and most effective way to use it?

To this end a number of studies have been done to demonstrate that this medication can be used in variety of clinical stiuations, but comparative studies of various protocols have been few. The article presented by Muller et al. compares the effectiveness of two protocols for administering oxytocin to induce labor.

The control and experimental groups in their study were remarkably similar in terms of patient demographics and indications for induction of labor. Bishop scores, cervical dilatation at the onset of induction, and use of prostaglandin gels and epidural anesthesia were likewise very similar.

The control group was given oxytocin at 1 to 2 mU/min, and the infusion was increased by 1 to 2 mU/min at 30-minute intervals until adequate labor occurred. The experimental group received the same starting dose, but infusion rates were doubled every 40 minutes until a rate of 8 mU/min was reached, and then increases were made in smaller increments to advoid hyperstimulation of the uterus.

Maximum doses of oxytocin tended to be higher in the experimental group, but this difference was not statistically significant. Dosages infused at the time adequate labor was achieved were similar in both arms of the study.

Hyperstimulation occurred in both groups with equal frequency but did not lead to untoward outcomes. Management difficulties were similar in both groups in that decreasing the infusion rate or discontinuing the infusion temporarily was required as often in the experimental group as in the control group.

Abnormal FHR patterns were seen more often in the experimental group. This was believed to be due to a higher incidence of variable decelerations in this group. Careful analysis failed to show a relationship between hyperstimulation and these decelerations, indicating this effect was not due to the ocytocin infusion protocol.

Cesarean section delivery occurred with equal frequency in both groups. Fetal distress was the indication

in only two of 62 patients in the control group and three of 69 in the experimental group. Dystocia was the most common indication, occurring with equal frequency in both groups.

More assisted vaginal deliveries occurred in the experimental group than the control group, most of which were for FHR changes in the second stage of labor. These were not believed to be due to uterine hyperstimulation.

Obstetric outcomes were uniformly good in both groups, and no infants delivered had 5-minute Apgar scores <7.

The experimental group achieved labor an average of one hour and 28 minutes faster than the control group, a significant difference. They were delivered 1 hour 12 minutes sooner than controls, but this differential failed to reach statistical significance.

Muller et al. have demonstrated that oxytocin infusion rates for the induction of labor can be safely increased by relatively large increments, provided adequate time is allowed for the maximal contractile response to occur. Fuchs et al.[2] have shown that plasma levels of oxytocin in patients receiving up to 3 mU/min are not significantly different from levels before the induction of labor. In their study plasma levels seen in patients in spontaneous labor were not reached until infusion rates reached 4 to 6 mU/min. Blood levels of oxytocin then increased linearly in relation to time and infusion rate.

By doubling the infusion rate at low dosage levels, Muller et al. have apparently demonstrated a method of reaching effective plasma concentrations of oxytocin in a shorter amount of time than traditional protocols allow.

I would like to ask Dr. Muller to comment on two points. First, the incidence of abnormal FHR changes seems quite high in both arms of the study. Your analysis suggests that epidural anesthesia is a major factor in these events. Are your patients who receive epidural anesthesia given preloads of intravenous crystaloid to prevent the hypotension that may accompany the onset of anesthesia and lead to placental underperfusion and subsequent FHR alterations? Second, can you cite any figures regarding the incidence of abnormal FHR changes in unstimulated labor?

DR. MULLER (Closing). Some of the literature suggests that expanding the time interval between increasing oxytocin doses gives a safer, and just as effective, method of induction. Our purpose in this study was to see whether we could get to adequate levels sooner by increasing the increment dosage while at the same time still using longer intervals. Specifically, we studied whether we could decrease the number of induction days or decrease the time to delivery by getting up to a higher oxytocin level sooner than in the ACOG protocol.

In answering Dr. Levenson's questions regarding epidural usage, the number of epidural anesthetics given were equal in both groups, as I noted earlier. They were placed by the residents on staff at Carolinas Medical Center in a similar manner. All patients were given 1 L of intravenous saline solution before the anesthetic was administered. I did not, however, collect data on patients as to whether complication such as hypotension occurred.

We did find a high rate of FHR alterations. This finding is of concern. However, we defined FHR alterations very strictly. If a patient had one episode of variable deceleration <100 beats/min, we labeled that patient as having had FHR alterations.

I do not have data available for the percentage of unstimulated labors with FHR alterations. Several studies exist that have compared the aggressive use of oxytocin versus not using oxytocin for augmentation with the percentages under 50%, whereas ours were all over 50%.

Further study has to be done concerning assisted vaginal deliveries. Some of the Canadian literature[1] also suggests that aggressive forms of oxytocin administration result in an increased incidence of assisted vaginal deliveries. At this point I do not have an explanation for our increased incidence other than that it does not seem to be related to hyperstimulation nor does it seem to be related to the oxytocin protocol.

The use of carbon dioxide laser laparoscopy in the treatment of tubal ectopic pregnancies

John D. Paulson, MD
Annandale, Virginia

OBJECTIVE: The purpose of this study was to assess the efficacy of the treatment of unruptured tubal ectopic pregnancies by the use of carbon dioxide laser laparoscopy.
STUDY DESIGN: A series of 125 consecutive ectopic pregnancies were treated laparoscopically; the tubal pregnancy was removed by a laparoscopic laser technique. Preoperative assessment included monitoring β-human chorionic gonadotropin levels, use of vaginal ultrasonography, and preoperative and postoperative hematocrit levels.
RESULTS: Laparoscopic laser surgery was successful for removal of tubal ectopic pregnancies in all but four patients, in whom a laparotomy was required. Hematocrit levels before and after surgery were similar. The time necessary for β-human chorionic gonadotropin to fall to nondetectable levels averaged between 3 and 4 weeks. There were five patients who had complications requiring additional surgery and/or medical treatment.
CONCLUSION: The techniques are easy to learn, and the use of laparoscopic laser surgery in the treatment of tubal ectopic pregnancies appears to be a safe procedure with definite advantages for both the patient and the physician. There are decreased operating times, shorter hospital stays, and lower medical costs compared wtih those for major surgery. Subsequent successful intrauterine pregnancy rates are comparable to those of conservative methods previously reported. (Am J Obstet Gynecol 1992;167:382-6.)

Key words: Laser, laparoscopy, ectopic pregnancy

Conservative surgery in the management of tubal ectopic pregnancies was uncommon during the early part of this century. There were several series in the German literature in the early 1940s[1, 2] describing reconstructive procedures. Some patients subsequently had intrauterine pregnancies. The first reference in the English literature was that by Stromme.[3] He described a conservative surgical procedure for the treatment of an unruptured tubal pregnancy in his patient's only remaining tube. The patient subsequently had two intrauterine gestations. In 1973 Stromme[4] published a 20-year review of his experience with these procedures. His technique was virtually unchanged during that time frame; only his choice of suture was different. The technique of linear salpingostomy has changed appreciably since that time because sutures have become less reactive, less traumatic forms of tissue incision have been implemented, and microsurgical technique has been used. It has become medically accepted that conservative management of a tubal pregnancy should be considered in any patient in the reproductive age group desiring further pregnancies. This surgery should be considered even if the opposite tube appears normal, because studies have demonstrated that either tube has the same chance of having a repeat ectopic pregnancy.[5] It has also been demonstrated that in women wishing to preserve their fertility the rates of recurrent ectopic pregnancy and intrauterine pregnancy after conservative management seem to be equivalent or superior to the results after radical treatment with salpingectomy.[6] These conservative methods were originally all performed during a laparotomy. In the early 1980s reports of laparoscopic removal of ectopic pregnancies began to proliferate.[7-9] Their procedures involved making an incision on the antimesenteric border of the tube overlying the ectopic pregnancy, controlling hemostasis with careful electrocoagulation and allowing secondary closure of the tube. Patency, subsequent fertility potential, and recurrent ectopic pregnancy rates were comparable with those procedures performed during laparotomy. As the methods and techniques in reproductive surgery have increased, the laser has become an important tool. Its use in laparoscopy has made it a valuable aid in the removal of ectopic pregnancies. A series of 125 consecutive patients with tubal ectopic pregnancies, primarily treated by laser laparoscopy, is presented.

Material and methods

Patient profile. One hundred twenty-five consecutive patients seen at the Institute for Reproductive Medicine

with ectopic pregnancy were included in this study. The average age was 36.4 years (range 26 to 40 years). The patients were fairly equally divided between primary (55 patients) and secondary (68 patients) infertility. The average duration of infertility was 2.85 years (range 1 to 7 years). Two patients did not have an infertility problem. Preoperative and postoperative hematocrits were determined, as were preoperative and postoperative β-human chorionic gonadotropin (β-hCG) levels. One hundred twenty patients had ectopic pregnancy in the ampullary portion of the tube, whereas five patients had isthmic tubal ectopic pregnancies.

Diagnosis of ectopic pregnancy. Patients undergo follow-up with β-hCG results when the diagnosis of pregnancy is established. It is expected that the β-hCG level will follow a curve that demonstrates a doubling in value every 2 to 3 days. If the level does not remain on this "normal" curve, it is assumed that the pregnancy is not normal. If the level is >1500 mIU/ml, a transvaginal sonogram can be obtained. If a gestational sac is seen, then for all intents and purposes an ectopic pregnancy is ruled out. If no sac is noted in the cavity of the uterus, then there is a high level of suspicion for ectopic pregnancy. If the β-hCG level does not continue a normal doubling and the level is >1500 mIU/ml, a curettage can be performed when there is suspicion of an ectopic pregnancy, and tissue can be sent for frozen section. If no chorionic villi are seen, a laparoscopy can be performed with the presumptive diagnosis of ectopic pregnancy.

Technique. The surgical approach to laparoscopic removal of ectopic pregnancy is one that involves a three-puncture technique. A laser laparoscope, which includes an operative-laser channel, is placed through an infraumbilical incision. The articulated arm of a carbon dioxide laser is connected to the channel allowing the laser beam to be delivered to the tissue. A 5 mm second puncture probe (suction and irrigation) is placed through a midline suprapubic incision. A third incision for the grasping forceps is made lateral to the rectus muscles at the level of the anterior external iliac spine on the ipsolateral side of the tubal pregnancy. All procedures are videotaped with a television camera that has a beam splitter coupled to the eyepiece of the laparoscope while the physician uses a video camera and works from the monitor. The size and site of the tubal pregnancy are identified, the mobility of the tube is assessed, and, if feasible, the procedure is carried out by first infiltrating a dilute solution of vasopressin (20 U in 40 to 50 ml normal saline solution) into the antimesenteric border or into the mesosalpinx of the tube in the area adjacent to the ectopic pregnancy to minimize bleeding from small vessels. If the size of the ectopic pregnancy is >6 cm in length and 3 to 4 cm in diameter, the expectation for increased bleeding is increased and it may prove more prudent to perform the procedure by laparotomy. The tube is then stabilized with the grasping forceps, and with the carbon dioxide laser beam through the operating channel of the laparoscope, an incision is made on the antimesenteric border over the area of the ectopic pregnancy. The power used is between 15 to 25 W in a superpulsatile mode with a spot size of 0.5 mm. Grasping forceps are then placed through the operating channel of the laparoscope after the coupling device of the laser is removed, and the tissue is gently teased out of the tube and pulled out through the operating channel. The bed is then inspected. If there is any bleeding, especially in the area of the tube where the incision was made, it can be coagulated with a bipolar cautery or with a defocused laser beam. Usually the tube has very little bleeding with this procedure. After hemostasis is secured, the instruments are removed and the patient can be brought to the recovery room and be discharged within 3 to 12 hours.

Results

Of the 125 consecutive patients seen with an ectopic pregnancy in the fallopian tube, four patients required laparotomy. One of the patients had a tubal pregnancy greater than 10 × 5 cm. It was elected during laparoscopy, on seeing the size of the ectopic pregnancy, to immediately perform a laparotomy for repair. A second patient had an ectopic tubal size of 6 × 3 cm. The ectopic pregnancy was successfully removed, but after a faulty bipolar cautery and continuous manipulation while trying to cauterize the oozing point, increased bleeding necessitated a laparotomy for "one stitch." The third and fourth patients had inaccessible tubes because of excessive adhesion formation.

The remaining patients had a benign postoperative course after laparoscopy. The preoperative hematocrit (37.2% ± 1.8%) was similar to that postoperatively (35.5% ± 2.8%). The patients left the outpatient surgical center or hospital 3 to 12 hours after the procedure. Their recuperation and ability to perform their normal everyday functions were similar to those of patients having laparoscopies for other indications. There were five patients in whom the serum β-hCG level did not continue to drop. In all these patients the levels of pregnancy hormone initially fell and within 1 week had risen, often to a level greater than that before operation. Two of these individuals had a partial salpingectomy. The remaining three patients had methotrexate therapy. With the exception of these five patients, the postoperative serum β-hCG levels continued to drop to <10 mIU/ml after an average duration of 21 to 28 days.

Tubal patency was determined in each patient 4 to 16 weeks after operation. With those patients who had laparotomies or additional treatments excluded, hysterosalpingography was performed in the majority of patients (71 patients), and a second-look laparoscopy was performed in 45 patients. Nonpatency of the in-

volved tube was noted in only two of the patients undergoing hysterosalpingography. Patency was seen in all patients who had laparoscopy; however, there were two patients who did not have total healing of the fallopian tube and in whom a rent or "hole" remained with tubal mucosa protruding out. Several patients also had granuloma-like areas in the affected tubal areas associated with tubal patency.

Forty-eight patients have subsequently attempted for at least one year to become pregnant. Thirty-eight have been successful. Of these patients, 26 have had intrauterine pregnancies and 12 have had repeat ectopic pregnancies, seven in the same tube and five within the contralateral tube.

Comment

The carbon dioxide laser for the treatment of tubal ectopic pregnancies has been used since the mid-1980s and was first reported in a small series by Johns and Hardie[10] in 1986. Although the tubal incision can be performed over the ectopic pregnancy by laser, scissors, or electrocautery, the laser holds several distinct and theoretic advantages over the other modalities. It is more hemostatic than scissors and there is less tissue reaction compared with electrosurgery in animal studies. The procedure is simple, quick, and easy to learn and perform. Other pathologic conditions within the pelvis can be easily addressed surgically and complications are uncommon.

Within this series there was no increased blood loss during or after the procedure. The time required for the laparoscopic procedure ranged from 20 minutes to just over 50 minutes of operating time. Hospitalization occurred only as a help to patients if the procedure was performed in the evening, to allow the patient to rest in a hospital bed, because the outpatient facilities in the hospital are not functioning at night. When done as an outpatient procedure, these procedures obviously decrease medical costs in comparison with laparotomy with its inherent hospitalization costs. The ability of the patient to return to normal function, whether at work or at home, allows for a diminished loss to the patient, family, or work area.

The management of tubal pregnancy by the laparoscopic approach offers most of the advantages of laparotomy without its disadvantages. A reduced morbidity and cost associated with equal or better subsequent reproductive outcome in these patients warrants a movement toward laparoscopy over laparotomy if surgically feasible. Laparoscopic laser salpingostomy as a treatment for tubal ectopic pregnancies appears to be a safe procedure with many advantages for the physician and patient. As a hemostatic procedure with good reproductive outcome for the patient, this surgical procedure offers itself as a possibility for reparative treatment of tubal pregnancies. As a procedure associated with decreased operating time, diminished hospital stay, and reduced medical costs in comparison with major surgery, laser laparoscopy is becoming a logical choice over laparotomy as a treatment for unruptured tubal ectopic pregnancies.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

Dr. W.E. Gibbons, Norfolk, Virginia. Dr. Paulson's thoughtfully prepared manuscript on laparoscopic treatment of ectopic pregnancy with the carbon dioxide laser represents one of the largest reported experiences in this area. He correctly documents the shift in therapy of this disorder from laparotomy and salpingectomy to linear salpingostomy by laparoscopy. The approach to diagnosis and surgical management were straightforward and conventional. Initial laparoscopic approach to management was achieved in all except four patients and in only one case was it a method failure due to inability to control bleeding. The carbon dioxide laparoscopic management as complete therapy was unsuccessful in only five women in whom postoperative, increasing hCG titers were observed (5/121, 4%). This demonstrates a very successful treatment outcome for an outpatient, surgical therapy where the options are either a major surgical procedure with its associated increased morbidity or protracted medical therapy, which has a similar failure rate and its own set of complications.

An important component of this manuscript is the

follow-up data. Only two of 71, or 3% of subjects undergoing hysterosalpingographic evaluation had tubal blockage demonstrated in the treated tube. Of the 45 subjects undergoing second-look laparoscopy, all of the treated tubes were patent. A question for Dr. Paulson concerns how the decision was made to perform second-look laparoscopy as to why some underwent the procedure and others did not and as to how the timing of the follow-up procedures (4 to 16 weeks) was arrived at. It would be interesting to have information from the second-look laparoscopies concerning new adnexal adhesion formation resulting from the earlier treatment laparoscopy and how often lysis of adhesions was performed during the second-look procedure. The subsequent intrauterine pregnancy rate and ectopic pregnancy rate are similar to those of other series reported in the literature.[1, 2] Was information gained at the second-look laparoscopy useful in predicting who would ultimately conceive? Would life-table analysis of this information be productive? The publication of the hCG disappearance curve will prove useful to others who appropriately follow the hCG titer after conservative surgery.

Recently, Vermesh and Presser[3] reported on 60 women with ectopic pregnancy undergoing linear salpingostomy who were randomized between laparotomy and laparoscopy. Although even though there was no difference observed in the subsequent viable pregnancy rate at 36 months (laparoscopy 12/19, 63%; laparotomy 11/21, 52%), life-table analysis demonstrated that the laparoscopy patients conceived earlier. Lundorff et al.[4] reported last year that in 73 of 105 ectopic pregnancy patients treated with conservative surgery by either laparotomy or laparoscopy who underwent second-look laparoscopy the laparotomy patients developed significantly more adhesions in the ipsilateral adnexa than did the laparoscopy patients. These data support Dr. Paulson's assertion of the desirability of the laparoscopic technique in the hands of a trained laparoscopist.

Stoval et al.[5] reporting on the largest experience with methotrexate therapy in this country recently reported a similar method failure rate (4/100) and similar follow-up rates for tubal patency hysterosalpingogram, 85%) and percentage of subsequent ectopic pregnancies (11%). Perhaps in the future medical therapy will be the standard of therapy. In my opinion, until the experiential base with medical therapies markedly increases, laparoscopic, outpatient management with its clear end point is still the therapy of choice with medical therapy reserved for treatment failures, the ectopic pregnancy whose location cannot be determined, and the rare condition of disseminated peritoneal trophoblastic implants.

DR. FRANK MCDONALD, Hickory, North Carolina. I was interested in the five patients with treatment failure. You mentioned that you got frozen sections for villi from curettage reports. I wonder, if you had frozen sections from those five ectopics, whether there was truly ectopic tissue and villi there and whether you would consider frozen sections for your ectopic tissue in the future.

DR. JOHN SCOTT, Spartanburg, South Carolina. Dr. Paulson, I have several questions. Did you use serum progesterone values at all? When you made your linear incision did you use a superpulse mode or standard wattage and, if you did the latter, what wattage did you use? How did you remove the larger ectopic pregnancies from the abdomen? Did you ever have to do a colpotomy and remove it vaginally?

DR. WILLETTE L. LEHEW, Norfolk, Virginia. I would like to ask Dr. Paulson what, if any, indications he would use to close the tube with suture?

DR. PAULSON (Closing). I use the superpulsatile mode because it will cut through the edematous tissue that has also been injected with dilute vasopressin solution. If you use continuous 25 to 30 watts you get a lot of smoke, whereas superpulse, which can pulse from 250 to 500 watts as a small part of the duty cycle, cuts through very nicely.

Usually the ectopic pregnancy is removed from the abdomen piecemeal. You may have to do it by taking the whole scope out of the largest trocar sheath. You usually do not have to peform a colpotomy.

Normally I do not use suturing techniques. We might use suturing for hemostatic purposes if there was bleeding, but this is usually not a problem because we pick up our ectopic pregnancies very early in their course.

We did not get frozen sections on our ectopic tissue at the time of surgery. All specimens were subsequently evaluated and did show villi at least in this particular series.

I do not know how many patients in this particular series had a previous ectopic pregnancy. We have done many procedures since this series, and we have had repeats on some of them. We did not do life-table analysis. It would have been useful. We did find adhesion formation in the second-look laparoscopies but not in a large number. Every once in a while there would be adhesions on the tube that were usually very simple just to peel off. As far as predicting future pregnancies, I

cannot predict that even those with little rents in the tube won't get pregnant. I think we have women with intrauterine pregnancies even when they have something like that. At the time of a second-look laparoscopy, I might try to create a raw area over such a rent in the tube so it will reperitonealize.

I was asked why we did second-look laparoscopies instead of hysterosalpingography on some of our patients. It was mostly patient choice. I am very aggressive and I feel that second-look laparoscopies are helpful because it will add to future fertility and predictive values. However, the majority of our patients did not have second-look laparoscopies and we have not analyzed our data on second-look laparoscopy versus hysterosalpingography, so I don't know how predictive it would be.

Intrauterine pressure and fluid absorption during continuous flow hysteroscopy

Spyro P. Vulgaropulos, MD, Leigh C. Haley, MD, and Jaroslav F. Hulka, MD
Chapel Hill, North Carolina

OBJECTIVES: Our objectives were to document the causes of fluid absorption during continuous flow hysteroscopy and to determine under which operative conditions fluid overload may occur.
STUDY DESIGN: Fifteen patients underwent operative hysteroscopy with 2% ethanol solution for uterine distention. Absorption of fluid was measured by blood alcohol, sodium, osmolarity, and hematocrit. Intrauterine pressures were measured with an obstetric pressure catheter.
RESULTS: Alcohol absorption was noted in one patient during a myoma resection. Two additional patients, not in the study, had fluid absorption after partial perforations of the uterus. Under normal operative conditions there were no changes in sodium, osmolarity, or hematocrit. Intrauterine pressures ranged from 45 to 75 mm Hg. Experimental pressures of >200 mm Hg were not associated with fluid absorption.
CONCLUSIONS: Intravasation of fluid may occur through open uterine venous channels with extensive resections and under low pressures in the presence of unrecognized perforations. (Am J Obstet Gynecol 1992;167:386-91.)

Key words: Hysteroscopy, fluid absorption, intrauterine pressure, ethanol, partial perforation

Diagnostic and operative hysteroscopy procedures are done in a variety of settings with different distention media. The use of continuous flow distention with low-viscosity fluids such as 5% dextrose in water, saline solution, and glycine are popular for intrauterine laser, resections, coagulation, and ablations. However, there is a risk of irrigation fluid absorption leading to volume overload and a rare risk of death subsequent to pulmonary edema or hyponatremia.[1] The mechanism of this intravasation is poorly understood but appears to be similar to complications of urologic transurethral prostate resection.

The objective of this study is to measure some of the mechanisms involved in systemic absorption of irrigation fluid and to determine under which operative conditions volume overload can occur.

Methods

Fifteen study participants were chosen from patients scheduled for diagnostic and operative hysteroscopy; they gave their full informed consent as approved by the Committee on the Protection of Human Subjects

From the Department of Obstetrics and Gynecology, University of North Carolina School of Medicine.
Supported in part by Bard Reproductive Systems, Tewksbury, Massachusetts.
Presented as Invited Guest at the Fifty-fourth Annual Meeting of The South Atlantic Association of Obstetricians and Gynecologists, Palm Beach, Florida, January 26-29, 1992.

at the University of North Carolina Hospitals. Uterotubal cannulations, endometrial ablations, myoma resections, and septum resections were the indications for the procedures, which were mostly carried out with the patients under general inhalation anesthesia in the proliferative phase with no hormonal preparation. Pitressin was used during ablations and myoma resections only. A 24F Wolf resectoscope was used, and for myomas and resections the cervix was overdilated to 37F.

Glycine, a nonelectrolyte solution commonly used for transurethral prostate resection by urologists, was used as an irrigant. Ethanol was added to create a 2% solution. Fluid absorption was then measured directly by blood alcohol levels. In addition, indirect estimates of fluid absorption were made by measuring the volume of outflow collected and by subtracting this volume from the amount of irrigant (inflow) used. Also, calculations of intravascular fluid absorption were made by measuring plasma sodium, osmolarity, and blood hematocrit.

Blood samples were obtained and pressures were measured at the following times during a procedure:

Time 1 Beginning of the procedure (baseline)
Time 2 After 5 minutes with 8 feet of pump pressure
Time 3 After 5 minutes with 14 feet of pump pressure or at 8 feet with outflow restricted
Time 4 End of procedure

Intrauterine pressures were measured directly with a standard obstetric pressure catheter placed alongside the hysteroscope inside the uterine cavity.

A uterine model was also created for laboratory measures of flow rates and pressures with a variety of pump settings, pump types, and different hysteroscopes. The patients were used as their own controls, and one-way analysis of variance statistical measures were used to compare changes in plasma sodium, osmolarity, and blood hematocrit with a significance level at $p < 0.05$.

Results

In vitro studies. The laboratory model used (Fig. 1) documented that a number of independent variables influenced intrauterine pressure and flow rates. These included the following: (1) height of fluid column or pump setting, (2) manufacturer of hysteroscope, (3) degree of cervical dilation, and (4) outflow valve closed or open. We first calibrated the pressure reading of our uterine model with a closed system (no cervical or valve outflow) in an operating room, simulating conditions of surgery. The three points measured were at 4, 6, and 8 feet of direct gravity flow, resulting in intrauterine pressures of 118, 177, and 230 mm Hg, respectively. Higher direct gravity measures were not possible, because the operating room ceilings are not higher than 8 feet from the operating table surface. The Bard Hystero-Flo (C. R. Bard, Tewksbury, Mass.) pump matched this calibration curve at 8 and 14 feet of pressure.

We next measured the effect of opening the outflow valve and simulating cervical overdilation by allowing fluid to flow around the hysteroscope. Opening the outflow valve decreased pressure to about 50 to 60 mm Hg, and opening the cervix further decreased pressures to 40 to 50 mm Hg. Under these conditions there was minimal difference in intrauterine pressure with Bard pump settings of 8 or 14 feet of pump pressure.

Urologists routinely use the outflow valve to regulate flow rates and pressures. Using the outflow valve to maintain the intrauterine pressure at either 50 or 80 mm Hg (Fig. 2), there was only a 12% difference in flow rates with Bard pump settings of 8 or 14 feet, and flow was approximately 375 to 450 ml/min.

The Zimmer pump is designed with an upper limit of 80 mm of pressure, with a readout measured at the inflow valve (approximating intrauterine pressure). When 80 mm of measured intrauterine pressure was maintained, flow rates were reduced, even at the highest pump setting, to 150 ml/min (Fig. 2).

Fig. 3 shows intrauterine pressure and flow rates with two different hysteroscopes. Surprisingly, the larger (24F) Wolf resectoscope had lower flow rates and higher resistant pressures than the smaller (22F) Olympus pediatric resectoscope.

Clinical studies. Intrauterine pressure data from 14 patients thus far show a range of 45 to 75 mm Hg (with an average 63 mm Hg) under normal operative conditions (open cervix or outflow valve, no perforations). Closing overdilated cervices with a tenaculum for 5-minute periods raised intrauterine pressure to an average of 122 mm Hg. In some patients, both the cervix and outflow valve were closed, creating intrauterine pressures of 230 and 280 mm Hg with 8 and 14 feet of pump pressure, respectively. No fluid absorption as measured by blood alcohol, volumetric discrepancy, or hyponatremia was seen during these in vivo pressure experiments.

Blood studies on 15 patients revealed nonsignificant average declines in serum sodium from 139 to 136 (time 1 and time 4), $p > 0.05$. Average osmolarity was 285 to 289, and the mean hematocrits were 35 to 33. The mean measure of volumetric fluid deficit was 152 ml.

One patient out of 15 had ethanol detected (37 mg/dl) at the end of the procedure. This patient had had a myoma resection and both the cervix and outflow valve had been closed for 3 minutes to increase visualization due to excessive bleeding. Through an oversight the valve had remained closed for nearly 10 more minutes. The pressure catheter was not functioning in this case. The volumetric measurement of absorption in this case was 900 ml, equivalent to the estimated volume required to reach a blood level of 37 mg/dl

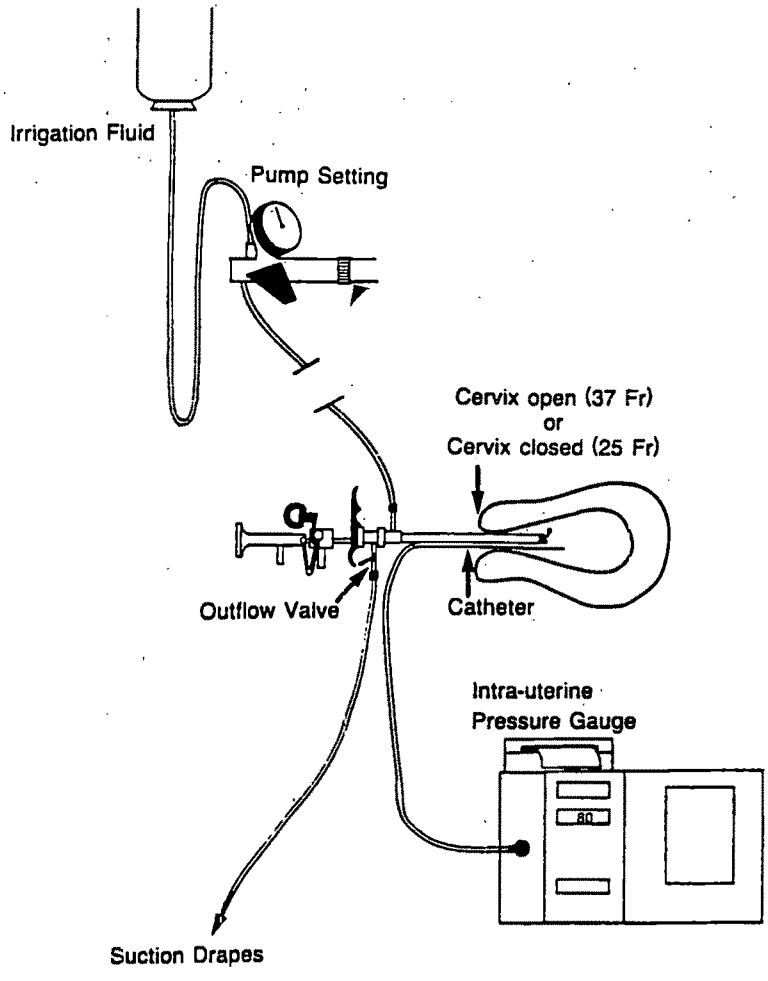

Fig. 1. Experimental model. Variables of fluid dynamics include pump settings and types, type of hysteroscope, cervical dilation, outflow valve.

ethanol, given a 5 L blood volume and 2% ethanol solution.

One other patient, not in the study, developed a lateral tear of the cervix after fibroid removal. The standard pressure settings, estimated at 75 mm Hg, were used for a 3-minute period to diagnose the perforation. During this time the patient had absorbed 1500 ml of fluid by volumetric estimation. This patient did not have any clinical signs of volume overload.

A third patient, not in the study because of severe diabetes and chronic renal insufficiency, developed acute pulmonary edema after a rapid (12 minute) endometrial ablation under local anesthesia. Serum sodium level was 129 mEq/L. There was an absorption, estimated by measuring input and output of the irrigation system, of 1300 ml. There was a suspected thinning and possible partial perforation of the fundus during the dilatation of the cervix during this procedure. There was good outflow from the cervix in this case, allowing an estimate of intrauterine pressure of 60 to 75 mm Hg.

Comment

Hysteroscopic surgery with low-viscosity, continuous-flow irrigation offers several advantages over other systems.[2, 3] These include better exposure in operative cases, continuous clearing of blood and tissue, and fewer reported complications.[4] Nevertheless, the risk of fluid overload and hyponatremia exists and is analogous to the complications with prostatic resection procedures.

The finding of minimal to no absorption during hysteroscopy detected in most of these patients to date is encouraging. Hysteroscopy should be expected to have less than the 5% to 10% incidence during prostatic resection by the urologists.[1, 5] This is due to the fact that prostatic tissue has an extensive plexus of venous sinuses that are opened up during resections, although paracervical venous plexi can be exposed during unsuspected cervical tears.[6]

We have drawn from studies in the urology literature that use ethanol added to the irrigation fluid to monitor absorption during prostatic resection.[7] Hahn[8] in 1988

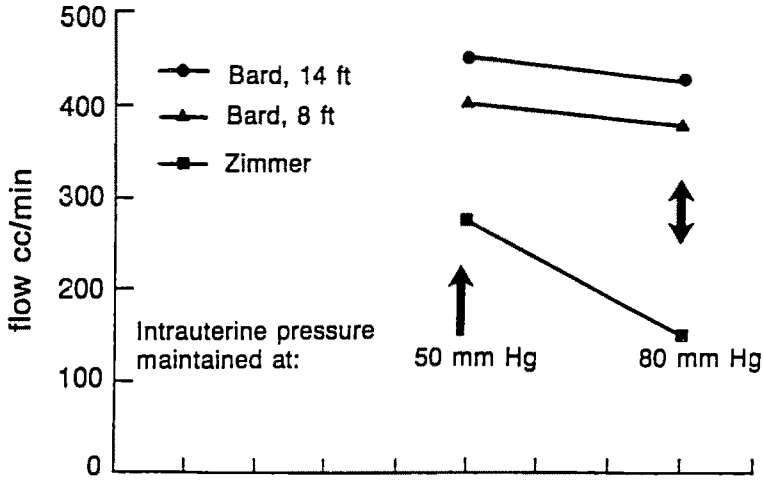

Fig. 2. Factors affecting flow rates (in vitro). Maintaining intrauterine pressures with outflow valve.

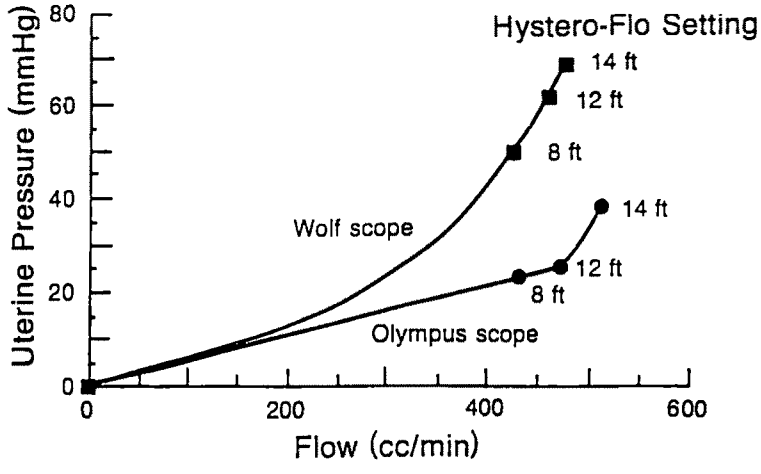

Fig. 3. Uterine pressure versus flow. In vitro comparison of hysteroscopes.

demonstrated that absorbed glycine levels are in direct proportion to serum ethanol levels, whereas there was a proportional decline in the serum sodium levels during prostatic resections. Norlen[9] determined fluid absorption on the basis of the osmolarity of the irrigation fluid (glycine) and the change in serum sodium seen postoperatively. The availability of inexpensive breath-alyzer units may make it possible to routinely monitor the expiratory gases continuously during surgery with a 1% or 2% ethanol irrigant, to detect fluid absorption as it occurs during surgery.[8]

In addition to case reports,[10, 11] Morrison et al.[12] have the only other study in the gynecology literature attempting to measure fluid absorption during hysteroscopic surgery. In one patient of the 12 in the study fluid overload developed after laser ablation procedure in which saline solution was the irrigation fluid. Measurements of absorption show a rise in central venous pressure and serum chloride while the plasma albumin and hematocrit decreased. Intrauterine pressures were not included in the study.

The urology patient tends to be older and more susceptible to volume shifts. Another interesting difference between our patients and the urology patients is gender. In 1986 Arieff[13] reported 16 postoperative deaths over a 10-year period in healthy women undergoing elective general and gynecologic surgery. They were found to have had fluid overload leading to the syndrome of inappropriate antidiuretic hormone resulting in severe hyponatremia. Fraser et al.[14] also reports similar findings in 11 deaths that he attributes to central diabetes mellitus and diabetes insipidus secondary to untreated severe hyponatremia. Fraser and Arieff[15] have also shown in rat studies that the Na^+-K^+ adenosine 5'triphosphatase pump system is less effective in female than in male brain synapses. Progesterone can also decrease pump activity in myocardial and kidney tissue.[13] These studies suggest that guarding against iatrogenic hyponatremia may be even more critical in female patients. However, animal studies in our laboratories have failed to confirm these hypotheses to date.

This is a preliminary report of our studies so far, presented to report some clinically useful unexpected findings. Different pump settings and pumps (Figs. 2 and 3), result in wide differences in pressures and flow rates, as do different hysteroscopes (Fig. 3). Contrary to the current assumption that elevated pressures cause fluid absorption, pressures >200 mm Hg did not result in fluid absorption, yet a rapid procedure under normal pressure conditions did.

We will continue to collect data on more patients, in collaboration with other hysteroscopists, to further determine which procedures are at risk and which are free of risk, of fluid absorption. We will also see if there is a pressure threshold above which fluid absorption occurs, keeping in mind the last patient cited, where symptomatic fluid overload occurred well within safe pressures.

Our conclusions thus far are as follows: (1) Significant intravasation of fluid may occur with extensive resections which open uterine venous channels; (2) significant intravasation also can occur at low pressures in the presence of unrecognized perforations; (3) alcohol is a reliable indicator for measuring fluid absorption and may be used to monitor this risk; (4) there appears to be a minimal risk of absorption during hysteroscopy under normal operative conditions.

Discussion

Dr. Ronald L. Brown, Charlotte, North Carolina. With increasing use of operative hysteroscopy as a surgical alternative for various gynecologic problems, there has become a heightened awareness of the potential complications associated with the procedure. The use of lasers and electocoagulation devices within the intrauterine cavity certainly poses a potential threat to the integrity of the uterine walls, which if violated can lead to a life-threatening situation. Fluid overload, as a result of excessive absorption of distention medium, is a potentially serious complication of hysteroscopy, the cause of which has never been fully understood. Goldrath was a pioneer of endometrial ablation with the Nd:YAG laser, and he recognized fluid overload in several of his patients. Goldrath et al.[1] hypothesized that insufficient dilatation of the cervix and prolonged operating time may be responsible for excessive fluid absorption. Others have suggested that if the fallopian tubes are not blocked that fluid will pass through them and into the peritoneal cavity and be absorbed into the circulation.

In 1990 Garry[2] reported a study of 63 women undergoing endometrial ablation. In 30 of these women fluid was infused with a simple roller pump, and in 33 women the pump was connected to a pressure transducer that maintained intrauterine pressure at a preset level or less. The pressure-controlled group showed an 86% reduction in the volume absorbed, which was measured by inflow-outflow volumes. He suggested that damaged peripheral uterine arteries were the pathway for fluid absorption and if intrauterine pressure was maintained at the patient's mean blood pressure or less, there would be no retrograde flow into the systemic circulation and no fluid overload.

Dr. Vulgaropulos has reported a clinical study of 12 patients in a well-designed protocol to directly measure fluid absorption and intrauterine pressure. This clinical study has been complemented by an experimental laboratory model that demonstrates the effects of several variables on intrauterine pressure and flow rates. It was shown very clearly in the experimental model that intrauterine pressure is primarily a function of the outflow resistance regardless of pump setting. If outflow

was unobstructed, intrauterine pressure was never >60 mm Hg. Conversely, closure of the outflow valve and cervix resulted in pressures >117 mm Hg at all pump settings.

In the clinical study 11 patients underwent various types of operative hysteroscopy and were maintained at intrauterine pressures of 45 to 75 mm Hg with ethanol-labeled glycine as the distention medium. At an undesignated time during the surgery and for an unspecified length of time, outflow of glycine was obstructed in some of these patients, generating intrauterine pressure of 230 and 280 mm Hg at different pump settings. In none of the 11 patients was there any evidence of fluid absorption. In a twelfth patient there was evidence of fluid absorption as measured by blood alcohol level. It is unfortunate that no intrauterine pressures were measured on this patient, but it is safe to assume that normal operating pressures (i.e., pressures >75 mm Hg) were exceeded and probably >200 mm Hg because outflow was totally obstructed. In this patient there was apparent excessive intrauterine pressure for 13 minutes at a time in the surgery when there were obviously open, damaged uterine vessels, and she did have evidence of fluid absorption. In the other 11 patients in the study there is no mention of how many had excessive intrauterine pressure and for how long the elevated pressures were present. It may also be of value to know at what point during the surgery excessive pressures were exerted (i.e., was there excessive intrauterine pressure after the resection of the tissue?). I would ask that Dr. Vulgaropulos comment on this and give his opinion of the significance of these temporal relationships.

It would seem that the cause of fluid absorption during hysteroscopic surgery is multifactorial. Certainly, perforation of the fundus of the uterus and cervical tears have been shown in other case reports to lead to fluid absorption and overload, as was the case with the two nonstudy patients in this report. The cardiovascular status, age, and hormone effect of the patient may also be factors.

Dr. Vulgaropulos's study has answered a number of questions about pressures, flow rates, and pumps used in operative hysteroscopy; however, I don't think we can as yet rule out excessive intrauterine pressure as having at least some role in fluid absorption in some patients.

DR. VULGAROPULOS (Closing). The temporal relationship and the timing is something that we have not quite worked out in our study design. The time the procedure takes is much the same except for the quicker diagnostic procedures. Regarding the elevated pressures, we are just trying to get an idea of how much pressure can be created, and we are holding them for 30 to 60 seconds as opposed to doing the complete resection with closed outflow. After the resection is done, we are basically still at open outflows but it is just within the procedure itself that we will close down the outflow to measure and see what pressures we get for a period of time. It appears that the patient with fluid absorption had it occur over a 10-minute period.

Obesity and lower urinary tract function in women: Effect of surgically induced weight loss

Richard C. Bump, MD,[a] Harvey J. Sugerman, MD,[b] J. Andrew Fantl, MD,[a] and Donna K. McClish, PhD[c]

Richmond, Virginia

OBJECTIVE: The subjective and objective effects of massive weight loss on lower urinary tract function in morbidly obese women were examined.

STUDY DESIGN: Thirteen subjects underwent a comprehensive evaluation of lower urinary tract function before and 1 year after surgically induced weight loss.

RESULTS: We demonstrated significant improvements in lower urinary tract function after weight loss. Of 12 subjects who complained of incontinence before surgery only three complained of incontinence ($p = 0.004$) and only one requested treatment after weight loss. Objective and subjective resolution of both stress and urge incontinence was documented. Statistically significant changes were seen in measures of vesical pressure, the magnitude of bladder pressure increases with coughing, bladder-to-urethra pressure transmission with cough, urethral axial mobility, number of incontinence episodes, and the need to use absorptive pads.

CONCLUSION: Weight reduction is desirable for obese women complaining of urinary incontinence and may obviate the need for further incontinence therapy. (Am J Obstet Gynecol 1992;167:392-9.)

Key words: Urinary incontinence, stress incontinence, detrusor instability, obesity, weight loss

Obesity is commonly cited as a factor related to the development and recurrence of urinary incontinence in women.[1-3] There are relatively few studies that have objectively examined this relationship, however. In 1988 Dwyer et al.[4] compared the prevalence of obesity in 368 incontinent women (232 with genuine stress incontinence and 136 with detrusor instability) with 1981 population norms for Australia. They found that obesity, defined as >120% of the average weight for height and age, was significantly more prevalent in both women with genuine stress incontinence and those with detrusor instability than in the normal population. They were unable to show any differences between obese and nonobese incontinent subjects on urodynamic testing, which included cystometry and uroflowmetry. In the same year Kolbl and Riss[5] examined the relationship between several indexes of body mass and genuine stress incontinence in 150 stress incontinent women and 43 continent controls. They found no significant differences in any of the indexes between the continent and incontinent groups. During urodynamic testing they demonstrated that subjects with a positive stress test had a significantly higher body mass index than subjects with a negative stress test and that an increased body mass index was associated with a significantly greater resting total urethral pressure but not with a greater resting or stressed urethral closure pressure. In a paper presented before the American Uro-Gynecologic Society in 1987 Wilkie and Stanton[6] reported the results of passive and dynamic urethral pressure profiles in five obese continent, five nonobese continent, five obese stress incontinent, and five nonobese stress incontinent women. Although they found significant differences in urethral measurements between the stress continent and incontinent groups, no significant differences were demonstrated between the obese and nonobese subgroups. Finally in 1988 Deitel et al.[7] reported a significant decrease in the prevalence of the symptom of stress incontinence (from 61.2% to 11.6%) in 138 morbidly obese women after weight reduction induced by bariatric surgery. No objective testing was performed.

In summary, previous studies have demonstrated disparate relationships between obesity and objectively documented incontinence. None have shown significant differences due to obesity in various urodynamic measurements. The only study to examine the relationship between successful weight loss and incontinence was entirely subjective.

The aims of the present study were to examine the subjective and objective effects of massive surgically

induced weight loss on lower urinary tract function in morbidly obese women.

Material and methods

Eighteen morbidly obese women who were considered candidates for bariatric surgery volunteered to participate in this study, which was approved by the Medical College of Virginia Committee on the Conduct of Human Research. To be a candidate for surgery, a subject had to be at least 45 kg above her ideal body weight as estimated by the 1983 Metropolitan Life Insurance tables for medium frame. Each subject completed approved consent procedures before initial evaluation. All underwent a comprehensive evaluation of lower urinary tract function as detailed below. After extensive medical, nutritional, and psychologic evaluation and counseling, 13 of the subjects underwent gastric bypass surgery; these women comprise the final study population.

The evaluation of lower urinary tract function included the completion of a detailed urogynecologic history, the performance of a genitourinary physical and neurologic examination, the completion of a prospective 1-week urinary diary,[8] and the performance of a standardized fluid loss quantitation test[9] and urodynamic evaluation. The urodynamic evaluation included uroflowmetry with postvoid residual urine volume measurement, retrograde provocative multichannel water urethrocystometry (in 45 degree upright, sitting, and standing positions) with microtip transducer catheters, passive (at rest) and dynamic (while coughing) urethral pressure profilometry, resting and stressed urethral axis determinations, and direct visualization testing for fluid loss. Specific details of the urodynamic methods have been published previously.[10-12] This entire evaluation was performed before gastric bypass surgery and repeated once weight loss had stabilized after surgery. The repeat evaluations were performed a mean of 14.5 months (SD 3.6, range 11 to 24) after the gastric bypass. No subject received any medical, surgical, or behavioral therapy for incontinence during the time between initial and repeat evaluations.

A subject was considered to have the symptom of stress incontinence if she complained of the objectionable and involuntary loss of urine coincidental with physical activity. The diagnosis of the condition of genuine stress incontinence was made if the subject had the symptom of stress incontinence and had observable leakage produced by stress without concurrently demonstrable detrusor activity during urethrocystometry or had a positive direct visualization test immediately after the catheters were removed in the total absence of detrusor instability during urethrocystometry. A subject was considered to have the symptom of urge incontinence if she complained of the involuntary loss of urine associated with the strong desire to urinate. The diagnosis of the condition of detrusor instability was made if the subject had the symptom of urge incontinence and had the objective demonstration of a detrusor contraction and urinary leakage, spontaneously or on provocation, during urethrocystometry while she was attempting to inhibit micturition. A subject was considered to have the symptom of mixed incontinence if she had the symptoms of both stress incontinence and urge incontinence. The diagnosis of the condition of mixed incontinence was made if the diagnostic criteria were fulfilled for both genuine stress incontinence and detrusor instability. Urodynamic techniques and measurements, terms, and diagnostic criteria conform to the recommendations of the International Continence Society.[13]

Quantitative data were analyzed for significance with the two-tailed paired t test. Unless otherwise noted, all quantitative data are expressed as the mean ± SEM. Simple regression analysis was used to analyze the relationship between body mass index and various measures of vesical pressure. Categorical data were analyzed for significance either with McNemar's χ^2 test or the two-tailed Fisher's exact test as dictated by expected cell size.

Results

The thirteen subjects who completed the study had a mean age of 41 years (SD 11.9, range 22 to 65); 10 were premenopausal and three were postmenopausal. The mean parity was 2.2 (SD 1.3, range 0 to 4) and the mean height was 1.63 m (SD 0.06, range 1.52 to 1.73). The mean preoperative weight was 131.5 kg (SD 19.9, range 99.8 to 153.3). The mean preoperative body mass index (calculated by dividing the weight in kilograms by the square of the height in meters) was 49.4 kg/m^2 (SD 7.9, range 38.6 to 62.2). All subjects experienced significant weight loss after gastric bypass, with a mean postoperative weight of 88.1 kg (SD 17.0, range 59.9 to 114.8, $p = 0.0000009$) and a mean postoperative body mass index of 33.1 kg/m^2 (SD 6.7, range 21.2 to 38.6, $p = 0.000001$).

Table I lists the preoperative and postoperative symptoms and urodynamic diagnoses of each of the 13 subjects. Twelve subjects (92%) had bothersome symptoms of urinary incontinence before surgery. After surgery only three subjects (23%) complained of incontinence ($p = 0.004$). Seven of 10 subjects with the symptom of stress incontinence ($p = 0.02$) and eight of nine subjects with the symptom of urge incontinence ($p = 0.004$) noted resolution of the symptom. The three subjects with persistent symptoms all had mixed incontinence before surgery; two noted resolution of the urgency incontinence component of their symptoms after weight loss.

Table I. Summary of subjects' symptoms and conditions before and 14.5 (SD 3.6, range 11 to 24) months after gastric bypass surgery

	Before surgery	*After surgery*	*No. subjects*
Symptoms	No incontinence	No incontinence	1
	Urge incontinence	No incontinence	2
	Stress incontinence	No incontinence	3
	Mixed incontinence	No incontinence	4
	Mixed incontinence	Stress incontinence	2

Conditions*	Normal	Normal	7
	Detrusor instability	Detrusor instability	1
	Genuine stress incontinence	Genuine stress incontinence	1
	Genuine stress incontinence	Normal	2
	Detrusor instability	Normal	1
	Genuine stress incontinence + detrusor instability	Normal	1

*Urodynamic diagnosis.

Only six of the 12 subjects with symptoms of incontinence before weight loss had objective documentation of incontinence during urodynamic testing (Table I). Four of the six had resolution of urodynamic abnormality after weight loss, three of four subjects with genuine stress incontinence and two of three subjects with detrusor instability. None of these differences in presurgical and postsurgical urodynamic diagnoses achieved statistical significance.

Of the twelve subjects with symptoms of objectional incontinence before weight reduction, only one desired treatment at the time of repeat evaluation. This was a 22-year-old woman with lifelong symptoms of mixed incontinence and enuresis. Her weight decreased from 160 to 107 kg, but she had persistent symptoms and persistent detrusor instability on urodynamic testing. She responded well to imipramine and a program of bladder retraining. Neither of the two subjects with persistent though diminished symptoms of stress incontinence, one of whom had persistent genuine stress incontinence on testing, desired treatment. They had both noted a decrease in the number of incontinence episodes per week, one from 18 to two and the other from four to one.

On the 1-week prospective urinary diary (Fig. 1), there were significant decreases in the number of incontinence episodes per week before and after weight loss (13.4 ± 2.9 vs 0.9 ± 0.5, $p = 0.001$) and in the number of incontinence pads used per day (2.0 ± 0.5 vs 0.08 ± 0.08, $p = 0.00008$). There were no significant differences in daytime voiding frequency (every 2.9 hours before surgery vs every 3.3 hours after surgery), or in episodes of nocturia per week (8.2 before surgery vs 6.9 after surgery).

During urodynamic testing all intravesical pressure measurements before weight loss were significantly greater than those after weight loss (Fig. 2). These included (expressed in centimeters water pressure) the initial pressure in the 45 degree upright position (40.3 ± 3.7 vs 25.3 ± 1.7, $p = 0.0007$), pressure at maximum cystometric capacity in the same position (45.0 ± 3.1 vs 27.2 ± 1.9, $p = 0.00006$), pressure sitting upright (56.1 ± 2.9 vs 32.9 ± 2.1, $p = 0.000006$), pressure standing (56.7 ± 3.4 vs 32.8 ± 2.1, $p = 0.00001$), and the increase in pressure from 45 degrees to standing (13.2 ± 1.4 vs 6.8 ± 1.0, $p = 0.005$). These changes were due to decreases in abdominal pressure rather than to decreases in true detrusor pressure. There was a significant positive correlation between body mass index and initial vesical pressure ($r = 0.50$, $p = 0.01$), pressure at maximum cystometric capacity ($r = 0.57$, $p = 0.003$), sitting pressure ($r = 0.60$, $p = 0.001$), and standing pressure ($r = 0.60$, $p = 0.001$).

There were also significant differences seen in all cough-related parameters before and after weight loss (Fig. 3). The increases in vesical pressure with four maximum effort coughs were significantly greater before weight loss (greatest amplitude cough 104 ± 10 cm water, mean of four coughs 93 ± 10) than after surgery (greatest 76 ± 6, mean of four 68 ± 5, $p = 0.001$ and 0.004, respectively). Cough pressure transmission from the bladder to the urethra was significantly improved (higher) after weight reduction (83% ± 3% before surgery vs 93% ± 5% after surgery, $p = 0.03$). Finally, urethral axial mobility with coughing was significantly less after weight reduction (stressed cotton swab angle 37 ± 4 degrees before vs 24 ± 4 degrees after surgery, $p = 0.005$).

There were no significant changes related to weight loss in any other urodynamic parameter, including measures of passive urethral function (functional urethral length or maximum urethral closure pressure), bladder capacity (first sensation of fullness and maximum cystometric capacity), and emptying function (mean and maximum flow rates and postvoid residual volumes).

No significant differences were noted during quantitation testing; however, the power to detect a difference was very low. Six subjects lost no fluid either before

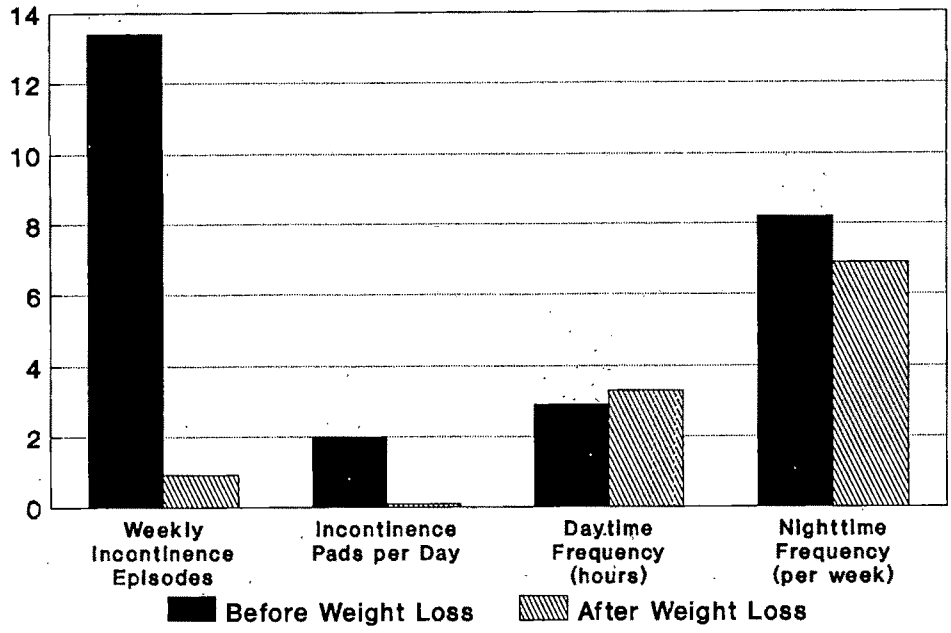

Fig. 1. Effects of surgically induced weight loss on number of incontinence episodes per week ($p = 0.001$), number of incontinence pads used per day ($p = 0.00008$), daytime voiding frequency in hours, and episodes of nocturia per week.

or after weight reduction and five subjects who lost 2, 5, 6, 35, and 173 gm before weight reduction recorded no loss after. One subject with persistent genuine stress incontinence lost 162 gm before and 147 gm after surgery; another with persistent detrusor instability lost 81 gm before and 226 gm after.

Comment

This study has demonstrated both statistically and clinically significant improvements in lower urinary tract function after marked, surgically induced weight reduction in morbidly obese women. This improvement has been seen in both subjective and objective parameters. Subjectively, nine of 12 women with bothersome incontinence before weight loss noted complete resolution of their incontinence after weight loss. Moreover, two of the three subjects with persistent symptoms of incontinence had noted improvement to the point that they desired no treatment for their residual incontinence. Only one of 12 incontinent subjects required treatment after weight reduction; she had had lifelong mixed incontinence and enuresis. Objectively, two of three subjects had resolution of pure genuine stress incontinence, one of two had resolution of pure detrusor instability, and one had resolution of mixed genuine stress incontinence plus detrusor instability on urodynamic testing. Although these changes did not reach statistical significance due to the small number of subjects, they had obvious clinical significance for the four women who normalized their studies. Our findings are in agreement with prior studies by Dwyer et al.,[4] which suggested that obesity contributed both to genuine stress incontinence and detrusor instability, and by Deitel et al.,[7] which showed that massive weight loss often led to the resolution of the symptom of stress incontinence.

Urodynamically we have demonstrated that massive weight loss in morbidly obese women significantly reduced intravesical pressure in all positions and reduced pressure increases seen with standing. Moreover, pressure increases with coughing were also significantly less following weight loss. Finally, there were statistically significant improvements in the stress competence (reflected by an increase in the pressure transmission ratio) and in the anatomic stability (reflected by a decrease in stressed Q-tip cotton swabs angle) of the urethra after weight loss. These are all measurements that were not recorded in previous urodynamic evaluations by Dwyer et al.[4] or by Kolbl and Riss.[5] In agreement with these authors, we did not see significant differences in other cystometric, urethral, or uroflowmetric measurements. Our results do differ from those of Wilkie and Stanton,[6] who demonstrated no differences in bladder pressure with position change or cough and no differences in passive or dynamic urethral function when comparing obese and normal-weight subjects. This discrepancy is likely explained by differences in study design, in that our comparison of the same subjects before and after weight loss minimizes many confounding variables that might have influenced these measures in Wilkie and Stanton's small study groups.

Our urodynamic results do suggest that the mechanism for improved stress continence in our subjects is related to lesser increases in abdominal pressure with

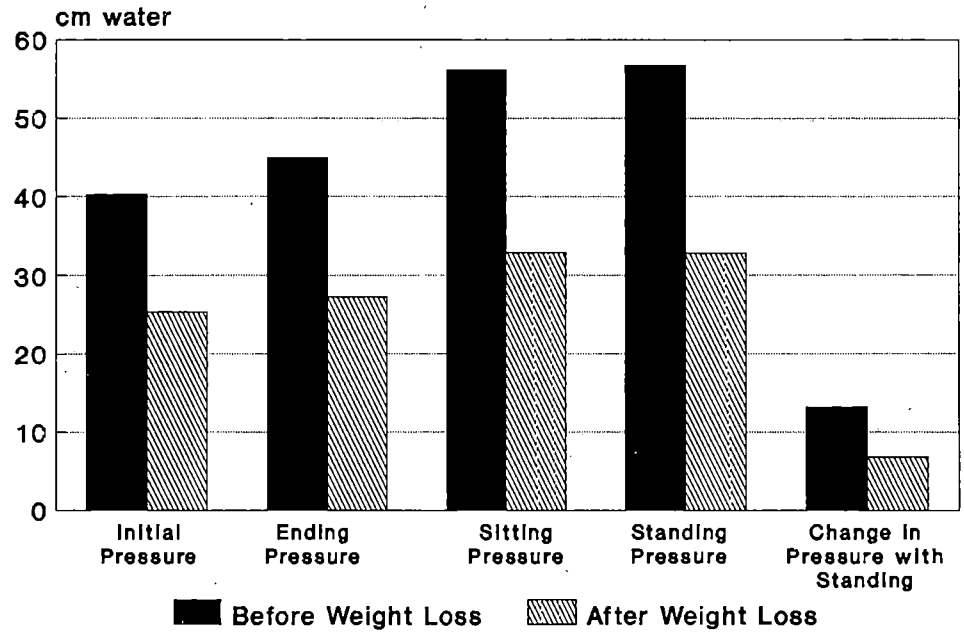

Fig. 2. Effects of surgically induced weight loss on intravesical pressure measurements at beginning of cystometry ($p = 0.0007$), at maximum cystometric capacity ($p = 0.000006$), sitting ($p = 0.000006$) and standing ($p = 0.00001$) at maximum cystometric capacity, and on the increase in pressure with standing ($p = 0.005$).

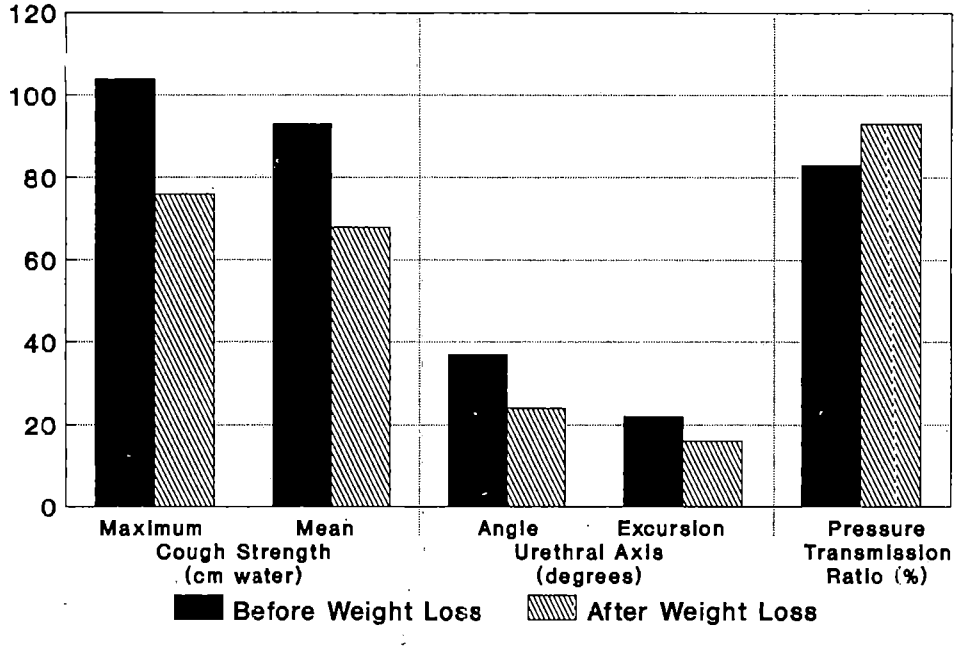

Fig. 3. Effects of surgically induced weight loss on maximum ($p = 0.001$) and mean (0.004) intravesical pressure changes, urethral axis ($p = 0.005$) and excursion arc ($p = 0.04$) and bladder to urethra pressure transmission ratios ($p = 0.03$) with coughing.

physical stress, improved transmission of this stress to the urethra, and decreased axial mobility of the urethra. All of these factors are felt to be important in the pathophysiology of genuine stress incontinence.[11] The data provide no indication as to the mechanism for the resolution of urge incontinence and detrusor instability. We are aware of no evidence that decreases in total bladder pressure, such as observed in this study, will improve one's ability to suppress detrusor instability. It is possible that alterations in autonomic nervous system activity related to obesity described in animals and humans[14] may normalize with weight reduction. Increased sympathetic and decreased parasympathetic stimulation to the lower urinary tract could consequently promote enhanced detrusor stability.

Two qualifying aspects of this study must be men-

tioned. The first is the profound degree of obesity demonstrated by our population. Obesity is defined formally by a body mass index >30 kg/m^2.[15] Our population's mean body mass index of 33.1 after weight reduction reflects the severity of its obesity; only five of 13 subjects achieved a body mass index of ≤30 after weight loss. We cannot be certain that our findings and conclusions can be generalized to the 10% to 12% of Americans who are defined as obese,[15] most of whom are significantly less obese that our study population.

The second qualification is our inability to establish an objective diagnosis of incontinence in half of the 12 subjects who complained of the symptom of incontinence. This compares with a nondiagnostic study rate of 9.5% (18/188) for other patients complaining of incontinence studied by the first author during the same time with the same diagnostic criteria and to a 10.3% (15/145) rate reported in a previous study from our laboratory.[16] This discrepancy may reflect technical difficulties in establishing the diagnosis of incontinence, particularly in directly observing leakage, in massively obese subjects. However, it may also reflect confusion regarding the source of perineal wetness in such women. In any event, we feel that this observation should generate a degree of skepticism regarding conclusions based on studies that use only subjective measures to study incontinence in obese subjects.

With the findings and qualifications of this study in mind, we conclude that weight reduction is desirable for obese women complaining of urinary incontinence. Successful weight reduction may obviate the need for further incontinence therapy in at least some obese patients. In addition, for obese women with genuine stress incontinence who undergo continence surgery, weight reduction may improve the technical ease, increase the durability, and decrease the failure rate of such surgery.[4] A comprehensive survey of the treatment of obesity and the role of surgery in the treatment of severe obesity is beyond the scope of this paper; the interested reader is referred to a recent National Institutes of Health consensus statement on this topic.[17] However, it must be emphasized that traditional diet and exercise treatment of obesity is often unsuccessful, with permanent cure realized by fewer than 10% of patients after a decade.[15] Thus for some morbidly obese incontinent women gastric bypass surgery would seem preferable to and of greater overall benefit than continence surgery.

Discussion

DR. JOHN W. LANE, Chapel Hill, North Carolina. In spite of the fact that we gynecologists are taught, beginning in medical school, that obesity contributes to female urinary incontinence, objective documentation of this is surprisingly lacking on our literature.[1, 2] Nor is there any prior objective prospective study which supports the recommendation of weight loss to the obese patient to reduce her incontinence symptoms. This is the first study that approaches this in a systematic, objective, prospective manner.

Bump et al. have reported a very interesting study of a group of extraordinary patients. They were enormously obese women, having an unusual procedure with which most gynecologists have little if any experience. Nevertheless, the experience with these patients can help us to understand the relationships between

obesity, weight loss, and female urinary incontinence. This study may have use for us in caring for the much more extensive group of obese women who are not as large, but with whom we are all well acquainted.

Most gynecologists would advise weight loss to obese patients as one part of a conservative program to help diminish or eliminate symptoms of incontinence, but objective evidence of improvement in urodynamic function after weight loss has heretofore been scanty to absent. Such evidence as does exist is fairly, clearly, and concisely reviewed by Dr. Bump in the introduction.

The purpose of this study, clearly stated, was to evaluate both subjective and objective effects of significant weight reduction the lower urinary tract function of obese women.

The patient selection was direct. Thirteen patients who were selected for gastric bypass surgery for weight loss entered the study. We are not told how many other patients were invited to participate but declined. Although a wide range of weights were included (99.8 to 153.3 kg) all were markedly obese as demonstrated by the mean weight of 131.5 kg and the fact that each was a minimum of 45 kg above ideal weight for medium frame.

This is an unique group of obese patients because each of them could reliably be expected to lose a large amount of weight because of surgery, thus making it possible to focus the study on subjects who would have successful weight loss. We can imagine how many subjects would have had to be studied to find a group this large that would successfully attain this degree of weight loss with traditional methods of diet and exercise.

The definitions and explanations of the terms used and the diagnostic criteria are succinctly stated and clearly explained. All techniques, parameters, measurements and criteria conformed to internationally established standards.

The patients underwent thorough and extensive lower urinary tract evaluation. The urodynamic studies are described in understandable and exacting detail. All studies were performed before surgery and repeated after the weight loss had stabilized after surgery. No other therapies were undertaken in the interim.

Of the 13 subjects, 12 reported preoperative incontinence. Nine of these 12 no longer complained of bothersome incontinence when reevaluated 1 to 2 years postoperatively. Three were still incontinent, although two of these were improved.

Of interest is the fact that six of the 12 subjects with symptoms of incontinence had normal urodynamic studies both before and after weight loss. The remaining six patients did have objective documentation of incontinence during testing. Of these six, four had resolution of their urodynamic abnormality.

There were three patients who still complained of incontinence, two of whom had objective incontinence and one with symptoms of incontinence. Two were improved and only one (with objective detrusor instability) sought further treatment.

Although statistical significance was not achieved due to the small numbers, one must assume that the patients who improved were pleased with this result. Even the six patients with symptomatic incontinence alone must have been delighted with remaining dry and were probably not at all concerned that their improvement was not confirmed by objective measurements.

The urodynamic studies support the view that the improvement was due to decreased intraabdominal pressure, increased pressure transmission to the urethra, and decreased urethral mobility. The authors submit that the improvement in detrusor instability may have been due to normalization of the effects of the autonomic nervous system on the lower urinary tract.

The authors warn us regarding two aspects of the study. First, these patients were massively obese. We cannot be certain that the same results would occur in more "normally" obese patients, which, of course, make the bulk of the obese population. Second, half of the subjects who complained of incontinence could not be shown objectively to have it. The nondiagnostic study rate is usually between 10% to 30%.[3] Several possible reasons for this were reviewed.

We can certainly agree that obese women with urinary incontinence should be counseled to lose weight as part of a conservative program to improve their symptoms. They may, indeed, need no further therapy. However, even if incontinence should persist after weight loss, surgery should then be technically less difficult, less risky, and more likely to be a long-term success.

I would like to ask Dr. Bump if there were many other gastric bypass patients who were invited to participate in this study but who declined.

I would also be interested to know if you have continuing studies on additional gastric bypass patients, or perhaps studies on less obese patients in more traditional weight reduction programs.

Dr. A. Cullen Richardson, Atlanta, Georgia. You didn't specify how many of these women were parous.

Dr. Bump (Closing). A number of patients were offered the opportunity for free urodynamic testing. The ones who refused were all continent. We had hoped initially to look at a group of incontinent and a group of continent women, but as you see only one of the 13 was continent. We would have liked to have compared test results after weight loss in those who did not complain of incontinence.

The study is not continuing. The most practical reason is that the motor on our urodynamic chair was in danger of burning out. It usually took me, the nurse,

and the resident to tip the chair backward, assisting the grinding gears. We did a gastric bypass study because our chances of finding a group of 13 women who are going to lose over one half ton of weight in 14 months is relatively low; Dr. Sugerman is pretty good at achieving that weight loss for us.

One of the five patients who was initially evaluated but decided not to go ahead with bypass surgery is actually continent now, having lost a little over 52 kg on her own through a weight loss and exercise program. Another three who did not change their weight report that they had no change in their symptoms. One could not be located.

Dr. Richardson, one subject was nulliparous. The mean parity was 2.2. Interestingly, all of these patients had delivered vaginally. There were no cesarean sections in any of the subjects.

The incidence of genital prolapse after the Burch colposuspension

Anne K. Wiskind, MD, Sarah M. Creighton, MD, and Stuart L. Stanton
Atlanta, Georgia, and London, England

OBJECTIVE: Our objective was to determine the incidence of postoperative genital prolapse after the Burch colposuspension and to identify risk factors for the development of subsequent prolapse.
STUDY DESIGN: The charts of 131 patients who had a Burch colposuspension performed by the senior author (S.L.S.) between 1977 and 1986 were reviewed at the Urodynamic Unit of St. George's Hospital, London. Emphasis was placed on the degree of genital prolapse on clinical examination and whether further surgery was required to correct the prolapse.
RESULTS: Thirty-five patients (26.7%) required a total of 40 operations to correct genital prolapse after colposuspension. At 20 operations, more than one procedure was required to correct combined prolapse. The patient's age, weight, parity, menopausal status, and prior pelvic surgery did not affect the incidence of postoperative prolapse. The only preoperative risk factor identified was the presence of a large cystocele.
CONCLUSION: Postoperative genital prolapse is a significant complication of the Burch colposuspension. It is unclear whether this is due to a disruption of the vaginal axis or to an intrinsic weakness of the pelvic floor in these women. (Am J Obstet Gynecol 1992;167:399-405.)

Key words: Stress incontinence, prolapse, Burch colposuspension

Although there are many operations used for the treatment of urethral sphincter incompetence (genuine stress incontinence), the Burch colposuspension is one of the most popular and most successful. The first retropubic urethrovesical suspension was described by Williams in 1947, who placed sutures between the bladder wall and the periosteum of the symphysis.[1] In 1949 Marshall et al.[2] described their operation in which sutures are placed between the vaginal wall and periosteum and cartilage of the symphysis. Hampered by sutures pulling out of the periosteum with this technique, Burch,[3] in a procedure published in 1961, suspended the paravaginal fascia first to "the white line" of the levator fascia and eventually to Cooper's ligament. Subsequently, the Burch operation has been called by many different titles, although it appears the term colposuspension was first used by Warwick and Whiteside in 1970.[4]

In spite of the success achieved with the Burch colposuspension, with incontinence cure rates ranging from 71% to over 95% reported,[4-17] there are several recognized complications resulting from the operation. These include postoperative detrusor instability and

6/6/38057

voiding disorders.[4, 7, 12, 18-21] One of the less noted complications is the occurrence of enterocele and rectocele. In Burch's original description of the procedure, he states that in cases of doubt it is best to repair the posterior vaginal wall at time of colposuspension. After the operation he noticed an elevation in the posterior vaginal wall just in front of the cervix that appears after the anterior vaginal wall is elevated. He thought this change predisposed to enterocele formation.[3] This tenting of the posterior vaginal wall after colposuspension has also been described by Stanton and others as a cause of dyspareunia and as an aggravation of posterior vaginal wall weakness.[4, 11, 12, 14, 16]

The incidence of enterocele after the Burch procedure reported in the literature ranges from 3% to 17%, but there are little data on postoperative rectocele development and uterine descent.[1, 3-6, 11-17] Furthermore, there is sparse information on factors that may predispose patients to genital prolapse after a Burch operation and little consensus on the appropriate operative management of this potentially significant complication. With these issues in mind, we reviewed the outcome of patients who had a colposuspension operation, specifically focusing on the issue of postoperative prolapse.

Material and methods

The medical charts of 131 consecutive patients who had a Burch colposuspension operation for the treatment of genuine stress incontinence between 1977 and 1986 were reviewed at the Urodynamic Unit of St. George's Hospital, London. All of the operations were done or supervised by the senior author (S.L.S.) at either St. James Hospital, St Helier Hospital, or St. George's Hospital. Information sought from the charts included the age, weight, parity, menopausal status, and estrogen therapy (if applicable) of the women before surgery. Previous incontinence surgery, prolapse surgery, or hysterectomy were noted. All patients had preoperative urodynamic studies that included a cystometrogram or voiding cystourethrogram and uroflowmetry. The degree of genital prolapse was carefully evaluated by S.L.S. preoperatively and corrected at the time of the colposuspension, if significant. Postoperatively, the return of satisfactory bladder function as determined by the removal of the suprapubic catheter, the return of bowel function, the total number of hospital days, and any special complications were recorded. After discharge, the patients were usually seen at 2 to 3 months after surgery for clinical review and repeat urodynamic studies. Thereafter, they were seen annually for 5 years for review of symptoms, pelvic examination, uroflowmetry, and a pad test. At postoperative follow-up review in this study, the emphasis was on the degree of genital prolapse on clinical examination and whether further surgery was required to correct the prolapse. Patients who had not been examined in the past year were asked to come to the urodynamic unit at St. George's Hospital for evaluation. Only those patients with complete medical notes, a recent examination, and a follow-up period of >3 years were included in the study.

The patients were divided into two groups. Group 1 included the patients who did not require additional surgery for genital prolapse after the colposuspension operation. The patients who did have corrective surgery for prolapse were placed in group 2. The two groups were compared for any factor that may predict genital prolapse after colposuspension, with the hope of identifying preoperatively patients who may be at increased risk.

A modified Burch colposuspension, as previously described by Stanton,[4-6] was performed in all patients. After the induction of anesthesia, the patient was placed in the horizontal lithotomy position with the legs supported by Lloyd-Davis stirrups. Cystoscopy was performed initially in all patients to ensure they had no condition that would complicate surgery. If cystoscopy was satisfactory, the abdomen and perineum were prepped and draped in a sterile fashion. A transuretheral resection drape was used to cover the perineum, allowing access to the vagina with the sterile condom during the operation. A 14F Foley catheter was placed in the bladder to allow continuous drainage during the operation and to facilitate the delineation of the urethra and the bladder neck.

Access to the retropublic space was obtained through a low Pfannenstiel or Cherney incision. If a hysterectomy, tubal ligation, or culdoplasty was needed, it was accomplished before the colposuspension, and the peritoneum was closed with a 2-0 continuous delayed absorbable suture. Visualization of the space of Retzius was enhanced by the use of a Denis Browne self-retaining ring retractor. The bladder was carefully dissected from the symphysis. With a forefinger in the vagina, the operator elevated the lateral vaginal fornix and dissected the bladder base medially off the paravaginal fascia. Although this can sometimes be accomplished bluntly, scissor dissection was often required. Three of four pairs of No. 1 nonabsorbable polybutylate-coated polyester sutures (Ethibond, Ethicon, Ltd., Edinburgh) were then placed into the paravaginal fascia on each side and inserted into the ipsilateral ileopectineal ligament. The most distal (caudad) suture was inserted opposite the bladder neck. The remaining sutures were placed cephalad along the bladder base about 1 cm apart. Once all the sutures were in place, they were tied, approximating the paravaginal tissue to Cooper's ligament. The most caudad sutures were tied first, and then the remainder of the sutures were tied on alternating sides to ensure balanced elevation.

Once adequate hemostasis was achieved, the incision

was closed. A suction drain was left in the retropubic space. A suprapubic catheter was placed two fingerbreadths above the incision after the bladder had been filled through the Foley catheter. The catheter was then removed. Any necessary repair of the posterior vaginal wall was then accomplished.

Postoperatively, the retropubic suction drain was removed 24 to 36 hours after surgery. The suprapubic catheter was clamped on day 2 to allow the patient to attempt to void spontaneously. The catheter was removed once she voided amounts >200 ml, and the residual urine was <150 ml.

Results

The age of the 131 study patients ranged from 30 to 76 years with a mean of 47 ± 9.8 years. All of the patients had urodynamically proved urethral sphincter incompetence, although four patients also had a component of detrusor instability.

Group 1 consisted of 96 patients (73.3%) who did not require surgery for genital prolapse after colposuspension operation. Thirty-five patients (26.7%) required corrective prolapse surgery and were placed in group 2.

The surgical procedures used to correct postcolposuspension prolapse are listed in Table I. Of the 131 patients, 29 patients (22.1%) had a rectocele repair, 14 (10.7%) underwent an enterocele repair, 17 (13.0%) had a hysterectomy, and three (2.3%) had a repeat colposuspension subsequent to the initial colposuspension. A total of 40 operations were performed with 31 patients requiring one additional surgery, three patients had two additional surgeries, and one patient required three subsequent operations to correct genital prolapse. At 20 operations, more than one procedure was required to correct combined prolapse (i.e., enterocele and rectocele repair). The average time interval between the initial colposuspension and the operation to correct symptomatic prolapse was 40.23 ± 26.35 months (range 9 to 70 months). The period of follow-up in the study ranged from 3 to 14 years with a mean of 5.1 ± 1.41 years. Overall, 81.8% of the patients in the series were cured of stress urinary incontinence, 82.3% in group 1 and 80.0% in group 2.

Table II. Primary operation

Operation	*Group 1 (N = 96)*		*Group 2 (N = 35)*	
	No.	*%*	*No.*	*%*

$p = 0.889$ (χ^2).

A comparison of the clinical characteristics between those who had corrective prolapse surgery and those who did not demonstrates no significant difference in age, weight, parity, or menopausal status. There were only three patients in the study on hormone replacement therapy; two in group 1 and one in group 2, so this obviously had no relevance in the study.

The incidence of previous surgery also did not appear to be a significant factor for the subsequent development of prolapse. In group 1, 51 patients (53.1%) had no previous pelvic surgery compared with 20 patients (57.1%) in group 2. Of those that had previous surgery, 45 patients in group 1 had 59 prior pelvic operations, whereas 15 patients in group 2 had 30 previous gynecologic surgeries. Twenty-five patients (26.0%) in group 1 had a previous hysterectomy compared with 13 (37.1%) in group 2, again not significantly different ($p = 0.215$).

A summary of the principal surgical procedures in the study is seen in Table II. Overall, 104 patients (79.4%) had a colposuspension only, whereas the remaining patients had a posterior repair, abdominal hysterectomy, or culdoplasty in addition to the colposuspension. One patient had a uterine suspension. Although the number of patients who had additional procedures at the time of the primary colposuspension was small, they were evenly distributed between the two

groups, and the additional surgery appeared to have no effect on the incidence of subsequent prolapse surgery. An analysis of the spontaneous voiding day, postoperative return of bowel function, the total number of hospital days, and the perioperative complications demonstrated no difference between groups 1 and 2.

Preoperatively, there was no difference between the two groups in the clinical symptoms associated with prolapse, such as a feeling of prolapse and the need for manual reduction of the posterior vaginal wall to facilitate bowel movements. Not surprisingly, the symptoms of prolapse were significantly greater in group 2 after the initial surgery ($p = 0.00001$), because these patients eventually required corrective prolapse surgery. The overall incidence of dyspareunia was decreased after colposuspension and was not significantly different between the two groups.

In the objective evaluation of uterovaginal prolapse in these patients, mild prolapse was defined as any descent of the vaginal wall or cervix with abdominal straining short of the vaginal introitus. Marked prolapse was defined as descent of the vaginal wall to the introitus or beyond. Preoperative assessment of vaginal prolapse revealed a significantly higher incidence of a marked cystocele in group 2 than group 1 ($p = 0.027$). There was no difference in the incidence of rectocele, enterocele, or uterine descent preoperatively (Tables III and IV). Because the percentage of patients with prolapse in each group exceeds 100% obviously there were some patients with combined prolapse (i.e., cystocele + rectocele or enterocele).

After colposuspension there was a significant decrease in the incidence of cystocele with only three patients (2.5%) found to have a marked cystocele, compared with 36 patients (27.5%) preoperatively (Table V). Just over one third of the patients, evenly distributed between groups 1 and 2, were found to have after colposuspension an asymptomatic, mild cystocele located near the uterine cervix or vaginal apex.

A significantly higher incidence of rectocele, enterocele, and uterine descent was found postoperatively in group 2 than in group 1, with 10 patients in group 2 developing a marked rectocele, 7 developing a marked enterocele, and 9 with marked uterine descent (Tables V and VI). As was noted preoperatively, many of the patients had combined prolapse. Of the 19 patients in group 2 who had an intact uterus at the time of their second operation (first operation to correct prolapse), 17 patients (89.5%) had the uterus removed as part of the procedure to correct their prolapse. It should be noted, however, that 64 patients (66.7%) from group 1 had an intact uterus that remained asymptomatic throughout the follow-up period after the colposuspension. Furthermore, there was no difference in the percentage of patients with an intact uterus preoperatively in groups 1 and 2, and the presence or absence of the uterus had no effect on the operation's incontinence cure rate.

Comment

The Burch colposuspension procedure is an effective surgical means to treat urethral sphincter incompetence and to correct anterior vaginal wall prolapse. Our series confirms the findings of previous studies that a cystocele is well corrected by a colposuspension.[3-5, 22] We were also able to confirm that uterine preservation does not adversely affect the ability of the operation to cure stress incontinence. The fact that there was no difference in the percentage of patients who had an intact uterus between the two groups suggests that uterine preservation does not predispose to postoperative prolapse. However, if a patient who develops prolapse has an intact uterus, the uterus is likely to require removal as part of the corrective prolapse surgery.

We were surprised to find that neither age, parity, weight, menopausal status, nor prior pelvic surgery predisposed to postoperative prolapse. Although the incidence of curing stress incontinence had been found to be lower in postmenopausal women than their premenopausal counterparts,[23] the incidence of postoperative prolapse appears no different in our series.

The only factor we were able to identify as a preoperative risk for the development of postoperative enterocele, rectocele, and uterine descent was the presence of marked anterior vaginal wall prolapse (i.e., a

cystocele that descends to the vaginal introitus or beyond), although the majority of patients had no identifiable risk factor. The elevation of the anterior vaginal wall that occurs with the Burch colposuspension may change the axis of the posterior vaginal wall, exposing it to a greater degree of intraabdominal pressure. A large cystocele would tend to be quite mobile with a resultant greater elevation of the anterior vaginal wall after colposuspension, which may result in a greater tendency for the disruption of the support to the vaginal apex and the posterior vaginal wall. These findings may also reflect an intrinsic weakness of the pelvic support tissues in these patients. Sayer et al.[24] performed surgical biopsies of the pubocervical fascia in 60 women with uncomplicated stress incontinence. They concluded that the collagen in stress incontinent women with bladder neck prolapse is weaker than those without prolapse. Because all of fascia of the pelvic floor is interrelated, it is reasonable to assume this weakness may extend to the fascia of the posterior vaginal wall and uterine supporting ligaments as well. If this is the case, there may be little that can be done to prevent the postoperative prolapse from developing. Although only 20.6% of the patients in our series had transabdominal hysterectomy, culdoplasty, or posterior repair at the time of colposuspension, the addition of these procedures did not decrease the incidence of subsequent corrective prolapse surgery. This was also the experience reported by Burch.[3] In his initial report of 53 cases, four patients (7.5%) developed postoperative enteroceles. Three of the four had a transabdominal hysterectomy and culdoplasty at the time of colposuspension.

Although this study seems to confirm the suspicion that the Burch colposuspension weakens the support to the vaginal vault and posterior vaginal wall, it is possible that other life events in these women may play a role. As the average time from colposuspension to corrective prolapse surgery was 3 years, the effects of entering menopause, weight gain, changes in life-style, and aging of tissues may have an influence on the development of prolapse; these factors are difficult to quantitate. However, the potential of this operation to predispose to genital prolapse through the alteration of the vaginal axis cannot be ignored.

In conclusion, postoperative enterocele, rectocele, and uterine descent are significant late complications of the Burch colposuspension procedure in our series. The only preoperative risk factor identified is marked anterior vaginal wall prolapse, and methods to prevent postoperative prolapse remain unclear. We suggest that preoperatively patients be carefully evaluated for genital prolapse. If significant genital prolapse is present, it should be corrected at the time of colposuspension. In patients with a large preoperative cystocele, prophylactic culdoplasty and correction of minimal uterine descent and rectocele should be considered. However, all patients are at risk for the development of postcolposuspension uterovaginal prolapse. During preoperative patient consultations, the risk of postoperative prolapse after the Burch procedure and the possible need for subsequent corrective surgery should be discussed.

We thank Dr. William Graves for his statistical consultation.

Discussion

Dr. Stewart J. Wetchler, Newport News, Virginia. When an operation is performed to correct stress incontinence, the surgeon considers whether other procedures should be performed concomitantly. Most gynecologists will correct other detectable symptomatic defects in pelvic support. But should asymptomatic defects be corrected? Should any prophylactic procedures be performed to preclude the development of new defects, and are those prophylactic procedures effective? To begin answering these questions, one must know the actual incidence of genital prolapse after surgery to correct stress urinary incontinence. The authors have reported that incidence in this series from a very well respected service.

Wiskind et al. reviewed 131 cases of Burch colposuspension for stress urinary incontinence. They analyzed the need for subsequent surgery for genital prolapse. Of the 131 patients, 35 (or 27%) required 40 additional operations. Thorough analysis demonstrated that the presence of a marked cystocele was the only preoperative finding that predicted the development of postoperative relaxation.

While reviewing this paper, a few questions arise about the study design. First, how were patients selected for a second operation? Was the surgery performed only if symptoms were present or were asymptomatic defects repaired? Second, what were the criteria for "cure" of stress incontinence? The stated cure rate of 81.1% overall is slightly lower than quoted elsewhere, but this may simply reflect stringent criteria for cure. A third question is how many of the patients were menopausal? It is surprising that only three patients were on hormone replacement therapy. If a significant number of postmenopausal patients were included in this study and very few were on hormonal replacement, then their symptoms of genital prolapse might have been exacerbated by urogenital atrophy. Estrogens, of course, will not correct an anatomic defect, but hormone replacement might have relieved symptoms and so decreased the need for surgery to correct genital prolapse. The final question for Dr. Wiskind is how were patients examined preoperatively? Pelvic examinations are usually performed in the supine position. Dr. David Nichols and others have advocated performing examinations in the standing position. Such an examination is awkward to perform, but might detect more defects in support which could be corrected at the initial operation.

The authors state that if a large cystocele is present, "prophylactic culdoplasty and correction of minimal uterine descent and rectocele should be considered." The authors feel, however, that "there may be little that can be done to prevent postoperative prolapse from developing." It is suggested that the addition of a culdoplasty would not decrease the incidence of postoperative enterocele formation and that Dr. Burch had the same experience. In the original 1961 article Burch reported the occurrence of four enteroceles; however, three were after "plication of the cardinal and uterosacral ligaments." An actual culdoplasty was not performed. He goes on to say, "Since amending the plication of the cardinal and uterosacral ligaments and utilizing the Moschcowitz type of procedure the postoperative results have been much better and I do not believe that the development of a postoperative enterocele will be a major problem in the future."[1]

In 1968 Burch still strongly favored cul-de-sac obliteration, and he diagrammed a detailed closure of the pouch of Douglas.[2] Unfortunately, data do not exist to evaluate the effectiveness of such a procedure. The current paper reports a significant 27% incidence of postoperative genital prolapse. It therefore seems prudent to perform any reasonable procedure that should obviate the need for a repeat operation. At the time of retropubic urethropexy, I will therefore continue to perform prophylactic culdoplasty with permanent su-

ture and to correct other significant defects in pelvic support. In patients with severe medical problems, I will minimize anesthetic time and intraoperative risks by only correcting symptomatic or severe defects.

DR. WILLIAM T. MIXSON, Miami, Florida. I'm disturbed about the definition of mild prolapse; later you said minimal prolapse. That sounds about like the amount of mobility that is present in most parous patients. It is usually asymptomatic and not worthy of consideration either preoperatively or postoperatively. Why can't you leave those patients alone? If you could break the paper down into those who had true prolapse and leave out those that you define as mild prolapse, I think it would have more significance.

DR. WISKIND (Closing). I agree with your point, Dr. Mixson, and during our analysis we were much more concerned with those patients who had marked prolapse as opposed to those who had mild or minimal prolapse. However, mild prolapse was sometimes clinically important because there were patients who had symptomatic mild prolapse that needed to be corrected subsequent to the colposuspension.

As for how the patients were selected for postoperative surgery, most commonly it was by symptoms. Mr. Stanton believes that patients who have asymptomatic prolapse, unless the prolapse was quite significant, should be left alone due to the potential for scarring. Therefore the criteria for postoperative correction of prolapse was the patient's symptoms of pelvic pressure, back pain, or in the case of rectocele, the need for manual assistance during defecation.

The criteria for the cure for stress incontinence was both subjective and objective. First, whether the patient clinically said she was dry; second, the objective visualization of stress incontinence on examination; and third using a modified pad test, where the patients who came back to clinic were asked to do the provocative procedures for the ICS extended pad test while wearing a pad with a piece of nitrazine paper on it to check for urinary leakage. If the patients met all those criteria, they were considered to be dry.

I think that I can comment a little on Mr. Stanton's relatively low cure rate in that St. George's Hospital is a tertiary referral center and many of the patients had previous incontinence surgery before colposuspension.

As far as why so few patients were on hormone replacement therapy, I think that it is a function of the National Health Service in England. They don't advocate putting patients on hormone replacement therapy because it is expensive. The patients have to ask for hormone replacement therapy before they are placed on it. At least that was my experience. It is not encouraged and it is not discussed with patients as they are seen for their clinic visits.

As far as how the patients were examined preoperatively, they were examined with a Sims speculum by Mr. Stanton with the patients on their side. The Sims speculum was first placed against the posterior vaginal wall to look for anterior prolapse and then on the anterior vaginal wall to look for vault and posterior vaginal wall prolapse. Occasionally, the patients were examined erect, but that was certainly not the norm.

Evaluation of pretreatment transvaginal ultrasonography in the management of patients with endometrial carcinoma

Charles F. Shipley III, MD, Sidney T. Smith, MD, Edward J. Dennis III, MD, and George H. Nelson, PhD, MD

Columbia, South Carolina

OBJECTIVE: The objective of this study was to evaluate the usefulness of pretreatment assessment with ultrasonography in patients with endometrial carcinoma.

STUDY DESIGN: Fifty patients with endometrial carcinoma diagnosed by endometrial biopsy or curettage were studied before hysterectomy, bilateral salpingo-oophorectomy, and selected lymph node sampling. Ultrasonographic criteria for determination of tumor grade, depth of myometrial invasion, uterine volume, and tumor volume were established. Tumor grade was compared with preoperative and postoperative pathologic diagnoses, depth of invasion was compared with postoperative pathologic evaluation, and uterine volume and tumor volume were compared with postoperative evaluation of tumor grade and depth of invasion. Data were analyzed by χ^2 testing, and, where appropriate, sensitivity, specificity, and accuracy of the ultrasonographic measurements were determined.

RESULTS: The following statistically significant correlations ($p \leq 0.05$) were found. Ultrasonography predicted tumor grade as accurately as preoperative pathologic evaluation did. Depth of invasion ≤50% or >50% significantly correlated. Uterine volume ≤200 ml predicted ≤50% depth of invasion 28 of 32 times. Uterine volume >500 ml was noted in six cases; five of these had grade 2 or 3 tumor and four had depth of invasion >50%. Tumor volume ≤20 ml predicted a grade 1 tumor in 25 of 39 cases and depth of invasion ≤50% in 34 of 39 cases Tumor volume >20 ml correlated with a grade 2 or 3 tumor in 11 of 11 cases and a depth of invasion >50% in seven of 11 cases. In 25 grade 1 tumors diagnosed postoperatively by pathologic study, none was associated with a tumor volume >20 ml.

CONCLUSION: Pretreatment ultrasonographic measurements should be of value in the management of patients with endometrial carcinoma. (Am J Obstet Gynecol 1992;167:406-12.)

Key words: Pretreatment, transvaginal ultrasonography, endometrial carcinoma

Endometrial carcinoma is the most common malignancy of the female reproductive tract. Appropriate initial management is determined by correct preoperative clinical staging; however, the preoperative clinical staging is often incorrect when compared with intraoperative and postoperative pathologic findings.[1-3] We hypothesize that ultrasonographic knowledge of tumor differentiation, depth of myometrial invasion, uterine size, and tumor volume may be useful in making appropriate preoperative planning. The need for more sophisticated evaluation of potential distant metastasis or nodal disease with computerized tomographic (CT) scanning[4, 5] or magnetic resonance imaging (MRI)[6] could be identified. This knowledge might influence clinical management. The use of preoperative radiation[7] or more or less invasive surgical procedures might be indicated.

The evaluation of pretreatment transvaginal ultrasonography and its potential usefulness in the management of patients with endometrial carcinoma is presented.

Material and methods

Fifty-six patients with a diagnosis of endometrial carcinoma by endometrial biopsy or curettage were referred to the ultrasonography unit. Six patients were excluded from the study. Two patients evaluated by ultrasonography were thought to have endometrial hyperplasia (confirmed by a repeat curettage), two patients received radiation therapy, one patient refused surgery, and one patient died before surgery.

After ultrasonographic evaluation all patients had a total abdominal hysterectomy with bilateral salpingo-oophorectomy with selected pelvic or periaortic lymph node sampling.

All ultrasonographic examinations were performed by the same investigator (CFS) with an ATL Ultramark IV with a 5 and 7.5 MHz transvaginal transducer without knowledge of the tumor description on the pre-

operative pathology reports. All patients had the following evaluations.

Tumor grade was determined at ultrasonography with the following criteria: grade 1, hypoechoic appearance (relative to myometrium) with a complex mottled, cribriform pattern throughout the tumor; grade 2, hypoechoic appearance with a more homogeneously solid pattern; and grade 3, relatively isoechoic or hyperechoic appearance and a homogeneously solid tumor.

Tumor grade was determined in the preoperative and postoperative pathologic specimens by the Department of Pathology with the recommendations of the International Federation of Gynecologists and Obstetricians.

Depth of myometrial invasion was determined by measuring the distance from the endometrial cavity luminal interface with the myometrium to the most distal depths of tumor, dividing this distance by the total thickness of the myometrial wall involved and multiplying by 100.[8, 9] This is shown in Fig. 1.

Uterine measurements consisted of longitudinal length from the internal os to the outer serosal edge of the fundus in the sagittal plane. An anteroposterior diameter was obtained in the same sagittal view of the greatest diameter of the fundus 90 degrees to the longitudinal axis. The uterine transverse diameter was obtained at the largest diameter in the fundus in the transverse plane. These are illustrated in Fig. 1.

Uterine volume was calculated as a parallelogram by multiplying longitudinal length × anteroposterior diameter × transverse diameter, which is expressed in milliliters. Although this does not represent a true uterine volume because the uterine shape was not taken into account, the measurement of this volume (parallelogram) is approximately 1.6 times the volume of its enclosed uterus.[10]

Tumor measurements consisted of (1) a circumscribed area (square centimeters) of the tumor as viewed in its greatest dimension longitudinally and in a sagittal plane and (2) the transverse measurement of the tumor at its greatest distance in a transverse plane. These are also demonstrated in Fig. 1. Tumor volume was calculated by multiplying the circumscribed area (square centimeters) by the greatest distance in a transverse plane in centimeters; it is expressed in milliliters.

Table IA. Comparison of tumor grade: Ultrasonographic versus preoperative pathologic diagnosis

Ultrasonographic diagnosis	*Preoperative diagnosis*			χ^2	*p Value*
	Grade 1	*Grade 2*	*Grade 3*		
Grade 1	21	4	1		
Grade 2	1	9	2	43.2	<0.001
Grade 3	1	2	9		

Table IB. Comparison of tumor grade: Ultrasonographic versus postoperative pathologic diagnosis

Ultrasonographic diagnosis	*Postoperative diagnosis*			χ^2	*p Value*
	Grade 1	*Grade 2*	*Grade 3*		
Grade 1	24	2	0		
Grade 2	1	9	2	63.7	<0.001
Grade 3	0	1	11		

Table IC. Comparison of tumor grade: Preoperative versus postoperative pathologic diagnosis

Preoperative diagnosis	*Postoperative diagnosis*			χ^2	*p Value*
	Grade 1	*Grade 2*	*Grade 3*		
Grade 1	21	1	1		
Grade 2	3	10	2	51.3	<0.001
Grade 3	1	1	10		

Again, this volume does not represent the true tumor volume but is thought to be consistently related to tumor volume. The true volume can only be calculated when the exact, three-dimensional shape of the tumor is taken into account.

Statistical significance was calculated with the χ^2 test. When appropriate, sensitivity, specificity, and accuracy were determined with the following formulas: Sensitivity = True positive ÷ (True positive + False negative); Specificity = True negative ÷ (True negative + False positive); Accuracy = (True positive + True negative) ÷ (True positive + True negative + False positive + False negative).

Results

The age (mean ± 1 SD) of the study population was 63 ± 14 years with a range of 26 to 83 years. The body weight (mean ± 1 SD) was 185 ± 55 pounds with a range of 108 to 310 pounds. Nineteen (38%) of the patients weighed >200 pounds. The mean time between curettage or endometrial biopsy and ultrasonographic evaluation was 31 ± 16 days with a range of 6 to 71 days. The mean time between ultrasonographic evaluation and hysterectomy was 23 ± 22 days with a range of 1 to 150 days.

After hysterectomy, a diagnosis of endometrial carcinoma was confirmed in 44 patients. Six patients had malignant müllerian mixed tumors, all of which were poorly differentiated (grade 3). The grading of müllerian mixed tumors was based on their most malignant component.

Comparisons of tumor grade by ultrasonography and the preoperative and postoperative pathologic evaluations are presented in Tables IA, IB, and IC. As can be seen, there is good correlation between each pair of grading methods.

Table II compares the depth of invasion as determined by ultrasonography with the postoperative pathologic evaluation. Again, a significant correlation is found between these two measurements.

The relationship between uterine volume and tumor grade is shown in Table III. We examined three critical measurements of uterine volume, i.e., ≤100 or >100, ≤200 or >200, ≤500 or >500 ml. The only statistically significant correlation was found at critical uterine volume of 500 ml.

Table IV depicts the relationship between measurements of uterine volume and depth of invasion. There is a statistically significant correlation between these two measurements at the critical uterine volumes of 200 and 500 ml.

It can be seen in Tables V and VI that tumor volume is statistically significantly related to both tumor grade and depth of invasion. Three critical levels of tumor

volume were evaluated, i.e., ≤10 or >10, ≤20 or >20, ≤50 or >50 ml. Statistical significance was found at all three critical levels.

Comment

We have attempted to determine the practical usefulness of pretreatment measurements of tumor grade, depth of invasion, uterine volume, and tumor volume by ultrasonography.

Without ultrasonography (or some other imaging technique), the only information available to the gynecologic surgeon is uterine size by physical examination and tumor grade by endometrial biopsy or curettage. Because many of these patients are obese, viewing the uterus with ultrasonography should improve the estimation of uterine size. In addition, evaluation of depth of invasion and tumor volume are not available by standard procedures. Tumor extension into the cervix and extension beyond the uterus, although not presented here, have been described by other investigators.[11]

Comparing the accuracy of preoperative pathologic evaluation with ultrasonography in predicting the postoperative pathologic tumor grade, the postoperative pathologic evaluation showed grade 1, 2, or 3 tumors in 25, 12, and 13 patients, respectively. The preoperative pathologic evaluation correctly predicted grade 1, 2, and 3 tumors in 84%, 83%, and 77% of patients, respectively. The overall accuracy was 82%. Grading by ultrasonography was correct in 96%, 75%, and 85% of the patients, respectively. Overall accuracy was 88%. Another way of evaluating these data (probably a more useful way clinically) is to determine the accuracy of the predictions. The preoperative pathology report showed 23 grade 1, 15 grade 2, and 12 grade 3 tumors. The preoperative reports were correct 91%, 67%, and 83% of the time. Overall predictive accuracy was 82%. At prospective ultrasonographic evaluation, there were 26 grade 1, 12 grade 2, and 12 grade 3 tumors, respectively. The evaluations were correct 92%, 75%, and 92% of the time. Overall accuracy was 88%. It would appear that tumor grading by ultrasonography is at

Table V. Relationship between tumor volume and postoperative pathologic tumor grade

Tumor volume (ml)	*Tumor grade*			χ^2	*p Value*

>10	6	7	10		
≤20	25	8	6	9.6	<0.01
>20	0	4	7		
≤50	25	10	9	8.0	<0.05
>50	0	2	4		

Table VI. Relationship between tumor volume and postoperative pathologic depth of invasion

Tumor volume (ml)	*Depth of invasion*		χ^2	*p Value*	*Sensitivity*	*Specificity*	*Accuracy*
	≤50%	*>50%*					
≤10	25	2	8.9	<0.01	83%	66%	70%
>10	13	10					
≤20	34	5	14.2	<0.001	58%	89%	82%
>20	4	7					
≤50	36	8	6.8	<0.01	33%	95%	80%
>50	2	4					

least as accurate as grading by preoperative endometrial biopsy or curettage.

Knowledge of depth of invasion of the tumor into the myometrial wall is additional information available by ultrasonography not available by biopsy or curettage. When ultrasonography evaluation predicted depth of invasion ≤50% or >50%, the predictions were correct 88% and 70% of the time, respectively. This accuracy is comparable with more sophisticated imaging techniques.[11, 12]

With regard to the measurement of uterine volume, it would appear that knowledge of small (≤200 ml) or large (>500 ml) uterine volumes may be useful as predictive values. A uterine volume ≤200 ml predicted ≤50% depth of invasion 88% of the time. A uterine volume >500 ml predicted a grade 2 or 3 tumor and >50% depth of invasion 83% and 67% of the time, respectively. Although knowledge of large uterine volume (>500 ml) would appear to provide the more useful information, these volumes were found in only 12% of study patients.

Tumor volume ≤20 or >20 ml may be of predictive value. Tumor volumes ≤20 ml correctly predicted a grade 1 tumor and ≤50% depth of invasion 64% and 87% of the time, respectively. A tumor volume >20 ml predicted a grade 2 or 3 tumor and >50% depth of invasion 100% and 64% of the time, respectively. In none of 25 cases was a grade 1 tumor associated with a tumor volume >20 ml.

We conclude that these data support the hypothesis that pretreatment ultrasonographic measurements may provide useful information before surgery. The gynecologic oncologist might decide that further studies, such as MRI, are indicated or may modify the treatment plan to include radiation therapy or a more or less extensive surgical procedure.

Discussion

DR. MARK A. CROZIER, Greenville, South Carolina. No aspect of gynecologic oncology is more confusing and yet more relevant to obstetricians and gynecologists than the management of endometrial carcinoma. There is considerable variation in the type of surgery recommended; which, if any, adjuvant treatment is needed; and the timing of the adjuvant therapy. An attempt to clarify this confusion is not the purpose of this paper. What is well established is that there are patients with well differentiated cancers and superficial myometrial invasion who have a very low incidence of retroperitoneal nodal metastasis and survival rates around 90% that can be adequately treated with total abdominal hysterectomy and bilateral salpingo-oophorectomy without extended surgical staging or adjuvant irradiation. Patients with poorly differentiated or deeply invasive tumors have a higher incidence of nodal metastasis and poorer survival rates and probably should have adjuvant therapy or extended surgical staging.

Most patients with endometrial cancer are initially seen by or referred to an obstetrician or gynecologist. Few will be directly seen by a gynecologic oncologist. Most obstetricians and gynecologists in general practice are not comfortable performing the extended surgical staging currently recommended for endometrial carcinomas. However, a significant percentage of endometrial cancers are well-differentiated, superficial cancers that can be adequately treated with total abdominal hysterectomy and bilateral salpingo-oophorectomy without extended surgical staging or adjuvant therapy. Referral to a gynecologic oncologist results in additional expense, perhaps referral out of the patient's home community, and loss of continuity of care with the primary physician. In addition, many of these patients are elderly, obese, or have medical problems and can ill afford extended surgery or adjuvant irradiation therapy that will not benefit them. Several studies have established the relative inaccuracy of clinical staging, i.e., physical examination and curettage. This is one of the reasons that International Federation of Gynecologists and Obstetricians has adopted a surgical pathologic method of staging endometrial carcinomas. An accurate preoperative method of assessing prognostic factors such as grade and depth of myometrial invasion would allow the patients with well-differentiated superficial cancers to be treated by total abdominal hysterectomy and bilateral salpingo-oophorectomy without referral, while those with poorly differentiated or deeply invasive cancers could be referred for extended surgical staging or adjuvant therapy. This study has attempted to determine the ability of preoperative vaginal probe ultrasonography to predict two well-known prognostic factors in endometrial carcinoma, that is, final pathologic grade and depth of myometrial invasion. It has also introduced two ultrasonographic parameters that seem to correlate with grade and depth of invasion, that is, uterine volume and tumor volume.

Pretreatment vaginal probe ultrasonography predicted postoperative pathologic grade in 24 of 26 grade 1 tumors, nine of 12 grade 2, and 11 of 12 grade 3 tumors. All of these were statistically significant correlations. Preoperative vaginal probe ultrasonography predicted postoperative depth of invasion for 35 of 40 $\leq$50% and seven of 10 >50% invasion. Both of these achieved statistical significance. Tumor volume showed statistical correlation with both grade and depth of invasion. Of note was that no grade 1 cancer had a tumor volume >20 ml and that 11 of 11 tumors >20ml were grade 2 or 3. The numbers are small, but vaginal probe ultrasonography appears to predict, with a high degree of accuracy, both grade and depth of invasion. Combining this with the parameters of uterine volume and tumor volume, we may be able to accurately predict preoperatively significant pathologic prognostic factors and provide more effective and less morbid treatment.

I would like to close by asking several questions. First, have there been comparisons between vaginal probe ultrasonography, CT scan, and MRI in predicting grade and depth of invasion? Second, is there any reason to order an MRI if a vaginal probe ultrasonographic examination is done? Third, have tumor volume and uterine volume been looked at as independent prognostic factors in endometrial cancer? Finally, does uterine volume add anything that tumor volume won't tell you?

DR. CHARLES F. SHIPLEY III (Closing). Dr. Crozier has certainly identified several applications of ultrasonography in its use in patients with endometrial carcinoma. I would first like to address his questions individually. "Have there been comparisons between vaginal probe ultrasonography, CT scan, and MRI in predicting grade and depth of invasion?" I know of no study where all three techniques were performed on the same patient sample with direct comparisons made of the predictive accuracy of the methods. However, there are certainly several studies that have analyzed individual techniques for predicting grade and depth of invasion. Although I have not analyzed or compared them statistically, they certainly do not appear to be very similar in their predictions.

The second question was, "Is there any reason to order an MRI if vaginal probe ultrasonography is done?" If the history, physical examination, pathology reports, and ultrasonographic data collectively suggest a very good possibility of nodal disease or distant disease, then I certainly think CT and MRI may be helpful

and appropriate to evaluate the process. The corollary is also true; if the data strongly suggest that the tumor is limited to the uterus, then I suspect that CT and MRI would not be necessary.

Third, "Have tumor volume and uterine volume been studied as independent prognostic factors in endometrial carcinoma?" To my knowledge, tumor volume has not previously been evaluated as a prognostic factor in endometrial carcinoma transvaginally. Uterine size classically has been evaluated by measuring the depth of the uterine cavity in the past. I strongly suspect that this was a very crude attempt to define tumor volume as opposed to actual uterine size. I know of no study in which the evaluation of uterine size by measuring its volume has been adequately evaluated.

Finally, "Does uterine volume add anything to tumor volume that tumor volume won't tell you?" First let me say that the determination of uterine volume, as you can see from the presentation, is a very easy measurement to make and not extremely time consuming. It seems to me that the best way to use this measurement would be when the uterus is either very small or very large. Small uteri were associated with very, if you will, low risk or less aggressive disease and large uteri are associated with more severe disease. It simply contributes additional information when trying to differentiate between mild and severe disease. It also is very difficult in very large uteri to evaluate the endometrial cavity because of changes in the distance to the endometrial cavity where the resolution is not quite as good; therefore it may be helpful. It is my belief that the measurement of tumor volume will eventually be shown to be a more useful measurement; however, I see no reason to discontinue making the measurement at this time.

The treatment of pelvic soft tissue radiation necrosis with hyperbaric oxygen

James A. Williams, Jr., MD,[a] Dick Clarke,[b] William A. Dennis, MD,[a] Edward J. Dennis III, MD,[a] and S.T. Smith, MD[a]

Columbia, South Carolina

OBJECTIVE: The purpose of this study was to examine the therapeutic effects of hyperbaric oxygen on radiation-induced soft tissue necrosis in patients who previously received treatment for a gynecologic malignancy.

STUDY DESIGN: Fourteen patients whose necrotic wounds failed to heal after 3 months of conservative therapy were enrolled in a prospective observational study. Outcome of hyperbaric oxygen treatment was measured by resolution of necrosis.

RESULTS: Fourteen patients underwent 15 courses of hyperbaric oxygen treatments. All those with radiation necrosis of the vagina alone or in association with rectovaginal fistula had complete resolution of necrosis with hyperbaric oxygen. Only one treatment failure occurred.

CONCLUSION: Hyperbaric oxygen is a safe, effective, and well-tolerated treatment for radiation-induced soft tissue necrosis. (Am J Obstet Gynecol 1992;167:412-6.)

Key words: Soft tissue radiation necrosis, vaginal necrosis, rectovaginal fistula, hyperbaric oxygen

The efficacy of radiation therapy in the management of malignant disease is well established. Adequate tumoricidal doses may result in adverse effects on surrounding healthy tissue. The pathophysiologic characteristic of radiation tissue damage is one of a progressive obliterative endarteritis, leading to a hypovascular, hypoxic, and hypocellular tissue bed.[1]

Subsequent tissue breakdown may occur spontaneously, particularly when the total radiation dose is high or as a result of direct trauma. The greatly increased demand for oxygen and other cellular metabolites associated with tissue healing will exceed available supply in this setting, leading to a chronic, nonresolving wound. Although the sensitivity to radiation damage varies from tissue to tissue, therapeutic radiation-induced necrosis has been reported in a wide variety of anatomic sites. Hyperbaric oxygen therapy has recently been demonstrated to overcome the effects of late radiation-induced changes by a potent angiogenic effect. Intermittent exposure to elevated oxygen doses at 2.0 to 2.5 atmospheres absolute pressure will effectively manage tissue hypoxia and reestablish the oxygen gradient necessary to induce wound healing responses.[2] The majority of clinical experience has centered on the treatment of osteoradionecrosis of the mandible with limited experience involving soft tissue, bladder, myelin, and gastrointestinal tract.[3,4] This article documents the successful use of hyperbaric oxygen therapy in the management of radiation damage to the cervix and vaginal vault.

Material and methods

Patients referred from the Division of Gynecologic Oncology at the University of South Carolina School of Medicine to the Department of Hyperbaric Medicine at Richland Memorial Hospital for treatment of radiation-induced soft tissue necrosis were studied. Patients were examined by senior faculty, and aggressive attempts were made to rule out recurrent or metastatic disease with routine radiographic procedures and biopsy of necrotic wounds.

Patients accepted for hyperbaric oxygen therapy were free of active malignancy for at least 6 weeks before beginning treatment. Patients also had failure of healing after 3 months of conservative therapy. This therapy included hydrogen peroxide or antiseptic irrigation, topical conjugated estrogen, nutritional supplementation, and surgical debridement where indicated.

On referral all patients were examined by a hyperbaric medicine consultant. A thorough history was obtained and physical examination was performed to ensure that no medical contraindications to hyperbaric oxygen therapy were present. A course of therapy was then outlined to include number of treatments, total duration of each treatment, and number of treatments per day.

A Sechrist Monoplace (Sechrist Industries, Anaheim, Calif.) hyperbaric chamber was used for all patients. Compression to 2.0 atmospheres absolute pressure was undertaken while the patient breathed 100% oxygen. Patients were carefully monitored during each treatment session by registered nurses under the supervision of the Director of Hyperbaric Medicine.

Patients were examined by the Gynecologic Oncology faculty at the end of the recommended course of therapy, and results of treatment were documented.

Results

From 1986 to 1991, 18 patients with radiation-induced soft tissue necrosis were referred by Division of Gynecologic Oncology for hyperbaric oxygen therapy. Four patients did not complete therapy. Therapy was discontinued in three with histologic evidence of recurrent disease. A fourth patient refused to continue therapy because of severe anxiety associated with confinement in the hyperbaric chamber. Fourteen patients completed 15 courses of the recommended number of treatments. The mean age of the patients was 53 years, with a range from 35 to 78 years. The primary site of cancer was cervix (nine patients), endometrium (one patient), vagina (three patients), and colon (one patient). All patients had received external beam radiation with a mean dose of 4830 Gy. In addition, 53% of patients received intracavitary radiation.

Eleven patients received hyperbaric oxygen therapy for soft tissue radionecrosis of the vaginal vault alone. Two patients were treated for vaginal necrosis with an associated rectovaginal fistula. One of these patients had previously been successfully treated with hyperbaric oxygen therapy for soft tissue radionecrosis of the vagina 4 years before development of recurrent necrosis of the vagina with rectovaginal fistula formation. One patient was treated for necrosis of the abdominal wall in the area of external beam radiation therapy. Another patient developed massive necrosis of the abdominal wall, sacrum, and vagina with development of large vesicovaginal and rectovaginal fistulas.

Hyperbaric oxygen therapy was given at 2.0 atmospheres absolute pressure one to two times per day for 90 to 120 minutes each. The average number of treatments was 44 with a range of 18 to 143. Compression was well tolerated in all patients. The only complication was seen in one patient who suffered a ruptured tympanum, which healed spontaneously without sequelae. No patient required interruption of therapy due to a complication of compression.

Each of the 11 patients with soft tissue radionecrosis of the vagina alone showed marked improvement or complete resolution of necrosis at the completion of therapy. Complete resolution was seen in all patients within 8 weeks of hyperbaric oxygen therapy. One of these patients developed recurrent squamous cell carcinoma of the cervix in the bladder base. She underwent anterior exenteration one year after hyperbaric oxygen therapy. The vaginal cuff healed well, and there is no evidence of necrosis 9 months after surgery. Both

patients with rectovaginal fistulas underwent fecal diversion by loop colostomy followed by hyperbaric oxygen therapy with resolution of necrosis. Rectovaginal fistula repair was performed with subsequent closure of loop colostomy. Three years after surgery there is no evidence of recurrent necrosis or fistula. A patient with necrosis of the panniculus had complete healing after hyperbaric oxygen therapy.

The only treatment failure occurred in one patient who developed massive necrosis of the abdominal wall, sacrum, and vagina with rectovaginal and vesicovaginal fistula formation. She underwent urinary and fecal diversion, repetitive surgical debridement, skin grafting, aggressive wound care, nutritional support, and intensive hyperbaric oxygen therapy totaling 143 treatments. Bacterial overgrowth complicated wound healing and the necrosis progressed, eventually leading to her death.

Comment

The goal of radiation therapy is to deliver tumoricidal doses with minimum possible adverse effects on adjacent healthy tissue. In recent years a better understanding of radiobiologic principles has served to reduce the degree of iatrogenic damage through the establishment of upper radiation limits, fractionated exposure protocols, and the development of high-energy radiation delivery systems.

In spite of these improvements, localized radiation-induced tissue breakdown continues to present a clinical challenge. The most common form of this disease is osteoradionecrosis of the mandible, although it has been reported in a wide variety of other bony and soft tissue sites.[3-5] The pathophysiologic features of localized radiation tissue injury have recently been redefined.[1] The long accepted and empirically derived sequence of radiation, trauma, and infection has been replaced by a description that more accurately describes the biochemical and cellular pathology. Histologic analysis of tissue biopsies from 58 patients revealed the postradiation, iatrogenic process as one of a progressive, obliterative endarteritis. This process results in a decrease in blood flow, leading to a hypovascular, hypoxic, and hypocellular tissue bed.

Another misunderstanding of the pathologic process of radiation tissue injury has been that revascularization would gradually occur with time. Therefore it was thought that any surgical procedures contemplated in this area should be delayed as long as possible. Marx[6] has demonstrated that as time passes there is less vascularity, less tissue perfusion, and more fibrosis and greater risk for a nonhealing surgical site.

The treatment of local tissue breakdown as a secondary effect of radiation therapy is a frustrating medical and surgical dilemma. Hypovascularity predisposes to tissue breakdown, either spontaneously or after direct trauma. Radiation-induced ulcerations are painful, and adequate control of pain without addicting medications is often impossible. Surgical incision of the obvious lesion may lead to the development of a larger nonhealing wound because adjacent tissue is also compromised. Attempts to cover external wounds with skin grafts or flaps typically requires repeated procedures and, in many cases, still proves unsuccessful.

About 10% of all patients treated with radiation to the pelvis for a gynecologic malignancy will develop a superficial vaginal vault necrosis that may become a progressive problem predisposing to fistula formation. Traditional therapy of vaginal vault necrosis consists of hydrogen peroxide douches, sodium hypochlorite douches, and estrogen cream.[7-9] If fistulas develop, fecal or urinary diversion is required. Fistula repair, when attempted, is complicated by the hypovascularity and tissue hypoxia present in the irradiated vagina.

During the 1970s hyperbaric oxygen therapy was introduced for the management of radiation-induced tissue damage.[10, 11] The subacute and chronic phases of the radiation wound are particularly suited to this form of therapy. Hyperbaric oxygen acts to stimulate collagen formation at the wound edges through elevation of local tissue oxygen tensions.[2] New microvasculature dependent on a collagen matrix for physical support is greatly enhanced in this setting and allows reepithelialization to occur. A 20 to 30 day course of hyperbaric oxygen will provide a rich capillary bed in surrounding radiation-damaged tissue that, although hypoperfused and hypoxic, is still viable. This angiogenic effect is clearly dependent on the administration of oxygen under hyperbaric conditions. A recent comparative study failed to demonstrate such revascularization when oxygen was administered under normobaric conditions, in contrast to the effect when oxygen was administered under hyperbaric conditions.[12]

In 1977 Glassburn and Brady[13] reported on 27 patients who received hyperbaric oxygen therapy for necrotic wounds. Twelve patients were treated for necrosis of the vagina or perineum. All eight of the patients who completed therapy showed marked improvement or complete healing of their wounds. The only complication was rupture of a tympanic membrane.

Hyperbaric oxygen therapy for radiation-induced vaginal vault necrosis is safe and well tolerated by most patients. We believe hyperbaric oxygen therapy to be an effective method for promoting healing in areas of radiation necrosis. The effects of this healing improves patient comfort and may also prevent the more serious problem of fistula formation. In those patients with rectovaginal fistula, hyperbaric oxygen therapy after fecal diversion may decrease the morbidity and increase the success of fistula repair.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

Dr. W. Allen Addison, Durham, North Carolina. Regional necrosis induced by radiation directed toward the cure of cancer is a difficult and frustrating problem. Frequently the necessary concern about the possibility of uneradicated malignancy leads to the repeated trauma of biopsies in tissue already so compromised as to defy healing. Such biopsies, and possibly local measures meant to cleanse and debride, may well serve to aggravate necrosis in these fragile and sorely devitalized tissues.

I suspect that all services that treat gynecologic malignancy by radiation, and which have access to hyperbaric oxygen therapy, have put patients like those who constitute the subject of this report into the hyperbaric chamber. Our own experience with such patients has been mixed and includes both apparent dramatic successes and clearly dismal failures.

A Medline search done for the purpose of this discussion revealed that there are no published reports in the gynecologic literature about the use of hyperbaric oxygen in the treatment of radiation-induced necrosis. That fact alone certainly enhances the importance of this report.

Now one might be stringent and point out that in this report radiation-induced soft tissue necrosis is not clearly defined and that no measurements of the areas or volume of necrosis are given. Additionally, one might inquire of the authors precisely what determined the number of hyperbaric oxygen treatments that were given to each patient and why the evolving bacteriology of these necrotic ulcers was not followed during therapy. Or, one might be pragmatic and accept the fact that such a study as this cannot be fairly subjected to the sort of scientific exactitude demanded by maternal-fetal medicine.

It took the authors 5 years to find 14 evaluable patients. These patients had not responded to traditional and less expensive treatment than hyperbaric oxygen, and they were desperate. Their prospects included progressive disability, addiction, and death. In this setting, there are no options for the randomization and controls that would be demanded by a reproductive endocrinologist. The only real option was to pull out all stops, treat these desperate patients as intensively as possible, and observe the results as carefully as possible. This, I believe, is what was done. I for one continue to have faith in the careful observations of seasoned clinicians.

I have checked with experts on the subject at the institution where I work and have been assured that technically the hyperbaric oxygen therapy was administered appropriately. I have also been assured by them that a therapy as expensive as hyperbaric oxygen is not likely to be invoked if there are acceptable alternatives.

My only questions to Dr. Williams are the following: (1) What did determine the number of hyperbaric oxygen treatments a patient received? I assume it was healing of clinically detectable necrosis, but this is not stated in the manuscript. (2) What was the cost of this therapy? and (3) Would earlier institution of hyperbaric oxygen therapy in such patients as those presented arrest the process sooner and result in shorter necessary treatment and less ultimate expense? If so, could patients be identified who should be started on hyperbaric oxygen at the earliest signs of radiation-induced necrosis, such as those with preexisting microvascular disease?

Dr. Williams (Closing). The number of hyperbaric oxygen treatments received by each patient was determined by the hyperbaric medicine consultant. At the beginning of this project there were a larger number of treatments per person than there were toward the end. In 1988 Marks[1] working with Johnson, both dentists skilled in treating carcinomas of the mouth, reported on the measurement of transcapillary oxygen tension in irradiated tissues of the jaw. They described an S-shaped curve of oxygen tensions with three distinct phases. The first, or lag phase, identifies no measurable angiogenesis. This is a phase of collagen synthesis and capillary budding. Oxygen tensions remain approximately 30% that of nonirradiated tissue until the eighth exposure to hyperbaric oxygen. In the sec-

ond, or rapid-rise phase, oxygen tensions increase geometrically to a maximum of 82% to 85% between the eighteenth and twenty-third exposures. During this phase visible sign of angiogenesis are present. In the third or plateau phase the transcapillary oxygen tension values of the irradiated tissues are 80% to 85% of those of nonirradiated tissue. Oxygen tension never reaches the same value as in nonirradiated tissue. These levels do remain stable over several years. On the basis of these data, our current protocol calls for 20 hyperbaric oxygen treatments. At the end of this period the patient is reevaluated and may be referred for 10 to 20 more treatments if there is a good response but one that is felt to be inadequate. This may be particularly important in patients who have larger lesions.

A little bit more about the costs—The average total treatment cost is about $8000. No cost-benefit analysis has been done for the treatment of this particular condition, but extensive work has been done on osteoradionecrosis of the mandible.[2] It has been estimated that conventional therapy for osteoradionecrosis of the mandible costs about $69,000, with a cure rate of around 8%. The treatment of osteoradionecrosis of the mandible with a 100% cure rate costs about $30,000. The prevention of osteoradionecrosis with hyperbaric oxygen in those patients who may undergo surgery in this area is about 95% successful and costs $8000. So we see a significant cost savings in that particular area.

As far as identifying patients who may be at particular risk, our patient population had diseases that may have reflected some microvascular problem. There were a fair number of diabetics and hypertensives. Although we have a much larger number of patients with hypertension and diabetes who don't have development of radiation necrosis, of course, it would be very difficult to predict those patients.

Earlier treatment would be nice, but unfortunately our patients are first seen with this necrosis the same way that they are first seen with their cancers. Usually it is in an advanced stage and we are unable to catch it very early.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

The incidence of cerebral palsy

Mortimer G. Rosen, MD, and Janet C. Dickinson, BSN, MSW
New York, New York

The clinician is often held responsible for obstetric events that are suspected of being related to cerebral palsy. To review the incidence of cerebral palsy and to aid the clinician in this situation, a search of published studies was conducted. Composite rates of cerebral palsy in different birth weight infants and cerebral palsy with and without serious mental retardation were calculated. The cumulative incidence rate at the age of 5 to 7 years was 2.7 cases of cerebral palsy for 1000 birth cohorts. Approximately 36% of all cerebral palsy occurred in the infant <2500 gm. Serious mental retardation (intelligence quotient <50) accompanied cerebral palsy approximately 30% of the time for the term infant and 18% of the time when the infant was <2500 gm. On the basis of a past estimation that 70% of cerebral palsy is of antepartum or unknown origin, the term infant at risk for intrapartum-attributed cerebral palsy may be about 1 in 2000 term births. (AM J OBSTET GYNECOL 1992;167:417-23.)

Key words: Cerebral palsy, incidence, mental retardation

Cerebral palsy continues to pose a diagnostic and therapeutic dilemma for the obstetrician because its various causes are poorly understood. Electronic fetal monitoring, initiated in the early 1960s, raised hopes that some cases of cerebral palsy could be prevented through a better means of evaluation of the fetus during labor. Today, studies continue to find a lack of association between intrapartum fetal monitoring and long-term neurologic outcome.[1] Confounding the incidence issue is the fact that obstetric practices and neonatal intensive care have changed. With increased infant survival, increased neurologic morbidity may occur more frequently, offsetting the overall effects of clinical practice changes.[2]

This review attempted to evaluate current morbidity data with respect to the rates of cerebral palsy. Past studies have generally found a prevalence rate of about 2 per 1000 living infants at 7 to 10 years of age, with serious mental retardation (intelligence quotient [IQ] <50) present in 20% to 30% of these children.[3] The largest United States study, the Collaborative Perinatal Project, found a cerebral palsy cumulative incidence rate (which includes children with cerebral palsy who died) of 4.6 per 1000 of infants at 7 years of age.[4] The question raised in this review was whether the cumulative incidence of cerebral palsy has changed during the past 10 years, specifically the cumulative incidence in the term infant.

Methods

A Medline search was conducted of all original English language studies published since 1980, with major infant neurologic damage as an end point. Unfortunately, although these studies were published since 1980, the birth dates of the populations often went back to the 1950s. Few recent studies of the combination of mental retardation and cerebral palsy were found; therefore studies conducted before 1980 were included when that aspect is discussed.

Where possible, in some of the tables the birth dates were indicated rather than the publication dates of the studies, so that the reader could consider the possible differences in neonatal care in the different time periods. To be included in analyses, studies had to provide adequate raw numbers to determine the denominator for the rates of cerebral palsy either in the total population or by birth weight. Cumulative incidence at the age of 4 to 7 years was used because it provides more information than either a straight incidence or prevalence rate. The cumulative incidence rate used all births during a set period of time as the denominator, and numerator included infants with cerebral palsy who had died. Including infants who had died has been recommended to provide as complete a picture of cerebral palsy as possible.[5] Prevalence rate was not used,

§Did not indicate whether deaths were included.

because it can vary tremendously depending on the age of diagnosis and the length of time of survival. In the Collaborative Perinatal Project 15% of the children diagnosed with cerebral palsy at 12 months had died by the age of 7 years.[6, 7]

Studies with follow-up at different ages, between 4 and 7 years, were qualified by stating the different ages. Cases of cerebral palsy that were obviously caused postnatally were excluded. Studies usually did not differentiate cerebral palsy by degree of handicap, so a study's diagnosis of cerebral palsy was accepted. Figures from the Collaborative Perinatal Project were included to provide comparisons and because that study constituted a large and essentially singular United States cerebral palsy incidence study. The figures from the Collaborative Perinatal Project included both infants who had a diagnosis of cerebral palsy who had died and cases of cerebral palsy that they defined as mild (not requiring bracing, wheelchair, etc.)[8] because we decided that their "mild" category would be included in all cases of cerebral palsy in other studies. We primarily used later published reports about the Collaborative Perinatal Project because these categories were included. Earlier reports that excluded deaths and "mild" cerebral palsy yielded a 2.5 per 1000 rate.[8]

For types of cerebral palsy, the denominator is all cases of cerebral palsy. When discussing the different types of cerebral palsy, the most frequently used categories of cerebral palsy included diplegia (or paraplegia), a form of cerebral palsy where the legs are primarily affected; hemiplegia, where only one side of the body is affected; and quadriplegia (or tetraplegia), where three or all four limbs are affected. Extrapyramidal (or dyskinetic) cerebral palsy, including choreoathetotic and dystonic and ataxia, was included as much as possible when studies had this as a distinct category.

The analyses of cerebral palsy by birth weight were done with live births at that birth weight as denominators. Because studies used either cerebral palsy or mental retardation as starting points, both types of studies were considered. However, when considering studies using mental retardation as the starting point, the primary focus was that proportion of the mentally retarded who also had cerebral palsy. Mental retardation not associated with cerebral palsy was not reviewed.

Results

Excluding cases that had an obvious postnatal origin, 10 studies published since 1980 determined the cumulative incidence rates for cerebral palsy[2, 4, 9-17] (Table I). The average cumulative incidence rate of these studies was 2.7 per 1000 livebirths.

Table II describes studies that included the breakdown by type of cerebral palsy.[8, 9, 11, 13, 17-19] Years of birth, not publication, are given. Not all the previously discussed studies were included, because not all had breakdown by type of cerebral palsy. The average proportions of the different types of cerebral palsy of all with cerebral palsy were 34% diplegia, 30% hemiplegia, 20% quadriplegia, and 16% extrapyramidal.

Table III includes studies that grouped cerebral palsy by birth weight.[2, 4, 9, 11-17, 20] Years of birth, rather than dates of publication, are indicated for the reasons previously stated. The average proportions of cerebral palsy by birth weight of all children with cerebral palsy were 36% for those weighing <2500 gm and 64% for children weighing >2499 gm.

Some of these studies analyzed cerebral palsy rates by smaller increments of birth weight[6, 11, 13, 14, 16, 17] (Table IV). The increments varied too much to do an exact comparison, but the figures are helpful to determine any trends in the incidence by birth weight.

‡Figure from Dale et al.[19]

Some studies analyzed trends of cumulative incidences of cerebral palsy over periods of time[9-11, 13-17, 19] (Fig. 1). Some studies found recent minor decreases, others found almost no change in rate, and other studies found recent minor increases. When there was a minor increase, the type of cerebral palsy that increased the most was diplegia or cerebral palsy among low-birth-weight (LBW) infants.

A few studies analyzed the occurrence of serious mental retardation among children with cerebral palsy. Table V provides the figures from those studies.[18, 21, 22] The average rate of serious mental retardation (IQ <50) along with cerebral palsy for all birth weights was 25%, 18% for infants weighing <2500 gm, and 30% for those >2499.

A few studies analyzed the occurrence of cerebral palsy among children with serious mental retardation.[23-28] These figures are based on children surviving at the time of the study (prevalence). The composite rate for the studies of all cases of mental retardation with cerebral palsy was 16.8% (Table VI). McLaren and Bryson[29] reviewed studies for the presence of cerebral palsy in the seriously mentally retarded. They encountered difficulties due to differences in methodology and a frequent lack of differentiation between disorders; for example, neurologic, motor, and sensory disorders may have been combined. Four studies were sufficiently specific enough to be analyzed.[23-26] Kiely[30] analyzed two other studies[27, 28] for the occurrence of cerebral palsy in populations with serious mental retardation. Because of methodologic differences used in the studies, this composite rate should be considered as an approximation.

Comment

One task in standardizing studies was to consider when the follow-up was done and when the diagnosis of brain damage was made. Nelson and Ellenberg[6, 7] pointed out the difficulty of comparing studies because of the variation in timings of follow-up. Studies generally grouped all degrees of cerebral palsy together; however; milder cases often were not known until the child entered school and as many as 50% of patients diagnosed at 12 months were free of motor handicap at 7 years of age. A cumulative incidence rate addresses the problem of loss of cases through deaths.

There was a problem with the lack of data on births that occurred in the past 10 years. The only reviewed

studies where births did occur solely in the 1980s were the Meberg study[16] and the Pharoah et al.[17] studies. Some studies, published quite recently, were based on births from as far back as the 1960s or earlier, before the use of neonatal intensive care and before the means were established to prevent erythroblastosis fetalis.

With the advent of neonatal intensive care units in the 1970s, the survival of very-low-birth-weight infants has improved. The average survival rate beyond the neonatal period for the <1500-gm infant in developed countries was 15% to 40% in the early 1970s and 60% to 75% in the mid-1980s.[31] Although there is concern that, with this increased survival, the incidence of cerebral palsy among LBW infants has increased, we found the rate to be fairly stable at about 15 per 1000 LBW births (<2500 gm) since the 1950s (Fig. 1). For the very-low-birth-weight infant (<1500 gm) this rate is higher. Studies found rates of cerebral palsy of 13 to 90 per 1000 for neonatal survivors of 500 to 1500 gm at birth (Table IV). Other studies have had findings of a stable rate of neurologic impairment along with an increased survival rate for very-low-birth-weight babies. A review by Hagberg et al.[32] found that where a country had a higher perinatal mortality rate to begin with and a greater drop in perinatal mortality rate with the advent of improved neonatal care, the rate of cerebral palsy did not increase noticeably. However, when the rate was lower to begin with and neonatal care has been used with increasingly smaller babies, the cerebral palsy rate has increased to a greater extent. The implication is that babies who have needed minimal to moderate improved neonatal care to survive tend to have low morbidity, whereas the much smaller babies who need intensive, long-term care to survive are more likely to have permanent neurologic problems. Hagberg et al.[32] sees a 40 times higher live-birth prevalence of cerebral palsy in the very-low-birth-weight infant than in the normal-birth-weight infant.

One problem we encountered was the cutoff point for LBW babies. Some studies included the 2500 gm infant in the LBW group and others did not. This discrepancy could significantly change the final figure. Another problem was the interchangeable use of the terms LBW and preterm.[22] With these problems, the figures on cerebral palsy by birth weight are a close approximation of cerebral palsy by birth weight. An average

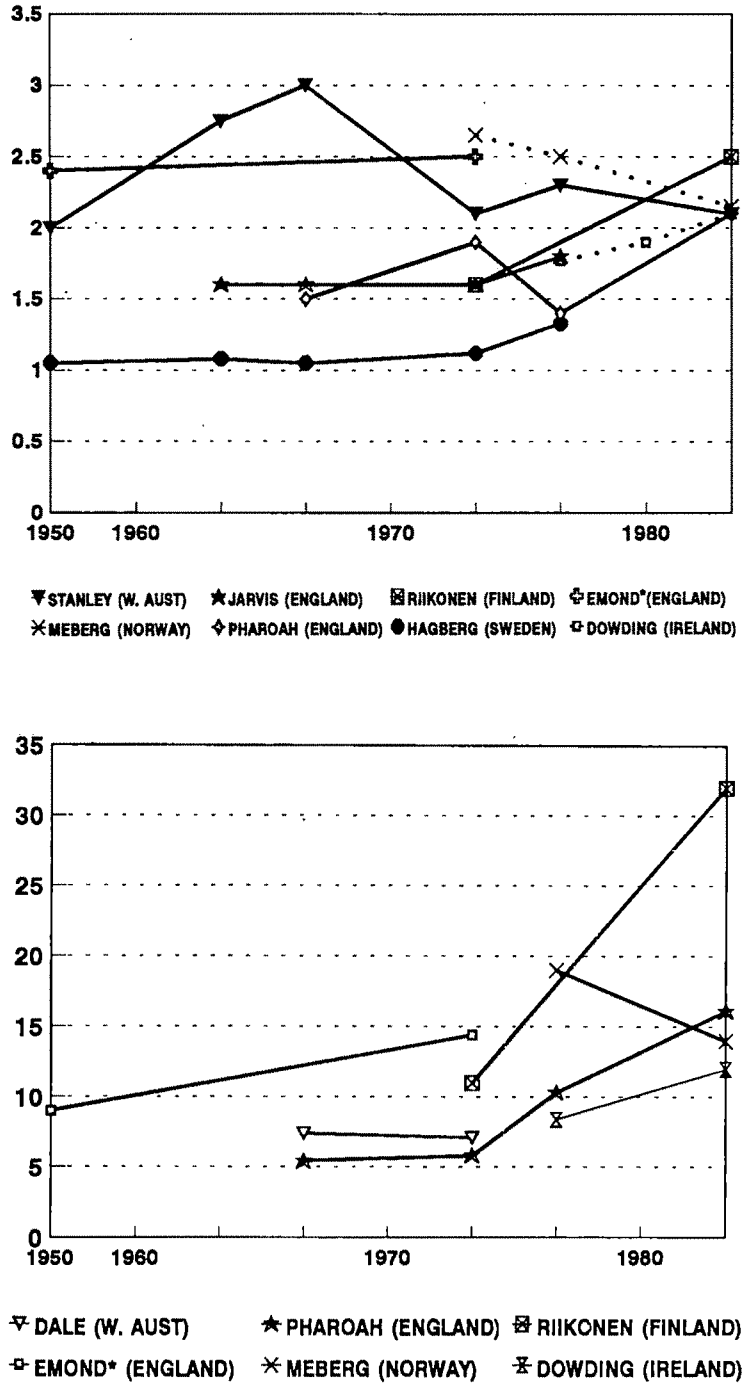

Fig. 1. Rates of cerebral palsy for all birth weights per 1000 live births *(top)* and per 1000 live births <2500 gm *(bottom)*. *Asterisk,* Neonatal survivors.

of 36% of all cerebral palsy occurred in the LBW population. Therefore approximately 5.3% of the birth population contributed 36% of the cases of cerebral palsy. When studies providing cerebral palsy rates over periods of time are considered, the rate for infants weighing >2499 gm was stable at 1 to 1.5 per 1000 births of infants of that birth weight. Our composite figure, which includes more studies, was 1.8.

There appeared to be some consistency in the rates of cerebral palsy for the different birth weights, so one would think that overall rates could be tentatively extrapolated on the basis of a combination of the LBW rate, which is higher in the United States and has remained relatively unchanged at about 6.8%,[33] and the survival of these infants. Because the percentage of LBW infants varies from country to country, we would then expect the percentage of cerebral palsy occurring ing FHR β-sympathetic and parasympathetic tone, re-

in different birth weights to vary in a similar fashion. However, this was not the case. Other variables seemed to be involved. Besides the socioeconomic and ethnic compositions of the population that appear to be associated with LBW, one also needs to consider health policies in and within different countries concerning access to prenatal care and the resuscitation and treatment of very small newborns.

As early as 1897, Freud noted that there appeared to be different types of cerebral palsy that probably had different origins, so they should be studied separately. Others have reiterated this message more recently.[18] Birth weights and types of cerebral palsy seem to be intertwined so it is difficult to discuss one without discussing the other. Diplegia, which occurs more often among infants of LBW, was 34% of all cerebral palsy cases, whereas LBW infants were 36% of all cases of cerebral palsy (although these two do not completely overlap).

The rates of serious mental retardation (IQ <50) occurring along with cerebral palsy also differed by birth weight. The composite rate of serious mental retardation in those with cerebral palsy was 25% for all birth weights, 18% for LBW, and 30% for those weighing >2499 gm. Therefore 75% of all children with cerebral palsy have IQs >50 with most of those having IQs >70, and the occurrence of serious mental retardation is more common with the normal-birth-weight infants who have cerebral palsy. Among all infants with serious mental retardation, the rate of cerebral palsy was approximately 16.8%. However, the sources of the populations for this last figure need to be considered. Many of these studies were based on institutionalized populations. Also, because these studies were based on survivors, it underestimates the overall incidence.

Thus we may estimate that intrapartum cause for cerebral palsy is <0.5 per 1000 term births and that active prevention for those infants awaits better understanding of cause of the disease, because the usual monitoring methods in labor do not allow for that diagnosis.[1] It is more probable that understanding and preventing premature birth and better means of antepartum surveillance are more likely to contribute to the prevention of cerebral palsy.

To the obstetrician the incidence of cerebal palsy has major clinical meaning. It is clear that the target population for cerebral palsy still hovers at about 2.7 per 1000 live births at 4 to 10 years of age. About 36% of cerebral palsy will have origins in infants weighing <2500 gm, with increasing risk for cerebral palsy with each decrement in infant birth weight. The emphasis in research should be on finding causes of and solutions for early prenatal problems that contribute to births at very low weights, to births of small-for-gestational-age infants, and to births of otherwise prenatally damaged infants. Tort reform needs to acknowledge these unknowns in the etiology of cerebral palsy, so the clinician can be enabled to practice his or her best without having to do so defensively.

In the term infant the incidence of cerebral palsy will be about 1.8 per 1000 of children with that birth weight. Thus the target for more than 90% of all deliveries is small. It is also important to understand that past estimates of origins of cerebral palsy for term infants are divided into perinatal (25% to 30%) causes and the remainder probably prenatal or unknown causes. A portion of those with perinatal causes will be intrapartum causes.

Villejuif and Lyon, France

OBJECTIVES: We assessed the effectiveness of ambulatory tocodynamometry in reducing the preterm delivery rate in women at risk of preterm delivery such as women with risk factors and women previously hospitalized and discharged.

STUDY DESIGN: In four public maternity units these women were randomly allocated to two groups: 84 had home uterine activity monitoring and daily midwife contact and 84 were given the standard care for high-risk women, which generally includes home visits by community midwives.

RESULTS: The proportion of deliveries before 37 weeks' gestation was slightly higher in the monitored group than in the control group (32% vs 22%). The corresponding odds ratio was 1.7 (95% confidence interval: 0.9 to 3.5).

CONCLUSION: Although the sample was small, these results suggest that home uterine activity monitoring was probably not beneficial to the population studied, or at least that any benefit would have been too small to justify extending this monitoring in this high-risk population. (Am J Obstet Gynecol 1992;167:424-9.)

Key words: Term Guard system, preterm delivery, uterine activity, prenatal screening, prevention

The identification of women at increased risk of preterm labor is one of the major issues in preventing preterm deliveries. At present, screening of threatened preterm labor is mainly conducted on the basis of the findings of vaginal examinations and the perception of contractions by women, but these criteria have limited usefulness. Certain signs of cervical maturation, especially the dilatation of the internal os, are predictive of preterm delivery[1-4] but have low sensitivity.[5] Furthermore, self-reported contractions are poorly correlated to uterine activity[6] and to preterm delivery.[3, 4]

Another approach to enhancing early diagnosis of threatened preterm labor was recently developed on the basis of assessment of uterine activity by ambulatory tocodynamometer in high-risk women. It was observed that women who subsequently experienced preterm labor had greater uterine activity than women who labored at term, and this difference was found up to several weeks before the onset of labor.[7] In the United States, the effectiveness of home uterine activity monitoring and daily nursing contact has been assessed in several randomized, controlled trials in which this type of care was found to reduce the preterm delivery rate[8] or to permit earlier diagnosis of preterm labor.[9-11]

However, because home uterine activity monitoring has positive effects in the United States does not guarantee that it will be effective in other settings. In France an active policy is pursued during pregnancy to prevent preterm delivery by routine vaginal examinations, bed rest, admission to the hospital, prescription of β-sympathomimetics and home visits by community midwives. To ascertain whether under these conditions home uterine activity monitoring reduces the number of preterm deliveries, we conducted a randomized, con-

trolled trial in which a group of women using the Term Guard uterine activity monitor (Tokos Medical Corporation, Santa Ana, Calif.) was compared with a control group given the usual obstetric care provided high-risk women in France.

Population and method

The trial included two groups of women: (1) women who had been discharged and sent home after hospitalization for threatened preterm labor (discharged group), and (2) women at high risk for preterm delivery (high-risk group). In the latter group, the risk factors were twin gestation, previous delivery at <35 completed weeks of gestation or cervical cerclage during the current pregnancy. Women were enrolled between 24 and 34 weeks of pregnancy.

We compared two groups of women: a monitored group and a control group. The monitored group was instructed at home in the use of the ambulatory tocodynamometer. The device was used for 1 hour every morning and evening. A midwife at the Tokos Medical Center contacted the women every day by telephone. The women were asked to state their symptoms and transmit the data recorded concerning their uterine activity. The women were also visited once a week by a Tokos Center midwife. Women with persistent symptoms or contractions in excess of their established baseline contraction frequency were sent to the outpatient clinic or the inpatient ward.

The women in the control group had home visits by a community midwife once or twice a week; this was the standard care prescribed by the participating centers for high-risk women. In addition, the women in both the monitored and control groups were given prenatal care by obstetricians or midwives at the outpatient clinics and were hospitalized if necessary.

Because the objective of the trial was to assess the Term Guard system in current medical practice, we did not alter this practice in the participating centers, and no specific recommendations were made to physicians regarding the diagnosis of threatened preterm labor or tocolytic treatments. In France women with severe symptoms of threatened preterm labor are usually admitted to the hospital and are administered intravenous β-sympathomimetics. The other tocolytic treatments are mainly inhibitors of prostaglandin synthesis and progesterone.

Our study was carried out in the four public maternity units located in Lyon. The women were enrolled between October 1988 and May 1989. After obtaining their informed consent we allocated them to the monitored and control groups by randomization with sealed envelopes. In each maternity unit randomization was done separately within the discharged and high-risk groups.

In all, 168 women were randomized into the monitored or control groups in a ratio of 1:1. As regards the two populations included in this trial, the overall sample comprised 74 women who had been discharged from the hospital (37 monitored and 37 control group women), and 94 high-risk women (47 monitored and 47 control). The risk factors of the latter group were the following: twin gestation (55%), previous delivery at <35 weeks (24%) and cervical cerclage (21%). One woman in the control group was lost to follow-up after enrollment, so that the analysis was conducted on 167 women: 84 in the monitored group and 83 in the control group.

During the study data were collected at entry and after delivery. At entry an information sheet was completed before randomization to confirm the eligibility of each participant and assess the risk of preterm delivery from the state of the cervix and the contractions perceived by the woman. After delivery data on prenatal care, delivery, and pregnancy outcome were obtained from hospital case notes.

Gestational age was assessed on the basis of last menstrual period and ultrasonography. If there were dis-

agreement the ultrasonographic data were used. Preterm delivery (before 37 full weeks' gestational age) was the primary outcome criterion. However, participating physicians or midwives sometimes stopped tocolytic treatment or uterine monitoring at 35 weeks, and this cut-off point was also selected for the analysis. To distinguish threatend preterm labor from preterm delivery, threatened preterm labor was defined as preterm labor not followed by delivery within 24 hours after the onset of the first symptoms (contractions, dilatation of the internal os of the cervix, or premature rupture of the membranes).

Statistical analysis was done by the χ^2 test and Student's t test. Analysis was stratified by group (discharged or high-risk). Results for gestational age and birth weight were given as odds ratios, and the corresponding confidence intervals were calculated according to the method of Mantel-Haenszel.

Results

At study entry the monitored and control groups were comparable for maternal age, number of previous pregnancies, family status, and social class (Table I). We found that the proportion of women who had a history of stillbirth, neonatal death, or delivery before 37 weeks of gestation was smaller in the monitored group than in the control group (Table II). No difference between the two groups was observed for two other risk factors: the proportion of twin gestations and episodes of threatened preterm labor treated by β-sympathomimetics or inhibitors of prostaglandin synthesis before study entry. The two groups were also comparable with regard to the state of the cervix and the contractions perceived by the women at study entry. Furthermore, the women in both groups were enrolled at a similar gestational age: 28.9 weeks (±3.3) in the monitored group and 28.6 weeks (±2.9) in the control group.

In the monitored group one woman refused to participate in the monitoring during the initial contact by a Tokos Center midwife; later, two others failed to comply with the Term Guard regimen and the monitoring was stopped. These three women were kept in the monitored group for the analysis. The average length of monitoring was 42.6 days (±42.0). During this period the women had 3.3 home visits (±1.7) by a Tokos Center midwife. For 69% of the women the monitoring was definitely stopped because the length of gestation was close to 37 weeks. The two other main reasons for the cessation of monitoring were admission to hospital for preterm labor or delivery (21%) or diagnosis of another complication (6%).

In the control group 87% of the women had home visits by community midwives (Table III). The average length of this care system was 42.3 days (±47.0). The women in both the monitored and control groups had three visits to the outpatient clinic between study entry and delivery.

The proportion of women admitted to the hospital for threatened preterm labor or other pregnancy complications was 37% in the monitored group and 40% in the control group. In the monitored group 21 (25%) women were admitted for threatened preterm labor. Of these, three had cervical dilatation >1 cm and two had premature rupture of membranes. In the control group, of the 16 (19%) women admitted for threatened preterm labor, two had cervical dilation >1 cm and four had premature rupture of membranes. In both groups all the women admitted for threatened preterm labor were treated with tocolytic agents; nevertheless, intravenous β-sympathomimetics were prescribed for 13 (15%) women in the monitored group and 6 (7%) in the control group. Overall prescription of contraction inhibitors (intravenous or oral β-sympathomimetics, indomethacin, or progesterone) was more frequent in the monitored group than in the control group (79% vs 59%; $p = 0.006$).

Table III. Prenatal care after study entry

*Not followed by delivery within 24 hours.

†β-sympathomimetics, indomethacin, or progesterone, prescribed in the inpatient ward or at the outpatient clinic.

In the monitored group six babies were stillborn or died before discharge (Table IV). Four were preterm (between 25 and 28 weeks). In the control group there were three stillbirths or deaths, one of which was preterm (25 weeks). The proportion of deliveries at <37 weeks of gestation was 32% in the monitored group and 22% in the control group (odds ratio = 1.7; 0.9 to 3.5). The trend was similar in the two stratified groups, that is, in the discharged group (22% vs 13%) and the high-risk group (40% vs 28%). The proportions of deliveries before 35 weeks were 19% and 11%, respectively, in the monitored and control groups (odds ratio = 1.9; 0.8 to 4.7). Among all the singletons and twins delivered, the proportion of babies weighing <2500 gm was similar in the two groups (36 vs 34%, odds ratio = 1.1; 0.6 to 2.1).

Comment

In our study we did not find home uterine activity monitoring to significantly reduce the number of preterm deliveries. Our sample size was not large enough to enable us to reach a definite conclusion regarding the effect of the Term Guard system. Nevertheless, our results showed no trend that argued in favor of this type of care and, if this system had a positive effect, it would be a very small one. According to the range of the odds ratio for preterm delivery, the relative decrease in the preterm delivery rate is very unlikely to be >10% through home uterine activity monitoring. Thus there is poor evidence that the Term Guard system can be useful in our population because the beneficial effect that could be observed would be too small to justify extending the use of such a system.

We originally planned to include 900 women in the trial. This sample size was based on the expected preterm delivery rates, which we estimated to be 25% for the control group on the basis of previous French studies.[12, 13] Thus a trial including 900 women had a 95% chance of showing a significant difference at the 5% level if the preterm delivery was reduced from 25% in the control group to 15% in the monitored group (two-tailed test). It was not possible to reach this sample size because the Tokos Medical Corporation was no longer funded in France. However, according to the preterm delivery rates observed in our study, the sample size originally planned would have been too small to show a significant difference between the monitored group and the control group.

Our results cannot be explained by a higher risk of preterm delivery in the monitored group than in the control group, because the two groups were similar as regards all risk factors except for a history of adverse pregnancy outcome, which was more frequent in the control group. A few more women were treated for threatened preterm labor before enrollment in the monitored than in the control group, but at study entry dilatation of the internal os of the cervix was equally frequent in both groups. After study entry we found that treatments for the inhibition of contractions, administration of intravenous β-sympathomimetics and hospitalization for threatened preterm labor were slightly more frequent in the monitored group than in the control group. This could have been because of the presence of more women with threatened preterm labor in the monitored group than in the control group. It could also be the very consequence of uterine activity monitoring because the aim of such monitoring is to detect contractions that would otherwise be unknown. Because the doctors knew the results of the monitoring, they might have diagnosed a larger number of cases of threatened preterm labor in the monitored group than in the control.

*Monitored versus control.

During the trial attention was paid to the adequate use of home uterine activity monitoring and nursing support. This care system was provided by the French branch of the Tokos Medical Corporation. The monitoring device used, the organization of home care, and the standards applied to the interpretation of the data obtained by monitoring were similar to those prevailing in the United States. The midwife in charge of the Tokos Center was experienced in the prevention of preterm births and had been trained in several Tokos Centers in the United States. This care system was tested in two different settings in France before the trial began.[14, 15] Furthermore, in the trial protocol home visits by a Tokos midwife were added to the care usually provided by Tokos Centers to make sure that the monitored group would not be at a disadvantage compared with the control group.

One of the published randomized controlled trials that assessed Term Guard effectiveness showed clear evidence of a decrease in the preterm delivery rate in the overall group of women who used a uterine activity monitor compared with those who used uterine self-palpation (15% vs 45%).[8] However, the results were based on a small sample (34 and 33 women, respectively), and the confidence interval of the odds ratio for preterm delivery was large. In other randomized controlled trials in which women monitored at home were compared with women given standard care and education on self-palpation for uterine contractions,[9-11] the positive effects observed on the preterm delivery rate were restricted to the women who experienced preterm labor after study entry, and no overall conclusion was reached for the entire group included in these trials.

It is often suggested that the Term Guard system might be effective in preventing preterm births because uterine activity monitoring twice a day and frequent contacts with nurses would help to diagnose preterm labor at an earlier stage, when the state of the cervix is considered to be favorable for tocolysis. This possibility has been confirmed by several randomized controlled trials in which, at the first preterm labor episode, women who were monitored daily had less advanced cervical dilatation than those given standard care, and there were fewer tocolysis failures in the former group than in the latter.[8-11] We were unable to verify this hypothesis ourselves because we only knew the state of the cervix for women who had threatened preterm labor and who were delivered >24 hours after admission to hospital. However, among these women we found no trend towards earlier diagnosis of threatened preterm labor in the monitored group.

If the Term Guard system has a beneficial effect in reducing the preterm delivery rate, the question is raised as to whether it is the monitoring data or the frequent nurse contacts that result in improved outcome. The results of several randomized controlled trials suggest that the information supplied by monitoring might be less effective than the support provided by daily contacts with a nurse. Thus Iams et al.[16-17] showed that the preterm delivery rate was not significantly different in the group monitored by the Term Guard system and in a group of women who only had daily contact with a Tokos Center nurse. Dyson et al.[18] compared a monitored group with a group of women who used the monitor and also had this daily contact but for whom the monitoring data were not available for care management. Dyson et al. found no significant difference in preterm delivery rates between the two groups. However, in patients with twin gestation they observed a significant reduction in the numbers of very low birth weight babies and admissions to the intensive care nursery in the group for whom the monitoring data were used. Porto et al.[19] made a similar comparison among women who had either single or multiple gestation and found no difference in the frequency of preterm delivery between the monitored group and the group with blind data. Nurses might, therefore, have a major role in the Term Guard system by providing

social support and paying attention to all the preterm labor symptoms reported by the women.[20]

If this is the case our finding that home uterine activity monitoring failed to reduce the number of preterm deliveries might be the result of the great attention devoted to the screening of threatened preterm labor and the efforts made to prevent preterm deliveries in France. For example, books aimed at pregnant women emphasize the risk of preterm delivery and the measures that can be taken to prevent it.[21-23] These publications also describe in detail the symptoms of preterm labor, thus inciting women to contact their physician and comply with the medical decisions. Furthermore, French doctors have a very active approach to the prevention of preterm deliveries. The effectiveness of all the measures taken to avoid this pregnancy outcome is not always known and some of these measures, such as home visits by community midwives,[24,25] have not been observed to have positive effects on the preterm delivery rate. Nevertheless, the overall policy conducted to prevent preterm deliveries may have beneficial results. The introduction of a new type of care such as the Term Guard system may not necessarily be useful within this framework, although it might be effective in a different medical environment.

Further research is needed to test whether home uterine activity monitoring improves the prevention of preterm birth as it was recently expressed by a multidisciplinary workshop.[26] Thus we will know in which countries or populations beneficial effects may be expected.

We thank the staff of the Tokos Medical Center, particularly Maryse Courbière and Christian Rochet, and the staff involved in the trial in each participating maternity unit. We also thank Professors Emile Papiernik and Michel Tournaire for their advice regarding the protocol.

Maternal hyperoxygenation in the treatment of intrauterine growth retardation

Cesare Battaglia, MD, Paolo G. Artini, MD, Gerardo D'Ambrogio, MD, Paolo A. Galli, MD, Alberto Segre, MD, and Andrea R. Genazzani

Modena, Italy

OBJECTIVE: In the current study the efficacy of maternal hyperoxygenation on growth-retarded fetuses was evaluated.

STUDY DESIGN: Thirty-six pregnant women with intrauterine growth retardation were studied. The patients were divided in oxygen-treated (n = 17) and untreated (n = 19) groups. Doppler analysis of the fetal circulation was performed on the arrival to the hospital, after 12 hours, and thereafter on alternate days until delivery. Fetal blood was sampled by cordocentesis for immediate blood gas analysis at entrance to the study and the day of delivery.

RESULTS: Significant improvement in Doppler flow patterns in treated patients were found when compared with untreated women. The Doppler variations were associated with complementary modifications in fetal blood gas. These differences resulted in a significant modification in perinatal mortality with an incidence of 29% and 68% ($p < 0.01$) in treated and untreated groups, respectively.

CONCLUSION: Our data suggest a benefit of maternal hyperoxygenation in the treatment of fetal growth retardation. (AM J OBSTET GYNECOL 1992;167:430-5.)

Key words: Hyperoxygenation, growth retardation, Doppler, cordocentesis

Uteroplacental insufficiency leads to intrauterine growth retardation (IUGR), which is a major cause of perinatal mortality and postnatal morbidity.[1, 2] IUGR and oligohydramnios in the second and early third trimesters of pregnancy indicate a poor prognosis for the fetus. These conditions may complicate about 1% of pregnancies.[3]

Arterial Po_2 in the fetus is 25% to 33% of the arterial Po_2 in the adult. Some authors referred to this as "physiologic hypoxia" even though it represents a normal state of fetal oxygenation.[4] However, in spite of the low Po_2, fetal blood is capable of transporting large amounts of oxygen from the placenta to the fetus. This is possible because (1) the hemoglobin of fetal red blood cells has a high affinity for oxygen and (2) the rate of perfusion of fetal organs is high in comparison with oxygen requirements.

Fetal hypoxia is induced by any decrease in fetal oxygenation below the normal level. Such a decrease may induce a reduction in the Po_2 of umbilical venous blood (hypoxic hypoxia). Chronic intrauterine hypoxia, hypercapnia, acidosis, hyperlacticemia, and erythroblastosis occur in many growth-retarded fetuses.[5]

Current management includes early diagnosis, bed rest, and antenatal monitoring of fetal well-being until the fetus reaches a stage of viability that allows delivery. In the current prospective, randomized study the value of long-term maternal hyperoxygenation in comparison with the traditional management of bed rest was evaluated in the treatment of growth-retarded fetuses.

Patients and methods

From October 1989 through August 1991 we studied 36 pregnant women at 26 to 34 weeks' gestation with IUGR. All the patients gave their informed consent to participate in the study. Patients included in the study fulfilled the following criteria: known last menstrual period, regular menses, absence of maternal diabetes, fetal ultrasonographic examination before 22 weeks with biometric data consistent with duration of amenorrhea, singleton fetus, no fetal malformation or chromosomal defects; reduced amount of amniotic fluid (oligohydramnios was defined by the absence of any amniotic fluid pocket measuring ≥2 cm in a vertical axis), abnormal Doppler flow velocity waveforms in maternal-fetal circulation (±2 SD of our reference ranges), ultrasonographic measurements of fetal abdominal circumference <5th percentile of our reference ranges, and reactive nonstress test.

The patients admitted in the study were randomly assigned to two different treatments: (1) the traditional

management of bed rest (plus antihypertensive medication, when necessary) and (2) the same management plus humidified 55% oxygen at a rate of 8 L/min administered continuously (except during meals, etc.) through an MC face mask for 24 hours a day.[3]

Ultrasonographic assessment of amniotic fluid volume was performed on alternate days until parturition. A weekly ultrasonographic measurement of fetal abdominal circumference was performed. Both assessments were performed with the patients in a semirecumbent position with a 3.5 MHz convex array real-time scanner (Ansaldo AU 940, Genova, Italy).

Doppler analysis of maternal-fetal circulation was performed on the arrival of patients to the hospital, after 12 hours (only on umbilical artery), and thereafter on alternate days until parturition. Flow velocity waveforms were recorded with a duplex pulsed Doppler (Ansaldo AU 940) with a 3.5 MHz convex transducer. Low-frequency Doppler signals originating from vessel wall motion were eliminated by a 100 Hz low-frequency filter. No fetal breathing or intervening fetal motion activity occurred during recording. Several arteries were analyzed transabdominally. We calculated the resistance index (Resistance index = Systolic − Diastolic/Systolic)[6] for the uterine and umbilical artery and the pulsatility index (Pulsatility index = Systolic − Diastolic/Mean)[7] for the descending thoracic aorta and middle cerebral artery. The time-averaged mean velocity in the descending aorta was calculated[9] (the pulsed sample volume was placed in the fetal descending aorta just above the level of diaphragm; the angle of insonation was between 50 and 60 degrees; and the results express the mean velocities over the cardiac cycle of the maximum frequencies recorded). For each examination we obtained the mean value of three consecutive waveforms.

Fetal blood was sampled by cordocentesis[10, 11] for immediate blood-gas analysis at entrance to the study while the mother was breathing air and again on the day of delivery while the mother was breathing oxygen. Cordocentesis was performed by an aseptic technique without maternal fasting, sedation, and local anesthesia. The umbilical cord vessel sampled was identified by ultrasonography as either vein or artery by turbulence produced after injection of 200 μl of saline solution.[10, 11] The fetal origin of blood was subsequently confirmed by the Kleihauer test. Fetal blood (100 μl) was collected into heparinized syringes, and blood-gas analysis was performed with a Radiometer AB-330 blood gas anlayzer (Radiometer, Copenhagen). On the day of delivery, after a further informed consent, cordocentesis was repeated, indicating to the patients that gas analysis would be useful to understand about fetal well-being.

The Doppler and cordocentesis indices were not revealed to the labor staff but were correlated with pregnancy outcome.

During the study all patients had the following maternal-fetal functional indices measured every 3 days: human placental lactogen, estriol, hematocrit, platelet count, mean platelet volume, and uric acid.

The potential harm of hyperoxygenation for the mother's lung was studied by serial determinations of pulmonary vital capacity.[12]

Statistical analysis. An unpaired *t* test was used to calculate the significance of the difference among the

Results

The 36 women were divided into oxygen-treated ($n = 17$) and untreated ($n = 19$) patients. In the treated group the duration of oxygen therapy was 10.1 ± 3.4 (mean ± SE) days.

At admission to the hospital the fetal abdominal circumference was as indicated in Fig. 1.

Many indices, such as demographic and clinical data, were not significantly different between the treated and untreated groups (Table I). Except for uterine artery waveforms, significant improvements were found in Doppler flow patterns (Table II) in treated patients compared with untreated women. The intraobserver variations were 5.8%. The Doppler variations were associated with complementary modifications in fetal blood gas (Table III). These differences resulted in a significant modification in perinatal mortality with an incidence of 29% and 68% ($p < 0.01$) in treated and untreated groups, respectively. A single case of intrauterine death resulted in the untreated group. The indications for delivery and perinatal outcome were similar in both groups (Table IV). In all the cases the birth weight was below the fifth percentile of Italian standards. In the treated patients the surviving fetuses had little morbidity with no severe neonatal complications. In the untreated group one of the surviving fetuses developed intraventricular hemorrage with subsequent severe handicaps. The fetal growth velocity was not significantly affected by therapy.

No fetal complications, except eight cases of transient bradycardia, were registered as a consequence of fetal blood sampling in either group.

No significant variations in maternal pulmonary capacity were found in the treated patients. The adverse effects of high oxygen concentrations on the fetus were not evaluated in the postnatal period because in our cases the rise in fetal blood P_{O_2} resulted in values within the normal range.

The obstetric management was decided by the labor staff on the interpretation of fetal heart rate tracings or the deterioration of maternal conditions.

Comment

Starting from the hypothesis that the most likely cause of IUGR is an impaired uteroplacental or fetal-placental perfusion with consequent reduced maternal-fetal exchange, maternal oxygen therapy was suggested to improve fetal metabolic conditions.

In the current study the efficacy of maternal hyperoxygenation was rather evident. After 12 hours of ther-

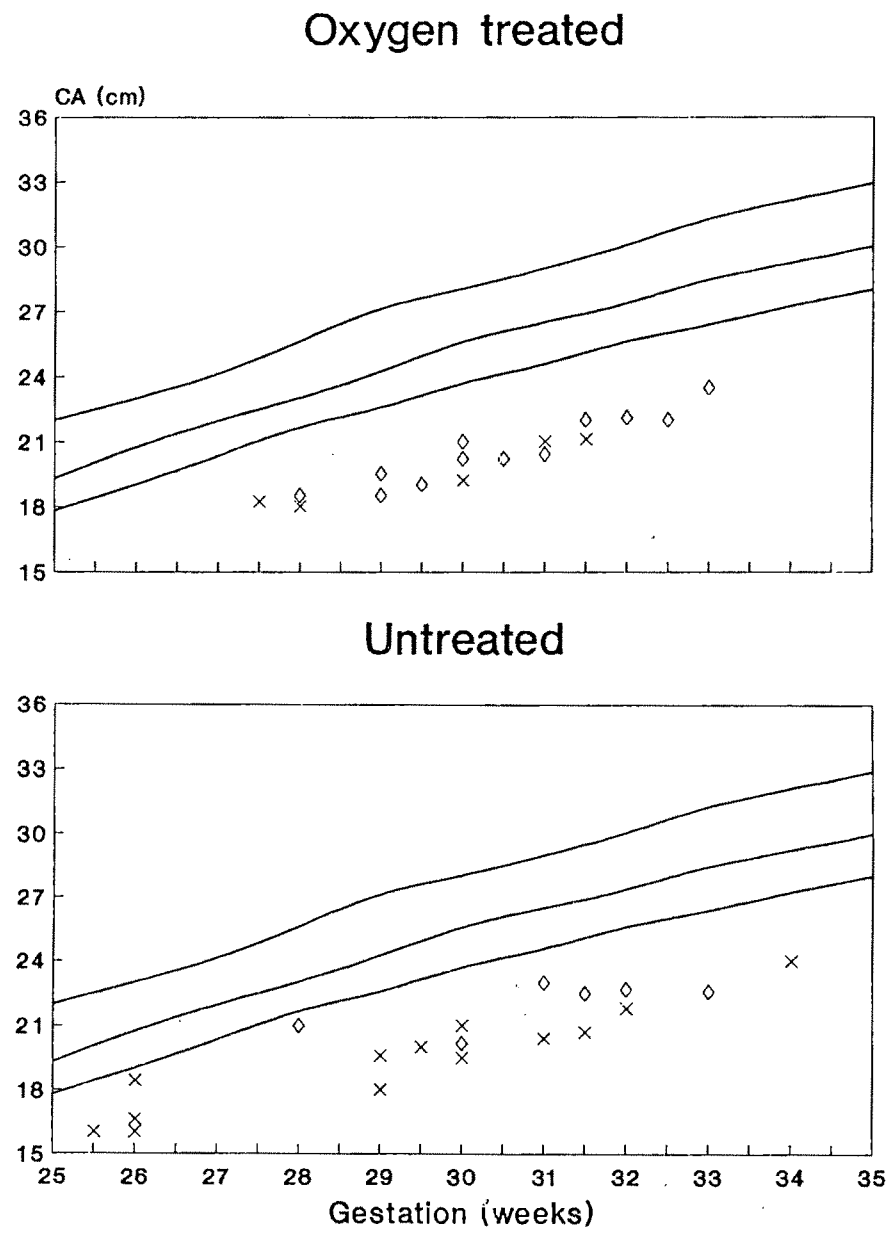

Fig. 1. Fetal abdominal circumference *(CA)* at admission to hospital in 17 IUGR fetuses who were subsequently treated with maternal hyperoxygenation, compared with 19 untreated fetuses. There were 18 (◇) surviving fetuses and 18 (×) dead fetuses.

apy no evident changes of Doppler flow waveforms were recorded. However, on the day of delivery, after a mean period of 10 days of oxygen therapy, modifications of the Doppler patterns were shown. At the level of umbilical artery in one case the reverse flow was modified to end-diastolic flow negative, and in two cases of end-diastolic flow negative a diastolic flow reappeared a few days before the delivery. In the treated patients a significant improvement of Doppler flow velocity waveforms in other districts was observed. Such variations were associated with a progressive improvement in blood-gas indices. On the other hand, untreated patients showed a worsening of the "brain-sparing effect." Hypoxia, hypercapnia, and acidosis worsened in the untreated group.

As previously described, some IUGR fetuses are hypoxemic, hypercapnic, hyperlacticemic, and acidotic.[5] Several mechanisms in the production of hyperlacticemia have been suggested. Increased placental production, impaired fetal gluconeogenesis, and inadequate oxygen supply represent possible sites of lactate hyperproduction.[13-15] In the current study the evaluation of maternal and fetal blood lactate concentration was not done.

The maternal hyperoxygenation in hypoxic and severely growth-retarded fetuses improved and maintained fetoplacental oxygenation. This effect resulted independently from the immediate response of the fetal-placental vasculature. Furthermore, the maternal hyperoxygenation modifying the fetal blood-gas concentrations and consequently the chemoreceptor-mediated vascular reactivity reversed the brain-sparing effect, probably restored an aerobic metabolism, and resulted in the decreased incidence of fetal death and neonatal complications. This is an indirect confirmation of what occurs in animal experiments, in which the more depressed the Po_2 and pH are, the more probable the development of brain injury is and the more difficult resuscitation is.[4]

In conclusion, maternal oxygen therapy improved the fetal condition and survival but was inadequate in increasing the placental transfer of nutrients, because fetal growth velocity resulted unaffected.[3]

The study suggests a benefit of oxygen therapy for the treatment of severe IUGR and should encourage further studies.

We thank Dr. Felice Petraglia for his kind collaboration in preparing the manuscript.

Behavioral treatment of menopausal hot flushes: Evaluation by ambulatory monitoring

Robert R. Freedman, PhD, and Suzanne Woodward, PhD
Detroit, Michigan

OBJECTIVES: We attempted to develop an effective behavioral treatment for menopausal hot flushes and to determine the active behavioral components of this procedure.
STUDY DESIGN: Thirty-three women with frequent menopausal hot flushes were randomly assigned to receive eight sessions of training in paced respiration, muscle relaxation, or α-wave electroencephalographic biofeedback (placebo control). Hot flushes were objectively measured by means of 24-hour ambulatory monitoring of the sternal skin conductance level.
RESULTS: Subjects undergoing paced respiration had significant reductions in hot flush frequency and respiration rate, as well as increases in tidal volume.
CONCLUSION: Paced respiration training may be a useful treatment alternative for the reduction of hot flushes in women who cannot tolerate hormone replacement therapy. (AM J OBSTET GYNECOL 1992;167:436-9.)

Key words: Hot flush, menopause, relaxation, sympathetic nervous system

Hot flushes are the most common symptom of the climacteric and occur in the vast majority of menopausal women. Although hormone replacement therapy is an effective treatment for hot flushes, it may be contraindicated for some women who have an increased risk of cancer. Central sympathetic activation is increased in women with hot flushes,[1-3] and agents such as clonidine, which inhibit this activation, have been shown to ameliorate hot flushes in some studies.[4-6]

Behavioral relaxation methods have been shown to reduce sympathetic activity in normal subjects[7-9] and in some clinical groups.[10] In a pilot study[11] we showed that a combination of progressive muscle relaxation exercises and slow, deep breathing reduced the incidence of self-reported hot flushes by about 50%. Since two treatment procedures were combined in that study, it was not possible to determine which component was responsible for the therapeutic effect. Therefore in the current investigation, the muscle relaxation and paced respiration exercises were administered to two separate groups. α-Wave electroencephalographic biofeedback was chosen as the placebo control procedure because it elicits subjective reports of relaxation without its physiologic effects.[12] We also sought to objectively determine the effects of the treatments with the use of 24-hour ambulatory monitoring of the sternal skin conductance level. This measure has been shown to correlate highly with patients' reports of hot flushes.[13, 14]

Material and methods

Thirty-three postmenopausal women were recruited from newspaper advertisements requesting women for participation in a research study of behavioral treatments for hot flushes. All women reported having at least five hot flushes per day and had been amenorrheic for at least 1 year. Three women had previously taken estrogen but stopped at least 1 year before the current study. All women gave written informed consent according to procedures approved by our institutional review board.

The women were randomly assigned, in equal numbers, to one of three behavioral treatment groups. Each woman received eight 1-hour, biweekly treatment sessions. Patients undergoing paced respiration had abdominal and thoracic chest excursions recorded with strain gauges and a polygraph. A research assistant viewed the polygraph tracings and instructed the patient to breathe at six to eight cycles/min and to increase the amplitude of the abdominal tracing. Patients learning muscle relaxation were given live training by a research assistant using previously published methods.[15] Patients were initially trained to systematically tense and then relax 16 gross muscle groups and to distinguish between sensations of tension and relaxation. In later sessions the procedure was reduced to seven and then to four muscle groups. α-Wave feedback patients received visual feedback for the production of 8 to 13

Hz electroencephalographic activity according to previously published methods.[11] In the procedure the patient watches a light that is activated when 8 to 13 Hz electroencephalographic activity reaches a preset amplitude level. The training is done in three 10-minute trials separated by 5-minute rest periods.

Before treatment, all women received 24-hour ambulatory monitoring of the sternal skin conductance level to detect hot flushes.[13,14] Two Meditrace disposable silver–silver chloride electrodes, 1.5 cm in diameter, were filled with 0.05 mol/L potassium chloride paste and attached over the sternum. Sternal skin conductance level signals were recorded on an Oxford Medilog 9000 recorder with a constant voltage circuit. The Medilog tapes were replayed at 60× real time with an Oxford Medilog playback unit, an analog-to-digital converter, and an IBM computer. The computer was programmed to detect any sternal skin conductance level increase ≥2 μmho in 30 seconds, which served as the objective definition of a hot flush. We have previously demonstrated[14] that the concordance between this measure and patient reports was 95% for spontaneous hot flushes recorded in the laboratory and 86% for those recorded during ambulatory monitoring. The ambulatory recording was repeated after completion of the last treatment session.

Before treatment, each patient also received a test of her ability to voluntarily relax. After a 10-minute rest period, the patient was instructed to relax as deeply as possible for 5 minutes, followed by a second 10-minute rest period. During the entire session, the patient's respiration rate and tidal volume were recorded with a Sensormedics MMC metabolic cart. This procedure was repeated after the last treatment session.

Pretreatment group differences in age, weight, years since menopause, hot flush frequency, and respiratory measures were tested with one-way analyses of variance. Hot flush frequency data were next analyzed with a two-way (Group × Pretreatment/Posttreatment) repeated-measures analysis of variance. The significant interaction effect was then decomposed into the pretreatment/posttreatment simple effects for each group.[16] Respiratory measures were analyzed with three-way (Group × Period × Pretreatment/Posttreatment) repeated-measures analyses of variance. As described, significant interactions were broken down into lower-order simple effects for further analysis. Possible relationships between changes in hot flush frequency and demographic variables were tested with Pearson product-moment correlation coefficients (age, weight, years since menopause) and *t* tests (race, type of menopause). The minimum level of statistical significance was $p < 0.05$.

Posttreatment			
Rate (cycles/min)	10.2 ± 3.3*	11.5 ± 2.7	13.7 ± 3.2
Tidal volume (L/breath)	0.55 ± 0.27†	0.48 ± 0.16	0.47 ± 0.11

*$p < 0.015$, significantly different from corresponding pretreatment value.

†$p < 0.03$, significantly different from corresponding pretreatment value.

Results

Before treatment, there were no significant differences among the three groups in age, weight, or time since menopause (Table I) or in the frequency of sternal skin conductance level–defined hot flushes recorded during ambulatory monitoring (Table II). The analysis of hot flush frequency demonstrated a significant ($p < 0.05$) Group × Pretreatment/Posttreatment interaction effect. Simple effects tests showed that hot flush frequency decreased significantly for the paced

respiration group ($p < 0.02$) but not for the muscle relaxation ($p > 0.2$) or α-wave feedback ($p > 0.5$) groups.

There were no group differences in respiration rate or tidal volume during the pretreatment voluntary relaxation test (Table III). The analysis of variance on respiration rate showed a significant ($p < 0.02$) Group × Pretreatment/Posttreatment interaction effect. Simple effects analyses showed a significant Pretreatment/Posttreatment decline on this measure for the paced respiration group ($p < 0.015$) but not for the other two groups (both $p > 0.4$). For tidal volume a significant ($p < 0.05$) Group × Pretreatment/Posttreatment interaction effect was also found. Simple effects tests showed a significant pretreatment/posttreatment increase in tidal volume for the paced respiration group ($p < 0.03$) but not for the muscle relaxation ($p > 0.8$) or α-wave feedback ($p > 0.5$) groups.

There were no significant relationships between any pretreatment variable and the pretreatment/posttreatment change in hot flush frequency.

Comment

In the current study patients who received paced respiration training significantly reduced their frequency of hot flushes, increased their tidal volume, and slowed their respiration rates. Patients who received muscle relaxation exercises or α-wave feedback showed no significant changes in hot flush frequency or in either respiration measure. Taken together with our previous findings,[11] these results show that training in slow, deep breathing alone will result in a significant reduction in the occurrence of menopausal hot flushes.

This effect was documented by 24-hour monitoring of an objective measure of hot flushes and therefore is not subject to the limitations of self-report data. Moreover, our recordings were performed over a 24-hour period; therefore they accurately detected both sleeping and waking hot flushes. Self-reports of events occurring during sleep are obviously less reliable than objective physiologic data, particularly since not all hot flushes result in awakening.[17]

It has previously been shown that yohimbine, an α_2-adrenergic antagonist, provokes hot flushes[2] and that clonidine, an α_2-adrenergic agonist, ameliorates them.[2, 4-6] Yohimbine increases central norepinephrine release by blocking inhibitory, presynaptic α_2-adrenergic receptors[18] and clonidine acts in the opposite manner.[19] The main metabolite of brain norepinephrine is 3-methoxy-4-hydroxyphenyl glycol,[20] and we have shown that plasma levels of this metabolite are significantly elevated in menopausal women with hot flushes as compared with levels in those without them.[3] Taken together, these data suggest that elevated central sympathetic activation is involved in the initiation of menopausal hot flushes.

We hypothesize that the slow, deep breathing exercises act in some way to modulate this activation and thereby reduce the frequency of hot flushes. However, the connection between changes in respiration and central sympathetic activation remains to be made. In cross-sectional studies, Schaefer[21] compared slow, deep breathers having high alveolar carbon dioxide levels with fast, shallow breathers having low carbon dioxide levels. The former group had slower resting heart rates, reduced adrenal cortical activity, and decreased autonomic responsiveness compared with the latter group, but measures of central sympathetic activity were not obtained. Further research in this area would be of great interest.

In conclusion, we have shown that training in a simple breathing procedure results in a significant reduction in menopausal hot flushes as measured over a 24-hour period. This technique may be useful for women with hot flushes who are unable to receive hormone replacement therapy.

Increased lipolytic activity and high ratio of free fatty acids to albumin in sera from women with preeclampsia leads to triglyceride accumulation in cultured endothelial cells

Marit J. Endresen, BScD, Bjørg Lorentzen, MD, and Tore Henriksen, MD, PhD
Oslo, Norway

OBJECTIVE: The null hypothesis of this study was that the triglyceride accumulation in endothelial cells exposed to sera from preeclamptic women was determined by the presence of triglyceride-rich lipoproteins in the sera.
STUDY DESIGN: The accumulation of triglycerides in cultured endothelial cells was studied using incorporation of tritiated glycerol.
RESULTS: Triglyceride-rich lipoproteins in the patient sera contributed little to the endothelial triglyceride accumulation. However, sera from preeclamptic women were found to have a higher molar ratio of free fatty acids to albumin compared with sera from women with normal pregnancies (1.6 ± 0.5 vs 0.9 ± 0.4, respectively, $p < 0.025$). In addition, sera from preeclamptic women, compared with sera from normal pregnancies, showed enhanced lipolytic activity (release of free fatty acids 0.85 ± 0.29 vs 0.17 ± 0.16 mmol/ml per 24 hours, respectively: $p < 0.025$) that further increased the free fatty acids/albumin ratio.
CONCLUSION: Sera from preeclamptic women have both a higher ratio of free fatty acids to albumin and increased lipolytic activity, resulting in enhanced endothelial uptake of free fatty acids, which are further esterified into triglycerides. (Am J Obstet Gynecol 1992;167:440-7.)

Key words: Preeclampsia, endothelium, hyperlipidemia, free fatty acids, lipolysis

Preeclampsia is a pregnancy-specific disorder characterized by increased blood pressure, urinary loss of proteins, edema, and activation of the hemostatic system.[1] It has become evident that many of these pathophysiologic changes may be explained by alterations in the maternal vascular endothelium.[2] However, factors that can cause disturbance of the endothelial cell functions in preeclampsia have not been identified.

Pregnant women have altered lipid metabolism as reflected in a marked hyperlipidemia.[3] Among those in whom preeclampsia develops, an additional change in the lipid metabolism seems to be present because the plasma levels of triglycerides are further increased as compared with those of women with normal pregnancies.[3] From the area of cardiovascular research there is increasing evidence that hyperlipidemia can cause endothelial dysfunction.[4] We have therefore raised the question whether the endothelial dysfunction of preeclampsia is causatively related to the alterations in the metabolism of lipids.

Recently we reported that sera from women with preeclampsia induced accumulation of triglycerides in endothelial cells.[5] This accumulation was accompanied by altered endothelial cell function as demonstrated by reduced prostacyclin release. In the current work we have studied the mechanism(s) responsible for the triglyceride accumulation in the endothelial cells. We demonstrate that both an increased ratio of free fatty acids to albumin and an enhanced lipolytic activity of sera from women with preeclampsia result in higher endothelial uptake of free fatty acids, which are further esterified into triglycerides.

Material and methods

Chemicals. Albumin, triglycerides, insulin, transferrin, oleic acid, stearic acid, and linoleic acid were all obtained from Sigma (St. Louis). Ham's F-10 medium and penicillin-streptomycin solution were purchased from Gibco (Grand Island, N.Y.). Tissue culture equipment was supplied by Costar (Cambridge) and Falcon (New Jersey, England). 1(3)^{3}H-glycerol, 99.9 GBq/mmol, were purchased from Amersham (Arlington Heights, Ill.). All organic solutions were of reagent grade.

Patient selection. A previously healthy normotensive

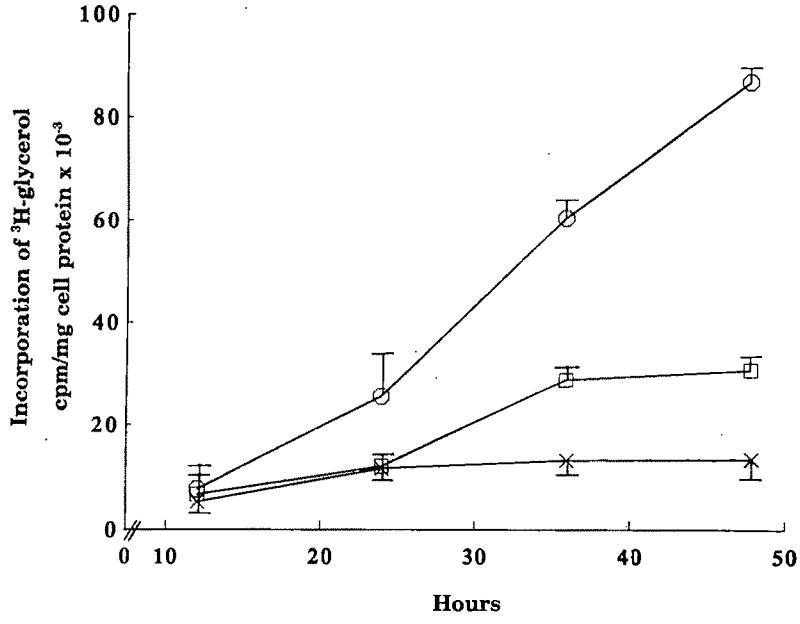

Fig. 1. Effect of various times of exposure of endothelial cells to sera from preeclamptic women (○), control pregnancies (□), and nonpregnant women (×) on incorporation of tritiated (^3H) glycerol into endothelial triglycerides. Each *point* represents mean ± SD of triplicate incubations.

woman was considered to have preeclampsia if the blood pressure after 20 weeks of gestation was >140/90 mm Hg on at least two occasions 6 hours apart. In addition, proteinuria of >300 mg/24 hours was required for the diagnosis. The control group consisted of healthy women of similar gestational age and parity with uncomplicated pregnancies and nonpregnant women.

Blood samples. Informed consent was obtained from each women. Blood samples were drawn after 8 to 10 hours of fasting. The blood was allowed to coagulate for 90 to 120 minutes at room temperature. Sera were obtained by centrifugation at 800*g* for 10 minutes and immediately placed at −70° C. Care was taken to handle the sera from preeclamptic and control women similarly and in parallel.

Cell cultures. Endothelial cells were isolated from the veins of umbilical cords obtained from normal pregnancies of women not included in the control group.[5] The cells were seeded in 2 cm² wells in 1 ml of culture medium consisting of Ham's F-10 medium supplemented with 2.5% (vol/vol) bovine calf serum, 7.5% (vol/vol) horse serum, penicillin (100 IU/ml), streptomycin (100 μg/ml), and amphotericin (2.5 μg/ml). Primary cultures were obtained from a new umbilical cord for each experiment, and the cells were used 2 to 3 days after seeding.

Preparation of isolated lipoprotein fractions. Very-low-density lipoprotein was prepared from freshly obtained sera from preeclamptic and control women by ultracentrifugation at density 1.006 gm/ml at 100,000*g* under sterile conditions for 24 hours at 4° C.[6] The fractions obtained were used immediately after preparation.

Table I. Endothelial content of triglycerides and tritiated glycerol incorporation into triglycerides after 60 hours' exposure to sera from preeclamptic women or sera from normal pregnancies

Sera	*μg Triglycerides per mg cell protein*	*Counts/min/mg × 10^{-3}*
Preeclamptic women	117 ± 13	140 ± 12
Normal pregnancies	29 ± 4	11 ± 2

Values are mean ± SD of triplicate incubations.

Measurement of tritiated glycerol incorporation into cellular triglycerides. In the experiments where tritiated glycerol incorporation into endothelial triglycerides was measured, the procedure was as follows: 5 μCi/ml tritiated glycerol and 0.1 μmol/ml unlabeled glycerol (both final concentrations) were added 12 hours before the end of each incubation (unless otherwise indicated) in a volume of 50 μl per well (containing

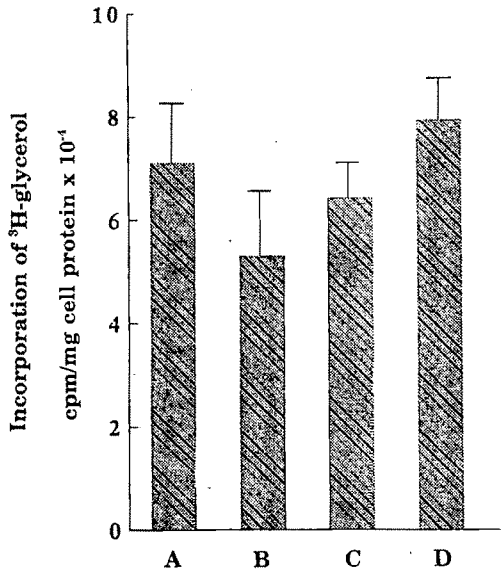

Fig. 2. Incorporation of tritiated glycerol into endothelial triglycerides in presence or absence of very-low-density lipoprotein. Endothelial cells were exposed for 36 hours to unfractionated preeclamptic serum *(A)*, very-low-density lipoprotein–deficient serum *(B)*, or very-low-density lipoprotein–deficient serum reconstituted with very-low-density lipoprotein (*C*, 1 μmol triglycerides per milliliter; *D*, 2.5 μmol triglycerides per milliliter). Each *bar* represents mean ± SD of triplicate incubations.

Duplicate determinations were done for each individual. Numbers of individual sera and SEM are indicated for each *bar*. Difference between sera from preeclamptic and normally pregnant women was significant, $p < 0.025$.

1 ml of medium). To end an experiment the cells were washed four times with phosphate-buffered saline solution with Hepes,[5] and cellular lipids were extracted in situ by exposure to 1 ml of hexane per well for 2 hours. The lipids were then separated by thin-layer chromatography on precoated silica gel plates (Polygram, Machery-Nagel, Germany) in a solvent system of petroleumether-diethyl ether acetic acid (85:15:1). The triglyceride-containing spots were scraped off, and the radioactivity was measured (Rackbeta 1217, LKB, Pharmacia, Oslo). Preliminary experiments showed that 85% of the hexane extractable lipids were found in the triglyceride fraction. In some of the experiments the endothelial content of triglycerides was determined as described previously.[5] Cellular protein was determined according to the method of Lowry et al., as described by Henriksen et al.[6]

Lipid staining. For staining of lipids the procedure was as follows: The cells were washed twice in Hepes and phosphate-buffered saline solution, fixed in 50% ethanol, stained in sudan red for 2 to 3 minutes, quickly washed in 50% ethanol, followed by another washing in purified water. The cells were afterstained in hematoxylin for 2 to 3 minutes, washed in purified water, and finally exposed to saturated lithium carbonate for a few seconds.

Experimental protocol

Effect of time of exposure of endothelial cells to sera from preeclamptic and normally pregnant women and nonpregnant women on incorporation of tritiated glycerol into cellular triglycerides. The cells were washed twice[5] with Ham's F-10 medium and then incubated for 12, 24, 36, and 48 hours with 1 ml of Ham's F-10 medium containing 30% (vol/vol) sera from either preeclamptic, normally pregnant women or nonpregnant women. Tritiated glycerol incorporation into endothelial triglycerides was measured as described above.

Cell incubations in presence and absence of very-low-density lipoprotein. Freshly isolated very-low-density lipoprotein in serum from a preeclamptic woman was added back to the very-low-density lipoprotein–poor bottom in two different concentrations (1.0 or 2.5 μmol of triglyceride per milliliter). The cells were washed twice[5] and then incubated with either unfractionated serum or the very-low-density lipoprotein–poor bottom with or without the two different concentrations of very-low-density lipoprotein. Tritiated glycerol incorporation into endothelial triglycerides was

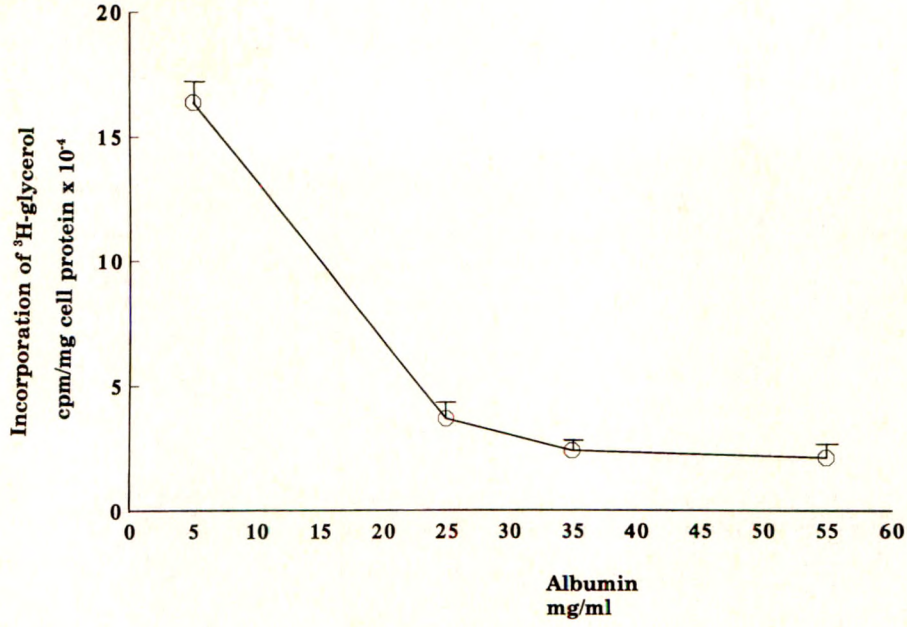

Fig. 4. Effect of albumin on incorporation of tritiated glycerol into endothelial triglycerides. Endothelial cells were exposed for 48 hours to serum from women with preeclampsia containing increasing amounts of albumin. Final albumin concentrations in culture media are given on *abscissa*. Each *point* represents mean ± SD of triplicate incubations.

measured as described in the preceding text. Parallel cultures were stained for lipids.

Cell incubations with various ratios of free fatty acids/albumin

Heat-inactivated sera. Three sera from women with preeclampsia and three sera from normally pregnant women (freshly obtained and stored at −70° C until start of experiment) with different ratios of free fatty acids/albumin were heat inactivated at 57° C for 60 minutes. Then the cells were washed twice and incubated with Ham's F-10 medium containing 30% (vol/vol) of the heat-treated sera. After 2 days the medium was renewed, followed by another 2 days' incubation. Tritiated glycerol incorporation into cellular triglycerides was measured as described.

Addition of albumin to serum from a woman with preeclampsia at start of cell incubations. Increasing amounts of albumin was added to serum from a woman with preeclampsia with an original albumin concentration of 17 mg/ml. The endothelial cells were then washed twice and exposed to Ham's F-10 medium containing 30% (vol/vol) of the serum with or without the additional albumin (final concentrations in the culture media were 5, 25, 35, and 55 mg/ml). After 48 hours' incubation tritiated glycerol was added, and after another 24 hours' incubation incorporation into endothelial triglycerides was measured as described. Parallel cultures were stained for lipids.

Addition of free fatty acids to sera from normally pregnant women at start of cell incubations. A total of 2 μmol of free fatty acids (360 μg of oleic acid, 120 μg of stearic acid, 90 μg of linoleic acid, and 30 μg of arachidonic acid) was dissolved in heptane and evaporated under nitrogen. The dry material was dissolved in 0.5 ml of ethanol containing 2.2 μmol of sodium hydroxide. After evaporation under nitrogen the free fatty acid salts were dissolved in 100 μl of purified water at 60° C. The free fatty acids were added to 2 ml of serum from normally pregnant women in 10 μl aliquots with gentle shaking at 37° C. The endothelial cells were then exposed to Ham's F-10 medium containing 30% (vol/vol) of the serum from normally pregnant women with or without the additional free fatty acids. The final total concentrations of free fatty acids in the culture medium were 0.74, 0.86, 1.11, and 1.61 μmol/ml. After 24 hours' incubation tritiated glycerol was added, and after another 24 hours' incubation the incorporation into triglycerides was measured as described in the preceding text.

Lipolytic activity in sera from preeclamptic and normally pregnant women and nonpregnant women. The lipolytic activity was determined as the difference in the concentration of free fatty acids at the start and end of incubations at 37° C for the times indicated in the figure legends. In three experiments the sera were heat inactivated by incubation for 60 minutes at 57° C. The concentration of free fatty acids in the sera or the culture media was measured with a kit for determi-

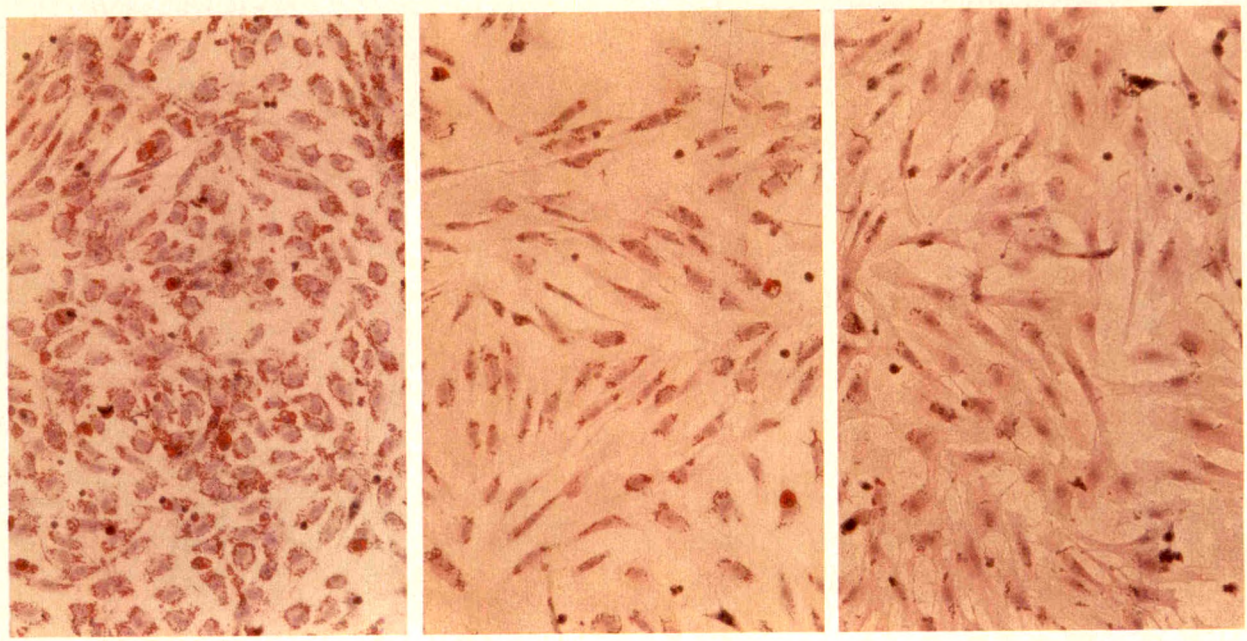

Fig. 5. Content of sudanophilic granules in endothelial cells exposed to preeclamptic serum *(left panel)* or to preeclamptic serum with additional albumin, 8 mg/ml *(middle panel)* or 18 mg/ml *(right panel)*.

nation of nonesterified fatty acid kit (Wako, Germany). Initial experiments showed that the release of free fatty acids during clotting of the blood contributed to <8% of the free fatty acid content of the sera. Furthermore, when sera were tested against plasma, similar levels of free fatty acids were found.

Statistical analysis. The Student *t* test was used.

Results

In five experiments with sera from five different individuals the incorporation of tritiated glycerol into endothelial triglycerides was up to 20 times higher in endothelial cells exposed to sera from women with preeclampsia than in the controls. Table I shows an experiment in which the tritiated glycerol incorporation was twelve times higher than in the control. The endothelial content of triglycerides was increased four times compared with that in the controls. The incorporation of tritiated glycerol was close to linear during a 48-hour incubation with serum from women with preeclampsia (Fig. 1).

Very-low-density lipoprotein is the major carrier of serum triglycerides and can lead to triglyceride accumulation in cells after endocytic uptake.[7] Addition of very-low-density lipoprotein from sera from women with preeclampsia to albumin-containing Ham's F-10 medium did not lead to accumulation of sudanophilic granules in the endothelial cytoplasm (data not shown). Furthermore, removal of very-low-density lipoprotein decreased the tritiated glycerol incorporation into triglycerides by about 20% compared with that observed for unfractionated sera from women with preeclampsia ($p > 0.025$). When very-low-density lipoprotein was added back to very-low-density lipoprotein–poor sera from women with preeclampsia, a 20% increase in the tritiated glycerol incorporation was found (Fig. 2).

A second possible cause of triglyceride accumulation in cells is increased uptake of exogenous free fatty acids.[8] The major determinant of the rate of cellular uptake of free fatty acids is the ratio of free fatty acids to albumin.[9] As shown in Fig. 3, sera from women with preeclampsia had a significantly higher free fatty acids/albumin ratio compared with sera from normally pregnant and nonpregnant women ($p < 0.025$). Given that the triglyceride accumulation in endothelial cells exposed to sera from women with preeclampsia is due to enhanced free fatty acid uptake, addition of albumin should have an inhibitory effect. As shown in Fig. 4, addition of increasing amounts of albumin to sera from women with preeclampsia almost completely inhibited the incorporation of tritiated glycerol into triglycerides. Furthermore, the cellular lipid accumulation induced by the sera from women with preeclampsia could be reversed by addition of albumin (Fig. 5). Conversely, addition of free fatty acids to a sera from normally pregnant women resulted in increased incorporation of tritiated glycerol into triglycerides (Fig. 6). A cor-

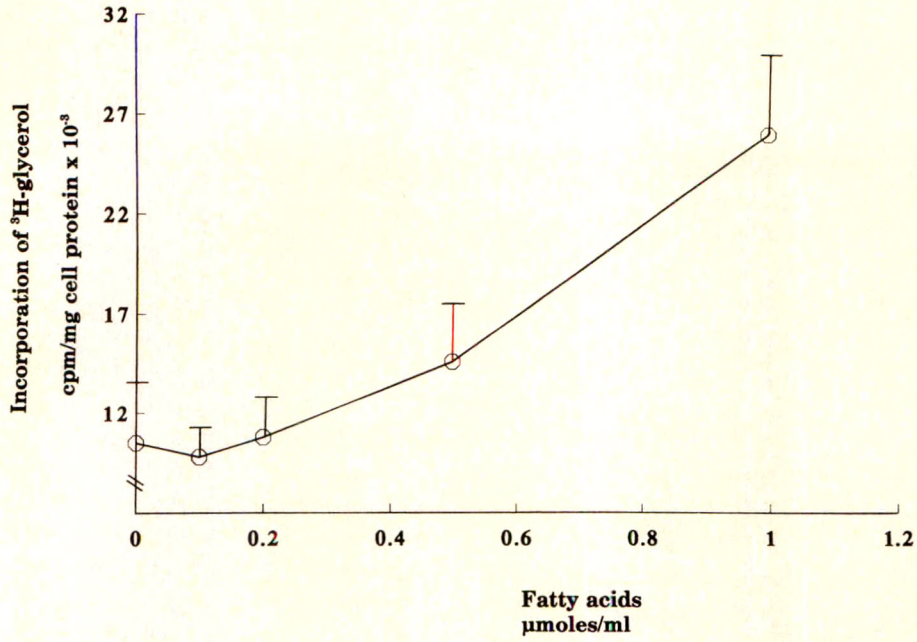

Fig. 6. Effect of fatty acids on incorporation of tritiated glycerol into endothelial triglycerides. Endothelial cells were exposed for 24 hours to sera from normally pregnant women with or without additional free fatty acids. Final concentrations of fatty acids in culture media are shown on *abscissa*. Each point represents mean ± SD of triplicate incubations.

responding increase in cytoplasmic lipid droplets was found (data not shown).

Release of free fatty acids as a result of enhanced lipolytic activity of the sera from women with preeclampsia could lead to a further increase in the ratio of free fatty acids to albumin. We therefore determined the lipolytic activity in sera from preeclamptic and normally pregnant women, and as shown in Fig. 7 the release of free fatty acids in the sera from women with preeclampsia was three to four times higher than in the sera from normally pregnant women ($p < 0.025$). Time-course studies showed linearity of the free fatty acid release up to 48 hours' incubation (data not shown). Eighty-five percent of this lipolytic activity could be inhibited by heat inactivation of both sera (data not shown). This procedure decreased markedly the incorporation of tritiated glycerol into endothelial triglycerides. However, a 100% higher tritiated glycerol incorporation into triglycerides was still present in endothelial cells exposed to heat-inactivated sera from women with preeclampsia as compared with heat-inactivated sera from normally pregnant women ($p < 0.01$) (Fig. 8).

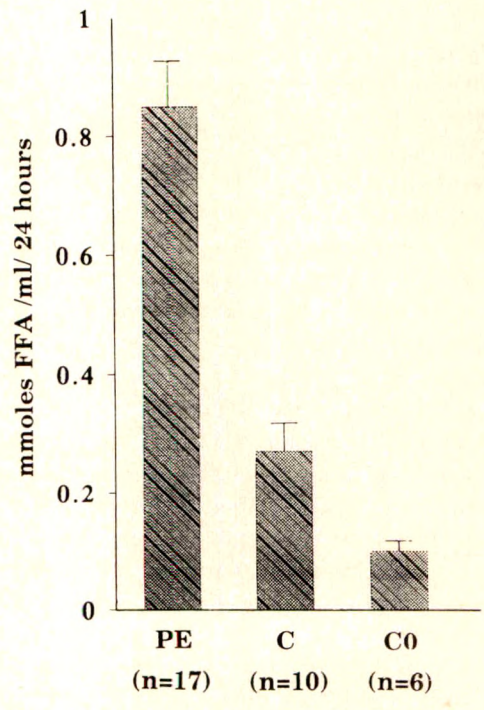

Fig. 7. Net increase in free fatty acids *(FFA)* in sera from preeclamptic women *(PE)*, from normal pregnancies *(C)*, or from nonpregnant women *(C0)*. A total of 50 µl of the various sera was incubated at 37° C for 24 hours, and increase in free fatty acid concentrations was measured. Numbers of individual sera and SD are indicated for each *bar*.

Comment

We recently reported that sera from women with preeclampsia induce accumulation of triglycerides in cultured endothelial cells.[5] In the current work we pro-

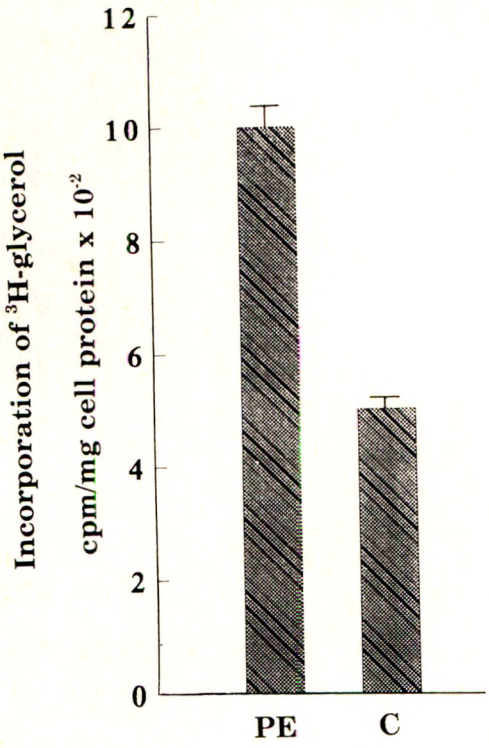

Fig. 8. Incorporation of tritiated glycerol into endothelial triglycerides after thermal treatment of sera. Endothelial cells were exposed for 96 hours to either sera from preeclamptic women *(PE)* or sera from normal pregnancies *(C)* that had previously been heat inactivated at 57° C for 60 minutes. Each *bar* represents mean ± SD of triplicate incubations.

vide strong evidence that the endothelial triglyceride accumulation is due to increased uptake of free fatty acids from the culture media containing sera from women with preeclampsia. We demonstrate that the endothelial triglyceride content increased by adding free fatty acids to the control sera. Conversely, by providing sera from women with preeclampsia with additional albumin the endothelial triglyceride accumulation was inhibited. Thus by altering the ratio of free fatty acids to albumin the degree of triglyceride accumulation in endothelial cells could be controlled. This is in accordance with the general conception that the major determinant of free fatty acid uptake in cells is the ratio of free fatty acids to albumin. Finally, we found only a minor effect of the triglyceride-rich very-low-density lipoprotein particles on the content of triglycerides in the endothelial cells.

The in vivo ratio of free fatty acids to albumin was higher in sera from preeclamptic women compared with controls. In experiments where the release of free fatty acids from the sera was minimized by heat inactivation of the lipolytic enzymes, a 100% higher incorporation of tritiated glycerol into endothelial triglycerides was still present after incubation with sera from women with preeclampsia compared with sera from normally pregnant women. In addition, the sera from women with preeclampsia contained an increased lipolytic activity that further amplified the ability of the sera to induce triglyceride accumulation in the endothelial cells.

Interactions of plasma lipids, lipoproteins, and the endothelial cells have been shown to be of major importance in the early development of atherosclerosis.[4] The endothelial cells can induce oxidative modifications of plasma low-density lipoprotein. Oxidized low-density lipoprotein is cytotoxic to endothelial cells and is taken up rapidly by macrophages, giving rise to foam cells.[4, 6] Also, remnants of triglyceride-rich lipoproteins are toxic to cultured endothelial cells.[10] Hyperlipidemia has been shown to inhibit endothelium-dependent relaxation of vasculature in vivo.[11] Furthermore, in vitro production of prostacyclin is influenced by both plasma lipoproteins and the types of fatty acids present.[12, 13] Thus there is ample evidence that the plasma lipids may interfere with the properties of endothelial cells.

Our previous work and the current study demonstrate that alterations in the lipolytic activity and the increased ratio of free fatty acids to albumin can change the properties of cultured endothelial cells. These findings have two aspects. First, the enhanced lipolytic activity of sera from women with preeclampsia further underscores that the lipid metabolism of women with preeclampsia is altered. Second, the free fatty acids and possibly other lipid or enzymatic components of the sera from women with preeclampsia may be mediators in inducing endothelial dysfunction in preeclampsia.

To further test "the lipid hypothesis of preeclampsia" studies are in progress to characterize the enhanced lipolytic activity of sera from women with preeclampsia.

We thank Hallvard Gjønnæss for valuable discussions and support and Antonio B.S. Poleo for helpful advice in the preparation of the manuscript.

Use of the fetal chest in estimating fetal weight

Hung N. Winn, MD,[a] Phillip N. Rauk, MD,[b] and Roy H. Petrie, MD, ScD[c]

St. Louis, Missouri, and Pittsburgh, Pennsylvania

OBJECTIVE: This study was designed to develop formulas using the chest circumference instead of the abdominal circumference for estimating fetal weight.

STUDY DESIGN: Ultrasonographic measurements of the chest circumference, biparietal diameter, abdominal circumference, humeral length, and femoral length were obtained in 75 term fetuses of uncomplicated pregnancies within 24 hours of delivery. Three equations for fetal weight estimation that used the chest circumference, instead of the abdominal circumference, in combination with the biparietal diameter or the humeral length were developed by regression analysis.

RESULTS: The average mean errors of fetal weight estimation for these equations vary from 7.1% to 7.6%.

CONCLUSIONS: These equations may be used in predicting the birth weight when the fetal abdomen is altered by certain fetal abnormalities. (Am J Obstet Gynecol 1992;167:448-50.)

Key words: Fetal chest, fetal weight

Estimating the fetal weight by ultrasonography on the basis of computer-generated equations has been useful in the clinical management of many obstetric conditions. Equations that use the abdominal circumference (AC) in combination with the head circumference (HC), the biparietal diameter (BPD), or the femoral length (FL) have been extensively used for this purpose.[1-3] Certain fetal conditions such as abdominal wall defects, significant uropathy, and intestinal ob-

struction or atresia may make the AC unsuitable for an accurate estimation of the fetal weight. This study was designed to develop formulas that use the chest circumference (CC) instead of the AC for estimating fetal weight.

Material and methods

This study was carried out at the Washington University Medical Center during the period from Aug. 1, 1989, to Oct. 30, 1989. Ultrasonographic measurements of BPD, HC, AC, CC, FL, and humeral length (HL) were made in 75 term fetuses of uncomplicated pregnancies within 24 hours of delivery with the use of a 3.5 MHz linear transducer. The BPD was measured at the level of the midbrain from the outer margin to the inner margin of the proximal and distal skull tables respectively. The femoral length was measured from the greater trochanter to the lateral epicondyle. The chest circumference was measured in a transverse plane at the level of the four-chambered view of the heart along the bony margins of the chest (Fig. 1). Anteroposterior (AP) and transverse (TRV) diameters were measured and the circumference was calculated according to the formula: Circumference = (AP + TRV) × 1.57. The relationship between ultrasonographic measurements (BPD, HC, CC, AC, FL, and HL) and birth weight (BWT) was retrospectively examined by stepwise regression analysis based on 45 patients. Equations for estimating the fetal weight by means of the chest circumference with the best correlations were developed. These equations were then prospectively used to estimate the fetal weight in 30 patients. For comparison, the estimated fetal weights were also obtained from the following previously published equations that utilize the AC: Log 10 BWT =

$-1.7492 + 0.166(BPD) + 0.046(AC) - 2.646(AC + BPD)/1000$ and Log 10 BWT $= 1.3598 + 0.051(AC) + 0.1844(FL) - 0.0037 (AC \times FL)$. These two equations are from references 1 and 2 and are identified as equations 4 and 5, respectively, in our subsequent discussion and in Tables II and III. Relative error was calculated by dividing the difference in the estimated fetal weight (EFW) and the BWT by the BWT. Underestimation of the birth weight results in a negatively relative error. The Student *t* test was used to compare the mean percentage errors of estimating fetal weight by our equations with those by equations 4 and 5. A *p* value of <0.05 is considered statistically significant.

Results

Birth weights range from 2260 to 4740 gm. The chest circumference varies linearly with the birth weight with a correlation coefficient of 0.69 and a *p* value of 0.001 (Fig. 2). The three best-fit equations that used CC in combination with BPD, HL, or FL are presented in Table I. The correlation coefficients of these equations are 0.86, 0.87, and 0.88, respectively. The accuracy of predicting the birth weight is summarized in Tables II and III. Table II shows the means and the standard deviations of the systematic percentage error. Table III shows the percentage of patients with the estimated fetal weight within 5%, 10%, or 15% of the birth weight, respectively. The equations containing CC tend to underestimate the birth weight. The difference in the relative mean percentage error of predicting BWT between the equations that use CC and those using AC as proposed by Shepard et. al.[1] or Hadlock et al.[2] is statistically significant (Table II). The intraobserver variation coefficient for measuring the chest circumference is 5%.

Comment

Chest circumference linearly increases while the ratio of the chest circumference to the abdominal circumference remains constant at about 0.89 as gestation advances during the interval of 16 to 40 weeks.[4] The chest circumference increases on an average 9.1 mm and 6.3 mm per week during the intervals of 20 to 30 weeks and 30 to 40 weeks, respectively.[5] Our study demonstrated that the chest circumference correlates proportionately with the birth weight in normal term pregnancies. In addition, the mean percentage error of fetal weight estimation with the CC, HL, and BPD as in our equation 3 is 8.1%, which is comparable to that reported by others using the AC.[1, 3] Fifty-seven percent of our patients have the estimated fetal weight within 10% of the birth weight. Similarly, Shepard et al.[1] reported that the fetal weight could be predicted within 10% of the birth weight with the use of the computer-generated formula and both the AC and BPD in 54.8% of their patients. Our study demonstrates that the equations that use the AC are more accurate in predicting the birth weight than those that use the CC for the same study population. Thus the previously published equations that use the AC in combination with BPD, FL, or both are preferable to ours in estimating fetal weights when AC can be accurately measured in term pregnancies. However, our equations could be reasonable alternatives when the measurement of the AC may not be optimal for the purpose of fetal weight estimation. The latter may occur in fetal conditions such as abdominal wall defects, obstructive uropathy, or bowel obstruction. The increased fetal abdominal circumference in these situations may not necessarily reflect the increased fetal weight.

Thus our equations that use the CC in combination with the BPD or HL can be used to estimate fetal weight with a high degree of accuracy. These equations may be helpful in selected cases of fetal abnormalities.

Oral condyloma lesions in patients with extensive genital human papillomavirus infection

Pierluigi Benedetti Panici, MD,[a] Giovanni Scambia, MD,[a] Lidia Perrone, MD,[a] Francesco Battaglia, MD,[a] Paola Cattani, MD,[b] Carla Rabitti, MD,[c] Giuseppe Dettori, MD,[b] Arnaldo Capelli, MD,[c] Alexander Sedlis, MD,[d] and Salvatore Mancuso, MD[a]

Rome, Italy, and Brooklyn, New York

OBJECTIVES: The incidence, location, and morphologic appearances of human papillomavirus oral lesions in patients with genital condylomatosis were investigated with clinical, colposcopic, and histologic examination as diagnostic procedures. The human papillomavirus types were also evaluated with filter in situ hybridization.

STUDY DESIGN: One hundred one patients, 66 female and 35 male, with genital condyloma underwent an oral cavity examination. Ninety-nine (99%) practiced orogenital sex, and all were asymptomatic for oral lesions.

RESULTS: Ninety-one underwent biopsy; histologic studies gave a diagnosis of condyloma in 48% of 101 specimens collected. In 8 of 91 (9%) oral lesions were suspected by naked-eye examination; they were confirmed histologically in all eight. Of 83 patients suspected of having oral condyloma on colposcopic examination, 38 (46%) were confirmed histologically. Thus 38 of 46 patients (83%) had oral condyloma not visible to the naked eye. Colposcopically, oral lesions appeared filiform (50%), moruloid (26%), and mixed (24%). Twenty cytologic oral samples were also collected for deoxyribonucleic filter in situ hybridization analysis. Human papillomavirus deoxyribonucleic genital types were observed in 45% (9/20) of all oral scrapings collected, and all were histologically confirmed.

CONCLUSION: Our data indicate that genital human papillomavirus types are capable of establishing a local infection in the oral cavity and demonstrate a high incidence of human papillomavirus oral lesions in patients with genital condyloma. (Am J Obstet Gynecol 1992;167:451-8.)

Key words: Oral condyloma lesions, human papillomavirus, colposcopy

In the oral cavity the presence of various clinical expressions of different human papillomavirus (HPV) types has been reported by several authors.[1-5] In particular HPV type 13 has been found to be exclusively associated with focal epithelial hyperplasia.[6, 7] Moreover, recently the presence of HPV types 6, 11, 16, and 18 has also been found in different oral lesions.[8-11] However, the prevalence and clinical spectrum of HPV oral cavity infection and the oncogenic potential of these lesions are still unknown. The manner of HPV transmission into the oral cavity is not precisely known. Direct contact and self-inoculation are probably the main contributors to the diffusion of the disease in sexually active individuals.[12-14]

In this study we wanted to investigate the presence, location, and morphologic appearances of HPV oral lesions in patients affected by genital condylomatosis by means of clinical, colposcopic, and histologic examination as diagnostic procedures. A series of 20 patients were also evaluated for the presence of HPV types in oral cavity lesions with filter in situ hybridization.

Material and methods

From February 1988 through February 1990, 101 unselected, consecutive patients attending the Colposcopy Clinic of the Department of Gynecology of the Catholic University were evaluated and enrolled for an oral cavity examination. All patients gave consent to participate in the study, and no one refused an oral cavity inspection with histologic examination. The study group consisted of 66 female (median age 33 years, range 18 to 45) and 35 male (median age 32 years, range 24 to 45) subjects with histologically confirmed genital condyloma. All patients were asymptomatic. The median age of the first coitus was 16 years (range 15 to 22), and the median number of partners was four (range 1 to 15). Ninety-nine of 101 patients (98%) practiced orogenital sex, and all showed one or more genital sites affected by HPV. In particular female patients showed vulvar (100%), cervical (56%), urethral (48%), vaginal (45%), and perianal and anal (38%) HPV lesions, whereas male patients showed HPV lesion of

the penile prepuce (87%), the penile shaft (25%), the glans with corona (35%), and the urethra meatus (3%).

The epithelial surface of the oral cavity was inspected visually and by colposcopic examination with a Opm1 CD PLUS Zeiss colposcope (Zeiss, Oberkochen Germany).

Excisional biopsies under colposcopic guidance were taken from suspected HPV oral lesions. Specimens were placed in formalin for routine histologic studies. Cytologic oral samples were collected from the last 20 patients with cotton exfoliating swabs before biopsy, and samples were put in phosphate-buffered saline solution and stored at −20° C until assayed by filter in situ hybridization technique.

Clinical and colposcopic terminology. After application of a 5% acetic acid solution in the oral mucosa and in the back and bottom of the tongue, which is left in place for 2 to 3 minutes, it is frequently possible to reveal the presence of white areas and colposcopic lesions similar to those observed in the genital tract. The following types of characteristic colposcopic lesions were observed: (1) white filiform lesions with an evident capillary loop (2) white, roundish lesions with a central capillary loop and irregular surface (like a microscopic mulberry), which we defined "moruloid" and (3) shiny white keratotic plaques.

Because of some morphologic similarites to HPV-related lesions of the genital tract, we hypothesized that these lesions could be indicative of HPV infection of oral cavity.

We recorded all lesions ≤2 mm or >2 mm in the two major perpendicular diameters and also the number of lesions more than five or less than five in number for each oral area affected.

Histologic terminology. Typical oral condyloma had histologic features similar to those found in the genital area, where squamous epithelium with mild infiltration of lymphoid cell is present. The epithelium showed acanthosis (increased thickness of the spinous layer), hyperkeratosis (increased thickness or density of the stratum corneum), and koilocytosis (normal to enlarged hyperchromatic mononuclear or binuclear cells with perinuclear cytoplasmic vacuolization). The presence of multiple koilocytosis was taken as the pathognomonic criteria to classify the lesion as condyloma. Therefore, lesions showing only minimal histologic changes, i.e., a mild degree of acanthosis and hyperkeratosis without koilocytosis or focal isolated koilocytotic changes, were not classified as condyloma.

Filter in situ hybridization. Filter in situ hybridization technique was performed according to the method described by Wagner et al.[15]

By means of a counting chamber, the number of cells was estimated to be about 1 × 10 E4 epithelial cells for each sample. After thawing, the cells were resuspended and filtered into a nitrocellulose filter (0.45 μm pore size, 25 mm diameter, Sartorius Filters Inc., Hayward, Calif.).

Cell lysis and deoxyribonucleic acid (DNA) denaturation were performed by overlaying the filter on a Whatman 3 MM paper, which was soaked in 1.5 mol/L sodium chloride and 0.05 mol/L sodium hydroxide for 5 minutes. Filters were then placed twice for 10 minutes on a Whatman 3 MM paper previously soaked in 0.5 mol/L Tris, pH 7.4, 20× saline sodium citrate (3 mol/L sodium chloride and 0.3 mol/L sodium citrate). Filters were air dried and baked at 80° C for 30 minutes to fix the DNA . Each filter was cut in half and stored in 50 ml plastic Falcon tubes (approximately 40 half filters per tube) until further processing.

The filters were prehybridized for 4 hours at 42° C. The prehybridization solution consisted of 50% formamide, 5× saline sodium citrate, 50 mmol/L sodium phosphate buffer (pH 6.5), 0.02% bovine serum albumin, 0.02% Ficoll 400, 0.02% polyvinylpyrrolidone, 0.05 mg/ml denatured transfer ribonucleic acid (Boehringer Mannheim, Germany).

Hybridization was performed for 40 hours under stringent conditions at 42° C, which corresponded to 20° C below melting temperature (−20° C). The solution was the same as above; however, the concentration of transfer ribonucleic acid was modified (0.1 mg/ml) with the addition of 2 × 10 E6 counts/min/ml of denatured phosphorus 32–labeled HPV DNA probe.

After hybridization the filters were washed three times for 30 minutes in 2× SCC containing 0.1% sodium dodecyl phosphate at 68° C.

The most filters were placed in stampholders and exposed to Kodak (Eastman Kodak Co., Rochester, N.Y.) X-Omat radiographic film for 5 days at −70° C.

(Original magnification ×12.) **B,** Some moruloid lesions of lateral border of tongue. (Original magnification ×12.) **C,** Both filiform and moruloid lesions are evident in this patient with oral HPV infection. (Original magnification ×12.)

Probe DNA and radiolabeling. Recombinant plasmid containing types 6, 11, 16, and 18 DNA were kindly provided by Dr. E. M. de Villiers (Deutsches Krebsforschung Zentrum, Heidelberg).

The HPV DNA recombinant clones were amplified by standard methods.[16] The HPV DNA insert was separated from the vector by restriction enzyme digestion, electrophoresis, and electroelution and was subsequently purified over NACs Prepac columns (BRL, Gaithersburg, Md.) as recommended by the manufacturer. The DNA was labeled with ^{32}P-deoxythymidine (New England Nuclear, DuPont) by nick translation to a specific activity of >10 E8 counts/min/μg of DNA.[17]

The filter in situ hybridization was performed with two mixtures of HPV types 16 and 18 DNA and HPV types 6 and 11 DNA, respectively.

Results

Oral lesion characteristics are shown in Table I. Of 101 patients with extensive genital HPV infection, 91 (90%) were found to have suspicious oral lesions. In all suspected patients the tongue was affected, and the lesions were located on lateral borders and lower and back surface (Fig. 1). Colposcopic findings of the tongue consisted of filiform (Fig. 1, *A*) or moruloid lesions (Fig. 1, *B*), whereas both types of lesion can be observed in the same patient (Fig. 1, *C*).

All patients with suspected oral condyloma lesions underwent biopsy. Seventy-five patients had a single biopsy, and 16 had two biopsies, for a total of 107 specimens. The histologic examination of the 107 specimens collected gave a diagnosis of condyloma in 49 out of 101 (48%) specimens. In six cases (6%), specimens were not sufficient for a diagnosis. In the remaining 52 specimens, histologic studies gave a diagnosis of papillomatosis in 10%, leukoplakia in 8%, hyperkeratosis in 7%, mixed in 10%, and normal tissue in 10%. No intraepithelial neoplasia was detected. Morphologically, the 107 specimens collected for histologic examination appeared as filiform lesions in 64 cases (60%), as moruloid lesion in 28 cases (26%), as leukoplakia in only one case (0.9%), and as mixed lesions in the remaining 14 cases (13%). Moruloid and filiform colposcopic lesions showed different histologic features; in the first form (Fig. 2, *A* and *B*) the epithelial lining surface was flat, whereas in the latter (Fig. 3, *A* and *B*) the epithelium covered dermal fibrovascular axes in fine digita-

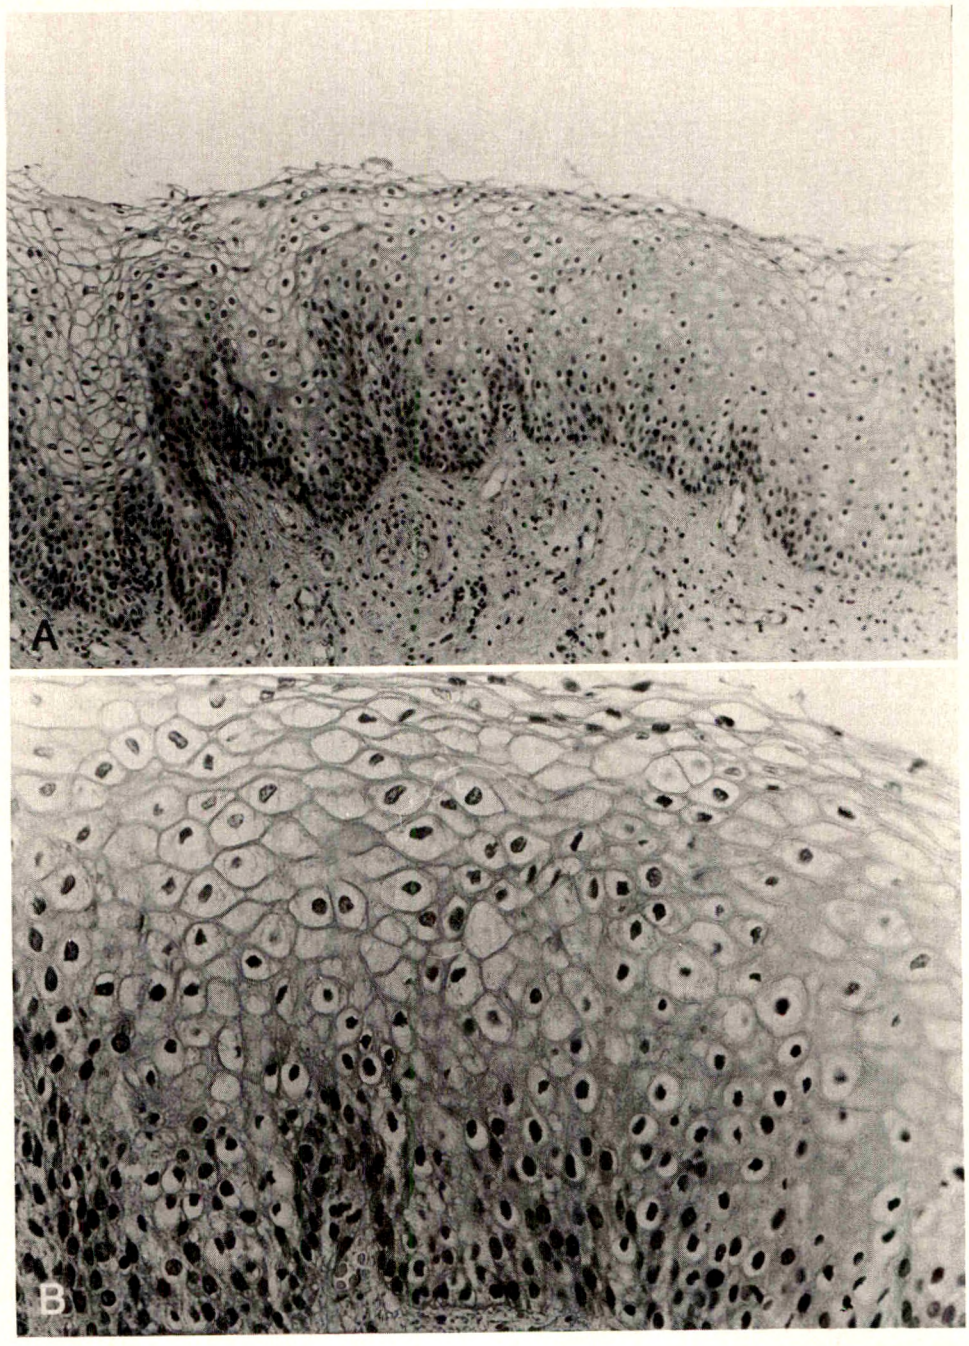

Fig. 2. A, Photograph shows epithelial lining with flat surface. There is a mild degree of papillomatosis and a moderate flogistic infiltrate in chorion. (Original magnification ×250.) **B,** Higher magnification showing epithelial koilocytotic changes. (Original magnification ×400.)

tions. Eight of 91 patients (9%) were found to have suspicious oral lesions by visual inspection, and all were confirmed histologically. Among 83 patients colposcopically suspected for oral condyloma, 38 (46%) were histologically confirmed; thus 38 of 46 patients (83%) had oral condyloma not visible to the naked eye.

Among 48 histologically confirmed diagnoses of tongue condyloma, 17% were located in the lower surface, 71% on the lateral borders, and 13% on the dorsum of the tongue. Histologic studies gave a diagnosis of condyloma in one of three biopsy specimens taken from lip and oral mucosa. Table II also shows the correlations between morphologic type, location of colposcopic lesions, and histologic type. The lateral borders of the tongue showed only filiform warts in 70% (42/60) of sites, and 66.6% of these were histologically confirmed. Most of remaining cases showed mixed morphologic types. On the other hand, all lesions lo-

cated on the dorsum of the tongue had a moruloid surface and were histologically confirmed as condyloma in 27.2% of cases.

The correlation between the colposcopic features and the histologic findings is reported in Table III. In particular, koilocytes were more frequently present in filiform lesions than in moruloid lesions.

Finally, to confirm the relationship between genital and oral condyloma lesions, cytologic oral samples obtained from the last 20 patients observed were analyzed for the presence of genital type HPV DNA by filter in situ hybridization (Table IV). HPV DNA were found in nine of 20 (45%) different patients. In five (56%) of the HPV-positive patients the viral sequences were homologous to those of HPV types 6 through 11, and in three (33%) they were homologous to types 16 through

Leukoplakia	2	—	—	1	50

18. In one case viral DNA homologous to that of types 6, 11, 16, and 18 was present. In the same 20 patients cytologic cervical samples were also collected. Among these 12 samples were positive for HPV types, with a concordance rate between cervical and oral samples of 80%. Finally, the correlations between the sites of tongue localization of lesions and HPV DNA type in the nine patients with oral HPV infection are shown in Table V.

Comment

Our study shows that 50% of patients with multiple and widespread genital HPV infection who practice orogenital sex had histologically confirmed oral condylomas. This high incidence in a large series of patients, all asymptomatic for oral lesions, has never been reported in literature, although in the last years an increasing interest in HPV research by oral pathologist has been reported, and the genital oral sexual transmission of the organism has been hypothesized.[9, 11, 13, 14]

Our results may be related to the particular sexual behavior of patients analyzed, who practiced orogenital sex. The simultaneous cytologic detection of the same HPV types both in the oral cavity and the genital tract of patients supports this mode of transmission. However, the systematic use of colposcopy as a diagnostic procedure must also explain the higher incidence of oral HPV lesions in our study, compared with other studies in which colposcopy was not performed.[7, 10, 11, 13]

In fact, the much higher sensitivity of colposcopy with respect to simple visual examination (83% vs 9%) suggests that magnification is a mandatory procedure for detecting oral lesions. Colposcopy also allows us to establish the exact location, number, and morphologic appearance and to perform direct biopsies of the oral areas suspected. In contrast to others authors who reported oral condylomatous lesions equally distributed among various oral cavity sites,[14] in our series the tongue represents the oral site most frequently affected. In our series oral condylomas appeared as multiple, small, white or pink nodules, sessile or pedunculate with a moruloid aspect, and as papillary growth with filiform characteristics. The size of oral lesions was >2 mm in >50% of lesions, and in 61% of cases more than five lesions were present. Therefore our data confirm and extend previous observations obtained in small series of patients.[9, 11, 14]

Histologic examination gave a diagnosis of oral condylomas in 48% of 101 biopsies collected, whereas 27% of the remaining negative specimens showed features usually indicative of the presence of HPV infection.[21] The histologic finding of normal tissue in 10% of our biopsy material could be ascribed at least in part to an incorrect sampling.

HPV types 6, 11, and 13 have been identified in warty lesions of the oral cavity.[5, 22] HPV type 16 has also been found, but it is less commonly associated with benign oral lesions.[5] The results reported in our study demonstrate that HPV types 16 and 18 and 6 and 11, which

are frequently found to be associated with genital lesions, can be also detected in cells obtained from oral condyloma with filter in situ hybridization. Moreover, the incidence of lesions positive for these HPV types in the oral cavity resembles the one previously demonstrated for the genital condyloma.

In fact, HPV DNA was observed in 45% (9/20) of all oral scrapings examined, and all were histologically confirmed. It is interesting to note here that the greater number of positive samples for HPV types 6 and 11 (55%) compared with those which had DNA homologous to types 16 and 18 (33%). These data might have a prognostic significance for these patients. Moreover, the presence in the oral cavity of HPV types 16 and 18, which are more frequently associated to malignant genital diseases, point to the importance of having a simple and noninvasive technique that allows screening and follow-up of a high number of subjects in whom HPV infection is suspected. On the basis of this report a large clinical trial is now in progress in our department, aimed at comparing the occurrence of HPV subtypes in simultaneous biopsies taken from different areas of the genital tract and oral cavity from patients with histologically confirmed genital and oral condyloma.

The presence of genital types of HPV DNA in cells obtained from oral condylomatous lesions indicates that these viruses are capable of establishing a local infection in different sites of the oral cavity. From our data and in agreement with other authors,[5, 20] it should be hypothesized that primary oral infection can follow a direct contact between virus and oral epithelium, as suggested by the sexual behavior of the patients studied, whereas secondary infections may result from hematogenous spread or autotransmission in patients with a HPV genital infection.[4, 5]

In conclusion, the presence of genital condylomas should alert the clinician to inquire about the presence

of simlar wartlike lesions in the oral cavity, with particular regard to those patients who practice orogenital sex. Moreover, colposcopy appears to be an invaluable aid in establishing the diagnosis of oral condyloma.

A comparison of circulating hormone levels in postmenopausal women receiving hormone replacement therapy

Raymond W. Jurgens, Jr., PhD,[a] Laurence J. Downey, MD,[a] William D. Abernethy, BS,[a] Neal R. Cutler, MD,[b] and Julie Conrad, RN[b]

Marietta, Georgia, and Beverly Hills, California

Seventeen postmenopausal subjects were randomized into this comparative study of esterified estrogen 0.625 mg (Estratab), esterified estrogen 0.625 mg plus 1.25 mg methyltestosterone (Estratest H.S.), or conjugated estrogen 0.625 mg (Premarin). Sixteen subjects completed the study in which plasma hormone concentrations of estrone and estradiol were assessed at various time points. There were no significant differences among the treatment groups. (Am J Obstet Gynecol 1992;167:459-60.)

Key words: Hormone levels, postmenopausal women, hormone replacement therapy

There are many different products available to clinicians for the treatment of postmenopausal symptoms, as well as a number of therapeutic regimens.[1] Each product has been shown to have particular benefits and allow for individual needs and concerns of patients, as well as their physicians. Management of postmenopausal symptoms usually includes oral estrogen, progestogen, and androgen formulations currently marketed. Whereas a number of estrogen formulations have been prescribed for decades, there is little comparative information available on the differences in potencies and pharmacologic effects. Some laboratories have measured free and total plasma estradiol and estrone levels during a 25-day administration of estrone sulfate and estradiol. Others have correlated estrogenic potency with hepatic protein production after administration of various oral, transdermal, and vaginally delivered estrogen preparations.[2]

The purpose of this study was to measure and compare plasma levels of estrone and estradiol in postmenopausal women after the administration of commercially available oral esterified or conjugated estrogen products.

Patients and methods

The investigation was approved by the local human investigation committee and informed consent was obtained. Seventeen postmenopausal subjects (14 natural and three surgical) entered the study. The demographic characteristics were similar across the three treatment groups. Mean age was 53.95 years with a range of 37.9 to 65.8 years. Two patients presented with menopausal symptoms at screening. At baseline (after washout) six patients were experiencing menopausal symptoms. Seventy-one percent of the subjects were white and 29% were categorized as other (Hispanic, $n = 3$; black, $n = 1$). Subject 60186 did not meet inclusion-exclusion criteria and was dropped from the study shortly after treatment was begun.

After patient randomization, blood samples were taken from patients at baseline and 8 hours after the first dose of drug. Patients returned to the clinic weekly for 5 weeks while taking medication at the same time daily after their morning meal. Blood samples were drawn 8 ± 2 hours after the dose of study medication at each clinic visit for assay of plasma hormone levels. The plasma follicle-stimulating hormone level was de-

termined at screening and on day 29. One week after administration of the last dose of study drug (day 36), patients returned to the clinic for final evaluation and blood drawing. Estrone, estradiol, and follicle-stimulating hormone were measured by radioimmunoassay (Nichols Laboratories, San Juan Capistranc, Calif.).

Results

Sixteen subjects completed the study: six in the Estratab group, five in the Estratest H.S. group, and five in the Premarin group. There were no significant differences between the treatment groups in the plasma concentrations of estrone and estradiol measured at any of the time points. The mean change in follicle-stimulating hormone from screening to day 29 was clinically insignificant among the three treatment groups (see Table I for subject levels). Vital signs remained constant over the course of the study.

Comment

As can be seen in Fig. 1, estrone and estradiol levels were fairly constant during treatment. Similar blood concentration levels appeared to be reached after a week of treatment with all three products. Circulating estrogens were cleared at the same rate after the end of treatment with all products and levels returning to approximately baseline levels within 7 days. The biologic action on the ovarian-pituitary feedback loop was apparently equivalent for all products, as they all appeared to suppress follicle-simulating hormone similarly after treatment with the study drug.

Prenatal diagnosis of human parvovirus B19 in nonimmune hydrops fetalis by polymerase chain reaction

Bruce W. Kovacs, MD, Dru E. Carlson, MD, Bejan Shahbahrami, MS, and Lawrence D. Platt, MD

Los Angeles, California

OBJECTIVE: Nonimmune hydrops fetalis is a potentially lethal condition reflecting the clinical manifestation of several pathologic processes. Recently maternal infection by human parvovirus B19 has been reported to result in nonimmune fetal hydrops. We sought to develop a rapid and sensitive test to detect the presence of this agent in utero.

STUDY DESIGN: Using a cloned isolate of the virus, we developed an assay based on enzymatic amplification of a segment of the human parvovirus B19 genome that allows direct detection of this agent in samples of fetal blood and amniotic fluid.

RESULTS: The method detected as few as 100,000 genome equivalences and was specific for the viral genome alone. We used this assay to evaluate nine fetuses initially seen with nonimmune hydrops. Three cases were found to be positive for the human parvovirus B19 genome.

CONCLUSION: The method is powerful in that it is rapid, sensitive, and simple. This assay may have general applicability in evaluation of nonimmune hydrops and in documentation of the natural history of fetal human parvovirus infections. (AM J OBSTET GYNECOL 1992;167:461-6.)

Key words: Prenatal diagnosis, parvovirus B-19, hydrops fetalis, polymerase chain reaction

Hydrops fetalis is a potentially lethal condition that can be caused by immunologic or nonimmunologic factors. The advent of measures to prevent rhesus factor isoimmunization has resulted in nonimmune fetal hydrops becoming the most frequently encountered form of this condition in the United States.[1] It is estimated that this condition complicates 1 in every 3000 to 4000 pregnancies.[2]

Importantly, a variety of conditions have been associated with nonimmune fetal hydrops. Therefore depending on the cause the fetal outcome can be quite variable. In some cases the hydrops appears to resolve spontaneously, resulting in an apparently normal offspring. However, in other cases the prognosis for the fetus is grave.[3] When fetal hydrops is diagnosed by ultrasonography a clinical dilemma arises with respect to the most appropriate counseling and management. Thus it is important that as much information as possible be gathered relative to the cause so that the antenatal management of this disorder is optimal.[4]

Recently maternal infection by human parvovirus B19 during gestation has been reported to be associated with nonimmune fetal hydrops.[5] Therefore in addition to other modalities of diagnosis a rapid test to detect the presence of human parvovirus B19 in utero would add to the clinical tools used in the evaluation of nonimmune hydrops and aid the clinician in management decisions. In this study we report on a sensitive method to detect the presence of the human parvovirus B19 deoxyribonucleic acid (DNA) in clinical specimens based on sequence-specific DNA amplification.[6] This polymerase chain reaction detection method was used to identify a portion of the parvovirus B19 genome in samples of fetal blood and amniotic fluid obtained from several pregnancies presenting with nonimmune hydrops fetalis.

Material and methods

A 20-base oligonucleotide probe complimentary to nucleotides 1730 through 1749 of a human parvovirus B19 isolate[7] was synthesized on an automated DNA synthesizer (model 380, Applied Biosystems, Foster City, Calif.) and purified by high-performance liquid chromatography and acrylamide gel electrophoresis. Hybridization of this probe to cloned plasmid DNA and DNA obtained from clinical samples was performed either in gel or with nylon membranes after radiolabeling the B19 oligonucleotide probe with phosphorus 32–labeled adenosine triphosphate T4 polynucleotide kinase.[8] The conditions of hybridization for both the dried gels or nylon membranes was at 60° C for 8 to 12 hours in 6× standard saline citrate buffer contain-

ing 10 μg/ml transfer ribonucleic acid and 2×10^{-6} cpm/ml of the B19 oligonucleotide probe.[8] After hybridizations the matrixes were washed in 6× standard saline citrate buffer for 2 to 3 hours at room temperature and 30 minutes at 65° C. Gels and membranes were then autoradiographed with intensifying screens at −70° C for 1 to 3 days.

The primer set for enzymatic amplification of the parvovirus B19 genome by polymerase chain reaction was synthesized and purified in the same way as B19 oligonucleotide probe. The 5′ primer was identical to nucleotides 1667 through 1686 of the parvovirus genome; the 3′ primer was the reverse compliment of nucleotides 1921 through 1940 of the viral genome.[7] The primers for the human genomic positive standard were composed of a pair of oligonucleotides that amplify a 700 base-pair segment previously described in the human actin gene.[9] The conditions for the polymerase chain reaction amplification were optimized for a 100 μl reaction volume with 2.5 units of Taq polymerase (AmpliTaq, Perkin-Elmer Cetus, Norwalk, Conn.). Each reaction mixture contained 50 mmol/L potassium chloride, 10 mmol/L Tris pH 8.3, 2.5 mmol/L magnesium chloride, 1.0 mmol/L deoxynucleoside triphosphates, 40 pmol/L each primer, 4 mmol/L spermidine hydrochloric acid, and various amounts of template DNA as noted in results. Each reaction mixture was overlayed with mineral oil; after an initial incubation at 97° C for 4 minutes, 30 cycles of amplification were carried out, each consisting of 1 minute at 94° C and 3 minutes at 65° C. After the amplification 10 μl aliquots of the reaction mixture were either subjected to electrophoresis in 2% agarose gels for 1 hour at 60 V or spotted onto nylon membranes with a dot blot device. Nonisotopic detection of the amplification product was done by staining gels with ethidium bromide for 15 minutes; the gels were then visualized and photographed with ultraviolet light.

The known positive standard template DNA source was the plasmid pYT104C (a gift from P. Tattersall) containing the entire coding sequence of a human parvovirus B19 isolate.[7] Before hybridizations and polymerase chain reaction amplifications the plasmid DNA was linearized by *Sal* I digestion.

Clinical samples consisted of 1.5 ml of amniotic fluid or 0.25 ml of fetal cord blood obtained antenatally by ultrasonographically guided amniocentesis or percutaneous umbilical blood sampling from gestations initially seen at various gestational ages with hydrops fetalis. Samples of maternal peripheral blood were also obtained at initial evaluation. The basic clinical aspects of the gestations evaluated are summarized in Table I. Blood and amniotic fluid samples were prepared for dot-blotting or polymerase chain reaction by a rapid freeze-thaw followed by centrifugation at 12,000 rpm in a microfuge for 5 minutes to obtain a supernatant free of cell debris. In both the dot blot and polymerase chain reaction experiments 20 μl of supernatant was used without further treatment. Approval for use of the test on material from human subjects was obtained from the institutional research committee.

Results

The sensitivity and specificity of the B19 oligonucleotide probe and the optimal conditions for hybridization were determined by dot blots with serial dilutions of DNA isolated from plasmid pYT104C suspended in buffer. The quantity of DNA spotted onto the nylon membrane for this determination ranged from 10 pg to 1 μg. In addition, 0.1 μg of plasmid DNA was added to 0.5 ml lysed whole blood from an uninfected individual and spotted onto the nylon membrane. An additional control of 0.5 ml lysed whole blood without pYT104C DNA was also used. The results of these hybridizations are shown in Fig. 1. This experiment demonstrated that, under our conditions, the B19 oligonucleotide probe detected as little as 10 pg of the parvovirus DNA, equivalent to about 2×10^5 viral particles. Parvovirus DNA was also detected in the presence of whole blood, although the signal strength was slightly less intense than that seen with an equivalent quantity of target DNA suspended in buffer. Thus

in the presence of whole blood the lower limit of sensitivity was about fivefold less than the sensitivity in buffer, or about 10^6 viral particles. No hybridization signal was detected at the spot containing only lysed whole blood, indicating absence of detectable nonspecific hybridization to human DNA.

We next used the primers B19A/B with the linearized whole plasmid DNA for polymerase chain reaction amplifications. To optimize the reaction, various parameters of thermal cycling were tried. In these experiments we used a 1 μg quantity of pYT104C DNA as the target for amplifications. Negative controls consisted of 1 μg of human DNA, a 30 μl sample of lysed whole blood (both obtained from a noninfected person), or an aliquot of sterile buffer. Gel electrophoresis of the amplification reaction products revealed that after an initial denaturation step at 95° C for 1 minute the 274-base-pair product was best amplified with a single temperature for annealing and extension. The negative controls did not yield any amplification product. To document that the amplification product was derived from the parvovirus genome the gels were hybridized to radiolabeled B19 oligonucleotide probe. The autoradiographs from this hybridization demonstrated that the DNA fragment amplified was specific for the segment of the parvovirus genome detected by the parvovirus-specific probe. We next determined the minimum quantity of parvovirus DNA necessary for amplification. Setting the number of amplification cycles at 30, with 1 μg of each primer 1 μl aliquots of serial dilutions of pYT104C plasmid DNA ranging from 100 pg to 0.01 pg were subjected to amplification. After this 50 μl quantities of the reaction products were electrophoresed for 1 hour, stained with ethidium bromide, and photographed. As shown in Fig. 2 these experiments demonstrated that as little as 1 pg or 2×10^4 viral particles could be amplified and detected under our conditions. When this experiment was repeated with the same amounts of pYT104C DNA suspended in whole blood lysate a reduction in sensitivity was again found. Thus under these conditions our lower limit of detection was 5 pg of pYT104C DNA, equivalent to 1×10^5 viral particles.

After these preliminary studies clinical samples obtained at prenatal evaluation of fetal hydrops were assayed by our polymerase chain reaction method with the optimized parameters developed in our preliminary studies. The results of these amplifications are shown in Fig. 3. With the method described we were able to detect the presence of parvovirus B19 in fetal blood samples in three of nine cases in which nonimmune hydrops was detected by ultrasonography. However, only in case 2356 was the virus also detected in amniotic fluid. In addition, as determined by visual inspection of the ethidium bromide–stained gel, the amount of virus in the fluid was much less than in the fetal blood in that the 274-base-pair amplification product was barely detectable. In all cases the success of polymerase chain reaction amplification was established by the presence of the 700-base pair actin sequence on the gels. In no cases was parvovirus B19 detectable in the samples of maternal blood obtained at the time of fetal sampling.

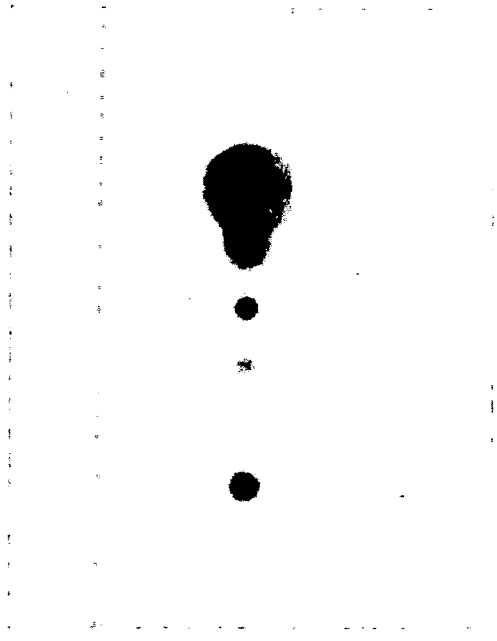

Fig. 1. Hybridization of B19 oligonucleotide probe to dilutions of parvovirus DNA. The range of concentration is from 1 μg of DNA in the first dot to 10 pg in the fifth dot. Positions 2 and 6 contain equivalent amounts of parvovirus DNA (0.1 μg) mixed with sterile buffer and whole blood lysate, respectively. Position 7 contains a negative control of whole blood lysate alone.

In all of the positive cases follow-up polymerase chain reaction analysis was done on fetal samples. In case 8217 the clinical manifestations of hydrops resolved and the patient was delivered of a male infant without any apparent sequelae. Test results for a cord blood sample obtained 4 weeks after the initial sample were still positive for parvovirus B19 in the subsequent polymerase chain reaction analysis. Notably, in this fetus the hydrops resolved within 4 weeks of our evaluation, and the pregnancy resulted in a live-born male infant without apparent problems. This infant died at home 53 days after delivery under circumstances presumed to be consistent with sudden infant death syndrome. An autopsy was not obtained on this infant precluding further analysis.

In case 2356 the hydrops persisted and worsened over a 7-day period. At 25 weeks' gestation ultrasonography revealed massive pericardial effusion, ascites, and no cardiac motion in the fetus. After documen-

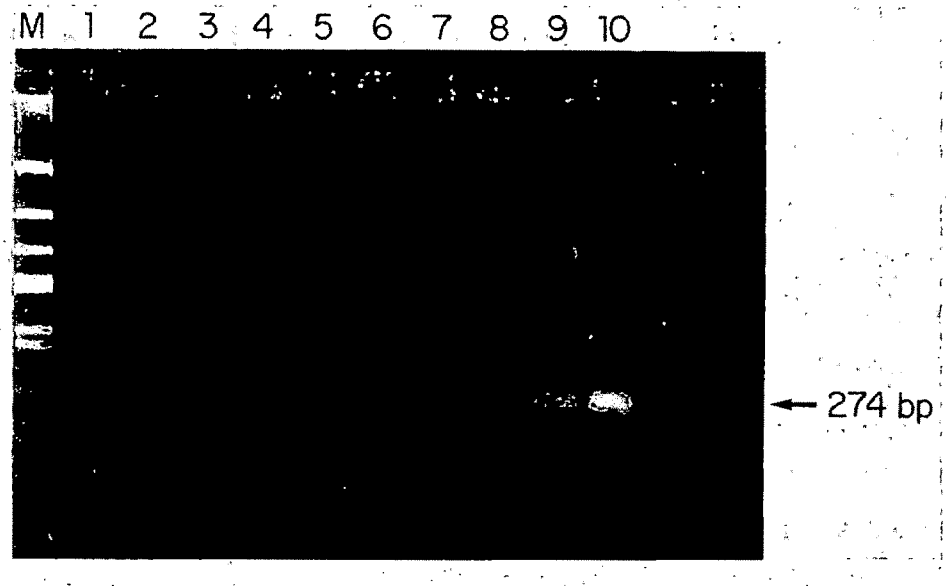

Fig. 2. Gel electrophoresis of polymerase chain reactions with various amounts of parvovirus B19 DNA with whole blood lysate. *Lanes 1, 2,* and *3* are negative controls with sterile buffer, 1 μg purified human DNA, and whole blood lysate as the amplification template. *Lanes 4* through *9* are amplifications with 0.1 pg, 1 pg, 5 pg, 50 pg, 100 pg, and 500 pg quantities of parvovirus DNA in whole blood lysate. *Lane 10* is a positive control of 500 pg of parvovirus DNA in sterile buffer. Fragment size is indicated in base pairs *(bp)*.

tation of an intrauterine fetal death the pregnancy was terminated. No autopsy was performed on this fetus; however, after delivery a portion of the placenta and fetal blood from cardiac aspiration was obtained, and test results for both were positive for parvovirus B19 with our assay method.

Case 5181 was delivered 36 hours after fetal blood sampling. The infant was delivered with marked hypotension and was admitted to the neonatal intensive care nursery, where he died 12 hours after delivery. Blood samples obtained in the nursery were sent for viral cultures, which were positive for parvovirus B19. In this case an autopsy revealed a 3280 gm male infant with generalized hydrops and edema. Hepatosplenomegaly was noted, along with an enlarged heart. Histopathologic examination of the heart demonstrated generalized inflammatory changes. The liver demonstrated perivascular mononuclear infiltrates. These findings were believed to be consistent with those reported in other cases of fetal infection with several viruses, including parvovirus B19.[5] Test results for a portion of fetal cardiac muscle and spleen tissue obtained at autopsy were positive for parvovirus B19 with the polymerase chain reaction assay.

The maternal histories obtained in the three positive cases were notable for several features. In case 8217 the mother gave a history of recent travel to Mexico to visit family. During that visit she came in contact with several children who had symptoms resembling "influenza." However, she never experienced any symptoms. In case 2356 the mother gave a history of "flu" with fever approximately 4 weeks before evaluation. Case 5181 was associated with maternal exposure to a child with nausea, vomiting, fever, and a "red face" in her home about 5 weeks before evaluation. Parvovirus-specific immunoglobulin studies were not obtained in any of these cases.

Comment

The polymerase chain reaction is a rapid and relatively simple molecular genetic technique that enzymatically amplifies exceptionally small amounts of a specific DNA present in clinical samples. Since the first description of this technology the polymerase chain reaction method has been applied to clinical specimens for diagnosis of a variety of neoplastic, genetic, and infectious diseases.[10] Indeed, at the same time the studies reported here were underway another group of investigators also reported on the use of polymerase chain reaction to detect the presence of human parvovirus B16 in formalin-fixed tissues obtained at autopsy from a case of an intrauterine fetal death.[11] In our study we used the polymerase chain reaction technique to amplify a different portion of the viral genome and demonstrated that the sensitivity of this method exceeds that which can be obtained with more traditional approaches, such as dot-blots. Importantly, both studies show that the detection of the viral genome was specific in that known parvovirus-negative samples did not yield amplification product. However, as has been

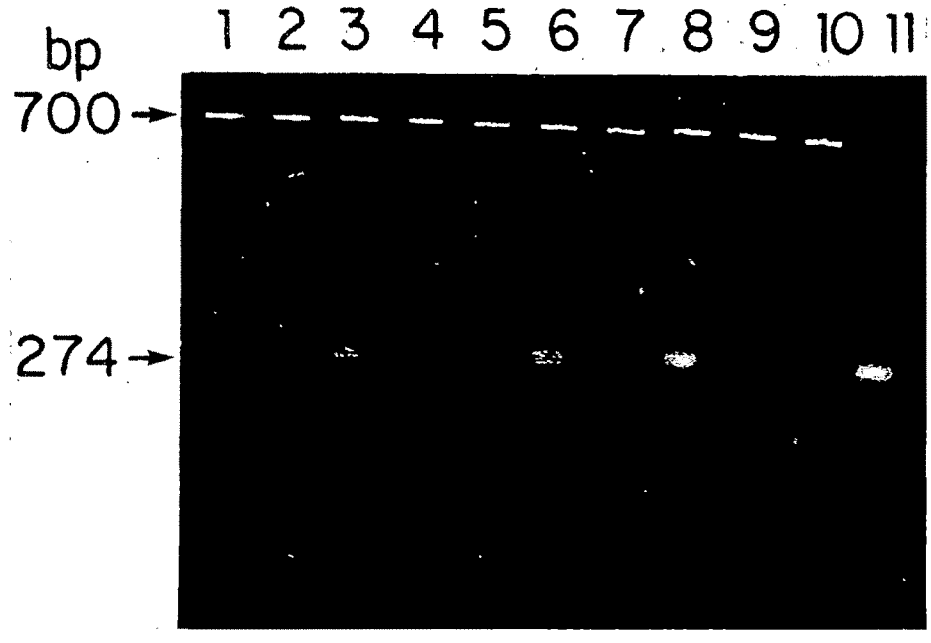

Fig. 3. Gel electrophoresis of the amplification products obtained from fetal blood samples in the nine cases initially seen with hydrops fetalis are seen in *lanes 1* through *9*. *Lane 10* is a negative control, and lane 11 is a positive control. The 274-base-pair *(bp)* fragment is the parvovirus amplification product, and the 700-base-pair fragment corresponds to the human actin standard.

noted by others, contamination of samples with exogenous target DNA template can be a potential problem in polymerase chain reaction–based assays.[10] Therefore appropriate measures must be taken to avoid this problem, and negative controls should always be used in amplification protocols.[12] Moreover, analysis of paired maternal samples will preclude the possibility of false-positive results resulting from cross-contamination with viral particles in maternal blood.

We also found that the sensitivity of the assay decreased in the presence of lysed whole blood. This is not entirely unexpected and is most likely the result of inhibition of the *Taq* polymerase enzyme by heme present in the sample. Alternatively, it could also be caused by some nonspecific binding of the oligonucleotide primer sequences to human genomic DNA possessing some homologic sequence because the effect was also noted in the dot blots. In the polymerase chain reaction amplification process nonspecific binding would result in a reduction of primer/template ratio, which would in turn affect amplification efficiency.[10] However, the sensitivity of the assay, even in the presence of blood, is at the level of about 100,000 viral particles. Moreover, the use of radioactive nucleotides in the polymerase chain reaction would result in even greater sensitivity, as would increases in the number of amplification cycles, without affecting specificity.

In our study we have demonstrated that parvovirus B19 DNA can be detected in amniotic fluid and fetal blood samples obtained in a prenatal diagnostic setting with enzymatic DNA amplification. This technique represents an extremely sensitive detection method that is especially useful when small sample size limits diagnostic techniques. It is also more rapid than viral culture for diagnosis, requiring only a few hours to perform. Morever, in applying this technique to a group of clinic patients we found that some gestations with signs of nonimmune fetal hydrops have definitive evidence of parvovirus B19 infection.

The basic pathogenesis of fetal hydrops is thought to be that of cardiovascular failure as precipitated by anemia, myocardial dysfunction, vascular shunts, and other alterations in cardiovascular dynamics.[4] In the case of parvovirus B19 infection, anemia or direct cytopathic effects on fetal organs, including the myocardium, have both been postulated to be responsible for the fetal hydrops.[13] In the cases reported here anemia was noted in the fetal blood samples, a finding that is consistent with other reports of fetal infection with parvovirus B19 but is not an invariable finding in all cases.[13] On the basis of the limited number of cases in this series we cannot speculate on the true incidence of anemia associated with human parvovirus B19 in fetuses initially seen with nonimmune hydrops. Neither can we be certain that the pathogenesis of the hydrops was in fact caused only by the anemia. The presence of detectable parvovirus in the myocardium of one case combined with relatively mild anemia in another suggests that more than erythroid cell destruction may contribute to the fetal hydrops; this has also been suggested

in other studies of fetal parvovirus B19 infections.[13] Most important, however, the variable outcomes of the pregnancies seen in our study indicate that many additional questions regarding the association of human parvovirus B19 infection and nonimmune hydrops remain to be answered. In our series we noted a live-born infant without obvious sequelae after an in utero infection. Thus our case of a documented fetal viremia and hydrops that spontaneously resolved adds to those cases reported by others of apparently normal outcomes in some fetuses after in utero parvovirus B19 infections.[13] However, in our case a sudden infant death without a definitive cause of death is disturbing and might be related to early and apparently persistent chronic infection. This case emphasizes that much is yet to be learned about the pathologic make-up of parvovirus infection and its long-term effects on fetuses that have viremia in utero. In sum, on the basis of the data presented here we believe that the simplicity of this diagnostic method presents clinicians with an important tool for evaluation of nonimmune fetal hydrops. When applied to larger clinical studies this method will be an important tool in understanding the natural history of parvovirus B19 infection occurring in pregnancy.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1992 issues from the Publisher, at a cost of $68.00 for domestic, $95.76 for Canada, and $91.00 for international for Vol. 166 (January-June) and Vol. 167 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351, or (314) 453-4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Angina and normal coronary arteries in women: Gynecologic findings

Philip M. Sarrel, MD[a], David Lindsay, MA,[b] Giuseppe M.C. Rosano, MD[c], and Philip A. Poole-Wilson, MD[c]

New Haven, Connecticut, and London, England

OBJECTIVES: Our aim was to evaluate the hypotheses that women with severe angina and normal coronary arteries (syndrome X) have an increased incidence of hysterectomy and show a positive cardiac response to 17β-estradiol replacement therapy.

STUDY DESIGN: The gynecologic histories of 30 women with syndrome X were determined. Anginal and 17β-estradiol insufficiency symptoms were recorded daily for 1 month. Subsequently, 20 of the women underwent hyperemic response testing before and after 2 months of estrogen replacement therapy. Hyperemic response results were compared with those of 12 asymptomatic post-menopausal women not receiving estrogen replacement therapy. Symptoms were recorded daily during estrogen replacement therapy.

RESULTS: A total of 18 women (60%) underwent hysterectomy. All were experiencing hot flushes. Hyperemic response was diminished in women with syndrome X compared with controls. Hyperemic response increased and anginal symptoms decreased during estrogen replacement therapy.

CONCLUSION: The incidence of hysterectomy was increased and estrogen replacement therapy alleviated cardiac symptoms and enhanced hyperemic response in a group of women with syndrome X. (Am J Obstet Gynecol 1992;167:467-72.)

Key words: Angina, estrogen, hysterectomy, vasodilatory reserve, syndrome X

Women with severe angina, exercise electrocardiogram changes suggesting ischemia, and normal coronary arteries (referred to as syndrome X or microvascular angina) present a challenging medical problem. These patients have an excellent prognosis with regard to myocardial infarction and cardiovascular mortality.[1] Nevertheless, existing cardiovascular medications are frequently ineffective in relieving pain, and follow-up studies indicate that many patients have significant limitation of daily activities because of pain.[2] Patients with this condition have shown a diminished hyperemic response, suggesting the chest pain to be a manifestation of a more widespread vascular disorder.[3]

One of the earliest observations about angina in women was made by Sir William Osler,[4] who in 1892 pointed out that anginal pain without coronary artery disease was more common in women than in men, carried a good prognosis, and was characterized by discomfort that was often long-lasting. LaCroix et al.,[5] in a recent national study reported by the Epidemiology Branch of the National Institutes of Health, found among white women aged 25 to 54 years that diagnosed angina occurs twice as often as it does among age-matched white men. In spite of the clinical diagnosis of angina pectoris, >50% of women undergoing coronary angiography have normal coronary arteries compared to <10% of men.[6] For these women an etiologic explanation for the chest pain remains elusive and a variety of noncardiac causes have been postulated.

Angina pectoris in women is frequently associated with other conditions of vascular disorder. These include hot flushes,[7] Raynaud's phenomenon,[8-10] and migraine.[11] In the study of LaCroix et al. 20.5% of the women with angina also experienced severe dyspnea, "... requiring the subject to stop for breath when walking on level ground."[5] In contrast, only 4.5% of the men in the same age group experienced severe dyspnea. Kronenberg[7] reported that 16% of 438 perimenopausal and postmenopausal women experienced significant chest pressure and 28% experienced cranial pressure when hot flushes occurred. Among women with Raynaud's phenomenon, an increased incidence of variant angina and migraine has been reported.[9, 10]

The association of angina and coronary artery disease with loss of ovarian function has been described in many articles in the medical literature. Wuest et al.[12] reported that women who underwent bilateral oopho-

rectomy and did not receive hormone replacement therapy showed an increased prevalence of severe atherosclerotic disease at autopsy, and Robinson et al.[13] found that castrated women showed a higher incidence of angina as compared with that of controls who had not had surgery. Although myocardial infarction and cardiovascular disease are most clearly associated with bilateral salpingo-oophorectomy,[14] elevated risks of cardiovascular disease have been reported even after simple hysterectomy,[15] and loss of ovarian hormone production after simple hysterectomy has been suggested as an etiologic factor.[16]

The possibility that ovarian insufficiency might be associated with syndrome X in women led to a gynecologic endocrine evaluation of 30 patients with this condition. The patients were seen at the Royal Brompton and National Heart Hospital in London, where their gynecologic histories and signs and symptoms of ovarian insufficiency were evaluated. Twenty of these women subsequently participated in a pilot study to determine whether 17β-estradiol treatment would have a positive effect on cardiac symptoms and measures of cardiovascular function.

Patients and methods

Thirty consecutive female patients previously diagnosed with syndrome X were recruited for this study. Before our investigations all of the women had been evaluated for chest pain by their family physicians and at least two consulting cardiologists. These physicians had concurred that the nature of the women's pain fit the criteria for a diagnosis of angina pectoris. The women were seen in the Cardiac Medicine Clinic of the Royal Brompton and National Heart Hospital in London. They were interviewed by a research team consisting of a cardiologist (DL or GR) and a gynecologist (PS). This interview further confirmed the presence of angina-type chest pain. In fact, all the women had a history of severe angina, a positive exercise test (ST segment depression >1 mm during treadmill testing), and normal coronary arteries at the time of coronary catheterization. The women were receiving a variety of cardiac medications including coronary vasodilators, calcium channel–blocking agents, β-adrenergic–blocking agents, and cardiac glycosides. The cardiac history was reviewed, and as complete an obstetric and gynecologic history as possible was elicited. A blood sample was drawn for determination of serum estradiol and follicle-stimulating hormone (FSH) concentrations. The control group comprised 11 women without chest pain or hot flushes (age 52.6 ± 4.5 years, mean ± SD). The women in the control group were not receiving hormone replacement therapy although all were postmenopausal, showing estradiol concentrations <25 pg/ml and FSH levels >40 mIU/ml. The women in the control group were not taking any cardiac medications. Patients with a history of hypertension were excluded from both groups.

After informed consent was obtained, all cardiac medications were discontinued for at least 1 week except for sublingual glyceryl trinitrates. Glyceryl trinitrate treatment was discontinued for a minimum of 24 hours before the first study visit. The subjects in both groups were not allowed to smoke cigarettes or drink tea or coffee within 4 hours of the study. Ten of the women with syndrome X either were taking or recently had been taking hormone replacement therapy. These medications were all discontinued for at least 6 weeks before the initial hyperemic response was measured.

The subjects reclined in a semirecumbent position on a couch, and blood pressure was recorded from the left arm. Hyperemic response was measured with a laser Doppler probe applied to the pulp of the right middle finger. The room temperature was maintained at 70° F. After a period of stabilization, arterial flow in the fingertip was determined for a 2-minute period. Limb blood flow was then occluded for 5 minutes with a sphygmomanometer inflated to 200 mm Hg. The laser Doppler probe continued to monitor flow through the period of occlusion and for 3 minutes after release of the cuff pressure.

All of the women maintained a daily diary for 1 month, during which they recorded the frequency and intensity of chest pain, sleep disturbance, headache, anxiety reactions, and depression. A rating scale ranging from 0 (no symptoms) to 4 (severe symptoms) was used. A minimum of a two-level change in a symptom (e.g., from 4 to 2) defined a "significant change."

At the follow-up visit, 20 of the women diagnosed with syndrome X agreed to participate in a 2-month trial in which they wore 17β-estradiol skin patches (Estraderm TTS) delivering 50 μg/day for the first month and 100 μg/day for a second month. The estradiol patches were changed twice weekly and were applied to the buttocks according to the usual prescription guidelines. The women agreed to discontinue cardiac medications except for sublingual nitrates. The diaries were maintained throughout this period, and the hyperemic response test was repeated at the end of the trial. The 10 women initially evaluated who were not included in the estradiol trial were those who were not willing to return for repeat visits because of the inconvenience of coming to the clinic in London, did not wish to receive estrogen treatment, or had return appointments after recruitment for the estrogen treatment study was completed.

Findings and results

Hormonal and nonanginal vascular findings are summarized in Fig. 1. The mean age of the women was 52 years (range 46 to 63, SD ± 6). Twelve of the women had experienced a natural menopause at a mean ± SD

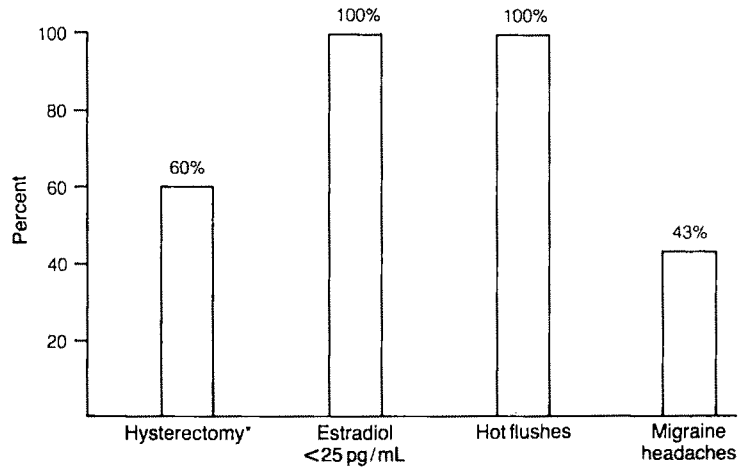

Fig. 1. Hormone and vascular findings in 30 women with syndrome X. Mean ± SD age of women was 52 ± 6 years. Average ± SD time from hysterectomy to onset of cardiac symptoms was 7.7 ± 5.7 years.

age of 49.5 ± 4 years (range 47 to 55). Eighteen of the 30 women underwent hysterectomy at an average age of 41 years. Sixteen of the 18 hysterectomies were abdominal procedures, and two women had vaginal hysterectomy for uterine prolapse and urinary incontinence. We were not able to determine the gynecologic diagnoses in many of the women as they themselves were unsure. However, it did appear that essentially all of the procedures were necessary, with the most frequent indications being uterine fibromyomas or excessive bleeding or both. Nine of the 18 women had ovaries removed at the time of surgery. Seventeen of the 30 women had received hormone replacement therapy at some time. However, only 10 of the women were taking hormone replacement therapy when first seen in this study. Nine of the 10 women using hormones had undergone hysterectomy, and eight of these women had bilateral oophorectomy. Seven women had discontinued hormone replacement therapy, including four who had been given estrogen plus progestin. These four women stopped hormone replacement therapy because of intolerable chest pain that developed during the time they were taking the progestin.

Angina developed at a mean ± SD duration of 7.7 ± 5.7 years after hysterectomy.

All the women, including those taking hormone replacement therapy, were experiencing hot flushes. In five of these women the flushes were mild (level 2), but 25 women rated the flushes as severe (level 4) in the monthly diaries. Sleep was disrupted in all of the women, usually because of awakening with hot flushes. All the women reported that at least some of their hot flushes were accompanied by chest pressure or pain. Thirteen of the 30 women had migraine headaches.

Serum estradiol and FSH concentrations were <25 pg/ml and >40 mIU/ml, respectively, in all of the women.

Hyperemic response results before 17β-estradiol treatment in the syndrome X women are compared with those of an age-matched, pain-free control group in Fig. 2. The ratio of postocclusion blood flow level to the preocclusion level was calculated at 20-second intervals for 2 minutes. It can be seen that the women with syndrome X do not show any response above baseline (i.e., they do not appear to have a vasodilator reserve), whereas the control group shows a significant response over the entire 2 minutes. Calculation of the ratio of the maximum response level to the baseline flow level (MBR) gave a value of 1.08 for those with syndrome X and 2.3 for the control group.

After estradiol treatment for 2 months, the MBR of the women with syndrome X was 2.07. The posttreatment MBR is compared with pretreatment and control group findings in Fig. 3. Response levels were almost doubled after estradiol treatment and approached the levels of the control group without angina.

Nineteen of the 20 women reported marked improvement (a minimum of a two-level decrease in the anginal symptom rating) or complete disappearance of chest pain. Cessation of hot flushes correlated with decrease or disappearance of chest pain. All of the women reported a decrease in the use of glyceryl trinitate tablets. Unfortunately, the diaries did not include quantification of glyceryl trinitate usage, and therefore we are not able to report the decline in usage with precision.

Comment

These findings suggest an association between hysterectomy, ovarian insufficiency, and the development of syndrome X. The average age of the patients studied was 52; in Great Britain, 8% to 12% of women in this age group have undergone hysterectomy with or with-

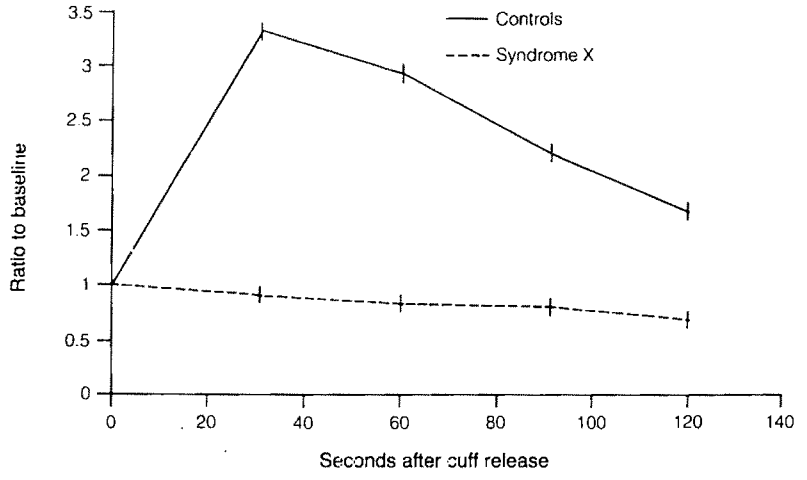

Fig. 2. Hyperemic response of 20 women with syndrome X compared with that of 12 control subjects. (See text for details of test.)

out removal of the ovaries.[17] In the current series 60% had undergone hysterectomy. All of the hysterectomies appear to have been indicated procedures.

Although the evidence in the medical literature relating hysterectomy to the development of coronary artery disease is more clearly associated with bilateral salpingo-oophorectomy,[14] studies indicate that simple hysterectomy is also reported to incur an elevated cardiovascular risk. As noted, the study of Siddle et al.[16] implies that the loss of ovarian hormone production with simple hysterectomy may be comparable to that occurring when the ovaries are removed. In the latter instance hormone replacement therapy is more likely to be initiated soon after the surgery. Unfortunately, when the ovaries are retained, it can be mistakenly assumed that normal ovarian function always ensues and there is no need for hormone replacement therapy. Moreover, most patients are lost to follow-up after hysterectomy, since neither gynecologists nor patients believe that continuing gynecologic care is necessary. In the current series only three women returned to their gynecologists for continuing follow-up after their scheduled postoperative visits. Nonetheless, most of the women with retained ovaries described symptoms of ovarian insufficiency to their primary care physicians. However, since their ovaries had not been removed, their physicians did not attribute the symptoms to ovarian insufficiency, and only one woman received hormone replacement therapy. Cardiac symptoms developed within 7 years of the hysterectomy.

Chest pain is not considered a reliable indicator of angina pectoris in women.[18] The cardiologists involved in the characterization of the chest pain in the women in our series determined to the best of their abilities that the pain was of cardiac origin, and the positive results of exercise tests would seem to confirm the impression of ischemic disease. The finding of a decreased vasodilatory reserve capacity in the syndrome X women compared with the age-matched control women suggests the problem to be due to altered cor-

onary hemodynamics in association with pathophysiologic changes other than atherosclerotic plaque formation.

All the women showed symptoms of estradiol deficiency. Twenty-five of 30 were experiencing >20 hot flushes each day. Chest pain frequently accompanied the hot flushes. Further evidence of a more widespread vascular disturbance was seen among 13 (43%) of the women who also experienced migraine headaches (Fig. 1).

The pretreatment hyperemic response results in the syndrome X women indicate diminished vasodilator reserve capacity. This finding confirms the observations of others who have concluded that reduced hyperemic response in syndrome X indicates the anginal symptoms to be a manifestation of a widespread vascular disorder.[3] The hyperemic response in the forearm to the release of arterial occlusion has been extensively studied. Sudden increase in blood flow in an artery is thought to stimulate the release of endothelial-derived relaxing factor (EDRF), and the hyperemic response is thought to reflect vasorelaxation induced by EDRF acting on the vascular smooth muscle.[3] Our finding of increased hyperemic response after 17β-estradiol treatment is consistent with those of others, including Williams et al.,[19] who reported that coronary vascular response to acetylcholine stimulation (another EDRF-mediated vasodilator response) in ovariectomized monkeys is increased after 17β-estradiol implants.

Hemodynamic changes reported after treatment with 17β-estradiol include restoration of vasomotor control, increased cardiac output, and decreased vascular resistance.[20] Increased hyperemic response correlated in our study with an increased vasodilator reserve as the syndrome X patients showed significant improvement in cardiac symptoms.

Estrogen replacement therapy in postmenopausal women has been shown to reduce cardiovascular morbidity and mortality.[21] Although effects on lipid metabolism appear to contribute significantly to this cardioprotection, the hemodynamic effects of 17β-estradiol also appear to be of significance. The current study shows an association between signs and symptoms of ovarian insufficiency and disturbed vascular function in women with syndrome X. The part of the study assessing the effects of 17β-estradiol treatment on cardiac symptoms and hyperemic response should be considered a pilot investigation into a potential mechanism through which estrogen treatment provides cardioprotection.

This study indicates that estradiol deficiency may induce pathophysiologic changes contributing to anginal symptoms in women diagnosed with syndrome X. The high prevalence of hysterectomy and the inadequacy of hormone replacement therapy observed in this study suggest the need for careful gynecologic endocrine evaluation of women presenting with this syndrome. A double-blind, placebo-controlled study of the effects of 17β-estradiol on cardiovascular parameters in women with syndrome X should determine which hormone effects account for the improvements seen thus far.

Modulation of cell-to-cell coupling between myometrial cells of the human uterus during pregnancy

Nobuyoshi Sakai, MD, PhD, Thomas Tabb, MD, and Robert E. Garfield, PhD
Galveston, Texas

OBJECTIVE: The purpose of this study was to investigate changes in cell-to-cell coupling of human myometrium during pregnancy to assess the presence and permeability of gap junctions.
STUDY DESIGN: To evaluate the coupling, input resistance was measured and intercellular spread of Lucifer yellow was observed with microelectrode techniques in intact myometrial preparations from four nonpregnant women, 13 women not in labor, and three women in labor. Octanol, isoproterenol, and dibutyryl adenosine 3′,5′-cyclic monophosphate were applied to the preparations to assess their effects on cell-to-cell coupling.
RESULTS: Input resistance of myometrial cells was decreased ($p < 0.001$) and intercellular spread of Lucifer yellow was increased during pregnancy. Octanol, isoproterenol, and dibutyryl adenosine 3′,5′-cyclic monophosphate rapidly and reversibly increased input resistance ($p < 0.001$ for all these agents) and blocked Lucifer yellow spread in tissues from pregnant patients.
CONCLUSIONS: Cell-to-cell coupling between human myometrial cells is spontaneously improved during pregnancy because of the presence of gap junctions. The coupling is rapidly and reversibly decreased by octanol, isoproterenol, and dibutyryl adenosine 3′,5′-cyclic monophosphate as a result of decreased permeability of gap junctions. These two methods of modulation of gap junctions are suggested to be major mechanisms for control of myometrial contractile activity in the human uterus during pregnancy. (Am J Obstet Gynecol 1992;167:472-80.)

Key words: Human myometrium, cell-to-cell coupling, β-adrenergic receptor agents, adenosine 3′,5′-cyclic monophosphate, gap junction

Gap junctions increase between smooth muscle cells of myometrium during labor and parturition in rats, humans, and other species.[1-5] These specialized cell-to-cell contacts are thought to provide intercellular pathways that allow the synchronization of electric and metabolic activities. Therefore the appearance of gap junctions between smooth muscle cells is thought to result in coordinated muscle activity due to better coupling between cells.

Previous morphologic studies of the human uterus have shown that gap junctions were present between myometrial cells in high numbers in term women with frequent uterine contractions or premature labor,[5] whereas they were present in very low frequency in women with infrequent uterine contractions and absent in most tissues from nonpregnant women.[6] In the myometrium of other mammalian species indirect studies of cell-to-cell coupling have shown that the muscle cells become better coupled when the gap junctions are elevated during labor.[7-9] However, there are no functional studies on the human uterus that have adequately described the change in the coupling between myometrial cells either during pregnancy or in the nonpregnant state. Recent studies have used microelectrode techniques to evaluate the coupling between myometrial cells by measuring input resistance and metabolic coupling (fluorescent dye injection).[10,11] A decrease in input resistance and an increase in dye spread between rat and guinea pig myometrial cells suggested that the coupling between muscle cells improved when gap junctions were increased in the myometrium at term.[10-12]

The purpose of this study was to use intracellular microelectrode techniques to functionally assess cell-to-cell coupling between cells of intact myometrial preparations from pregnant and nonpregnant women. The present study demonstrates that the coupling between human myometrial cells is dramatically improved during pregnancy because of the appearance of gap junctions. Furthermore, this study shows that octanol and agents that elevate intracellular adenosine 3′,5′-cyclic monophosphate concentration will rapidly and reversibly lower the coupling presumably through closure of the gap junctions.

Material and methods

Tissues were collected for this study from two groups of women at term pregnancy. Women in one group underwent elective cesarean section ("before labor"), and women of the other group sustained cesarean section for cephalopelvic disproportion when the cervical dilatation was ≥5 cm with contraction frequency being at least 3 per 10 minutes ("during labor"). Small segments (approximately 2 × 2 × 0.5 cm) of pregnant myometrium were excised from the superior aspect of the lower uterine incision. Similar sizes of myometrial segments from the fundus of the nonpregnant uterus were obtained from women who experienced hysterectomy with no obvious pathologic condition. This study was approved by the institutional review board. Informed consent to remove the tissue and participate in the study was obtained from each patient.

Tissue preparation. Strips of tissue were immediately placed in physiologic saline solution and stored at 4° C. All experiments were started <3 hours after obtaining the tissues. Each tissue was placed in an organ bath containing well-aerated (95% oxygen and 5% carbon dioxide) Krebs solution and pinned at its resting length. The connective tissue surrounding the tissue was carefully removed, and a thin preparation of the myometrium was made with fine curved forceps under a dissecting microscope. The myometrial preparation, approximately 1.5 × 1.5 × 0.1 cm, was cut free and pinned at its resting length to a rubber ring cemented on the bottom of a 35 mm Petri dish with a glass coverslip glued under a hole in the center. The dish was filled with Tyrode's solution (composition 135 mmol/L sodium chloride, 5 mmol/L potassium chloride, 1 mmol/L magnesium chloride, 1.8 mmol/L calcium chloride, 5.6 mmol/L glucose, 10 mmol/L Hepes, 0.05% gelatin) that was adjusted to pH 7.4 and warmed to 37° C. The myometrial preparation was viewed under an inverted microscope (Ernst Leitz, Wetzlar, Germany) equipped with a heating stage (37° C) and phase-contrast optics.

Electrophysiology. Electrodes were pulled from 1.2 mm outer diameter capillary tubes (World Precision Instrument, New Haven, Conn.) with a horizontal micropipette puller (Sutter Instruments, San Francisco). A microelectrode filled with 3 mol/L potassium chloride (40 to 100 MΩ) was connected to an amplifier (World Precision Instrument), and electrical currents were injected to the electrode by a stimulator (Grass Instrument, Quincy, Mass.). Signals were monitored on a two-channel digital storage oscilloscope (Nicolet, Madison, Wis.). The total resistance of an electrode impaled in a cell is determined by the sum of the electrode resistance and the resistance to current flow out of the cell (the cell input resistance). Input resistance

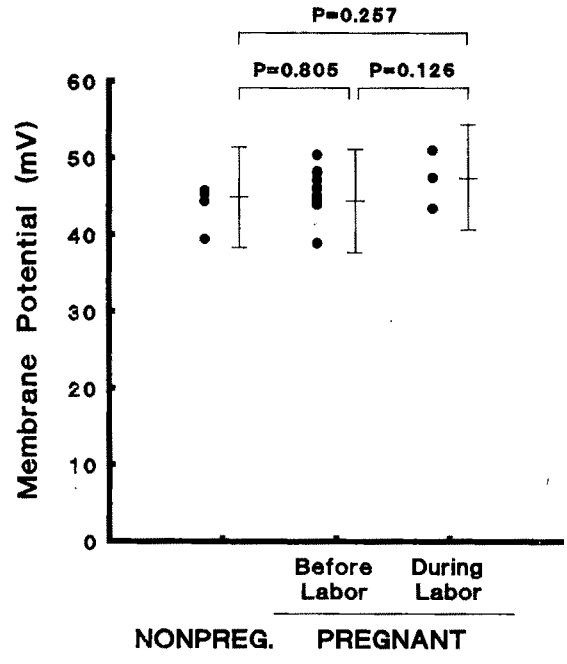

Fig. 1. Membrane potentials (representing intracellular negative values) measured in smooth muscle cells of myometrial preparations from women. *Closed circles,* Average value from impaled cells of preparations obtained from same women (four nonpregnant, 13 before labor, and three during labor); *bars,* mean values ± SEM obtained by combining all values from impaled cells of each group. *p* Values are analyzed by comparing values of membrane potential from impaled cells between groups.

reflects the combined resistance of the junctional membrane, the nonjunctional membrane, and the cytoplasm. Nonjunctional membrane is extremely high (nonjunctional membrane > > junctional membrane), and cytoplasm is nearly 0 Ω. Because changes in both nonjunctional membrane and cytoplasm under conditions of these experiments are thought to be very small, any alteration in cell coupling resistance is indicated by a modification in input resistance. During impalement of the bridge-balanced electrode into a cell, input resistance was determined from the hyperpolarization of electrical potential elicited by an inward current pulse (0.5 nA, 200 msec/sec) from the stimulator. The values of membrane potential and input resistance were accepted if the electrode potential and resistance returned to baseline after removal of the electrode from the cell. In the text and figures, values of membrane potential are shown as absolute values without indicating their negative sign.

Fluorescent dye injection. The injection of Lucifer yellow (Sigma Chemical Co., St. Louis) was used to examine intercellular diffusion capabilities. A 3% solution of Lucifer yellow (Lucifer yellow dissolved in 1% lithium chloride buffered to pH 7.6 with 10 mmol/L Hepes) was back-filled into the microelectrodes (40 to

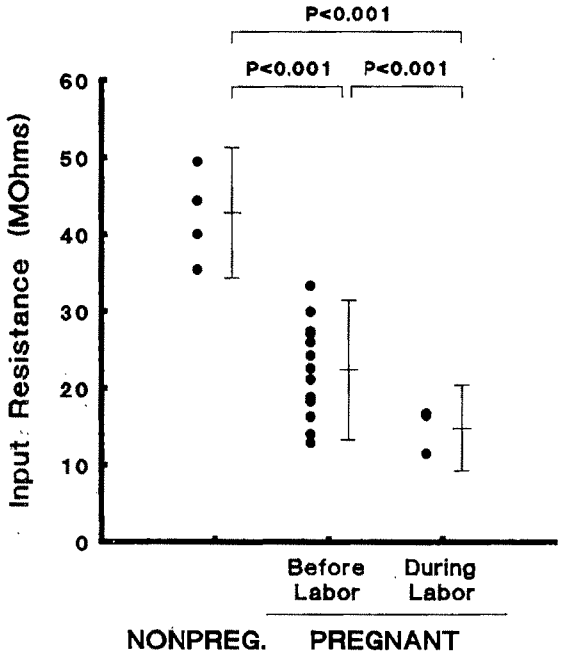

Fig. 2. Input resistances measured in smooth muscle cells of myometrial preparations from women. *Closed circles,* Average value from impaled cells of preparations obtained from same women; *bars,* mean values ± SEM obtained by combining all values from impaled cells of each group. *p* Values are analyzed by comparing values of input resistance from impaled cells between groups.

50 MΩ with 3 mol/L potassium chloride) with resistance of 150 to 200 MΩ. During impalement of the electrode into a single cell of a myometrial preparation, dye was injected with inward (hyperpolarizing) current pulses (5 to 50 nA, 200 msec/sec). The spread of Lucifer yellow from a source cell to neighboring cells was monitored under the microscope with epifluorescence optics (BP 450-490 excitation filter, RKP 510 dichronic mirror, and LP 515 barrier filter; Ernst Leitz). Lucifer yellow injection was terminated if values of membrane potential were markedly depolarized.

Drug treatment. All drug applications were conducted by exchanging the Tyrode's solution surrounding the tissue to the same solution mixed with one of the following agents: 1-octanol (1.2 mmol/L, Sigma) isoproterenol (10^{-6} mol/L, Sigma), or dibutyryl adenosine 3′,5′-cyclic monophosphate (5×10^{-4} mol/L, Sigma). Drug application was continued for 15 minutes, and then each solution was rapidly replaced twice with Tyrode's solution (washing).

Statistics. For the electrophysiologic measurements, results are mean ± SEM obtained by combining all values from impaled cells of preparations for each group. A one-way analysis of variance was used for comparisons of values among the nonpregnant group, the group before labor, and the group during labor, or among control, drug-treated, and washing groups. An unpaired Student *t* test was used to examine significant differences between groups. In some cases, the Mann-Whitney U test was used between groups with small numbers of samples. A p value <0.05 was considered statistically significant.

Results

Fig. 1 shows values of values of membrane potential of smooth muscle cells of human myometrial preparations obtained from a nonpregnant and two pregnant groups. There were no significant ($p = 0.303$ by analysis of variance differences in values of membrane potential among preparations from nonpregnant women (44.8 ± 6.52 mV [number of impaled cells = 25]), women before labor (44.4 ± 6.76 mV [105]), and women during labor (47.3 ± 6.86 mV [15]). Fig. 2 shows the input resistance values of myometrial cells in the above-mentioned three groups. There were significant ($p < 0.001$ by analysis of variance) differences in input resistance among these three groups. Input resistance was high in nonpregnant women (42.8 ± 8.52 mΩ [25]). However, input resistance was significantly ($p < 0.001$ by Student *t* test) reduced in women before labor (22.3 ± 9.06 MΩ [105]) and lowest in those during labor (14.8 ± 5.45 mΩ [15]). The input resistance in preparations from women during labor was significantly ($p < 0.001$ by Student *t* test) decreased compared with that before labor.

We applied a gap junction uncoupling agent, octanol, to further investigate the relationship between gap junctions and input resistance. Application of 1.2 mmol/L octanol caused an immediate relaxation in all myometrial preparations. Electric recordings showed that the values of membrane potential remained unchanged (nonpregnant p = 0.388, before labor p = 0.735, during labor p = 0.975 by analysis of variance) during octanol application and after washing in all groups (Fig. 3). However, input resistance was immediately (approximately 60 seconds after application of octanol) increased in pregnant groups (40.3 ± 7.90 MΩ before labor, 46.0 ± 3.04 MΩ during labor) to a similar high value to that in nonpregnant control preparations (Fig. 4). At 10 minutes after washing out the octanol, input resistance reversibly returned (19.8 ± 9.64 MΩ before labor, 14.4 ± 1.60 MΩ during labor) to the control value recorded before octanol application in the two pregnant groups. In contrast, the already higher input resistance in nonpregnant group was not significantly ($p = 0.962$ by analysis of variance) changed during octanol application (43.7 ± 4.40 MΩ) or after washing (42.3 ± 1.06 MΩ).

Injection of Lucifer yellow into a cell of myometrial preparations from women during labor (number of injections = 3) showed that the outline of the injected cells was illuminated brightly as an elongated spindle with the first two- to three-current pulses, and adjacent

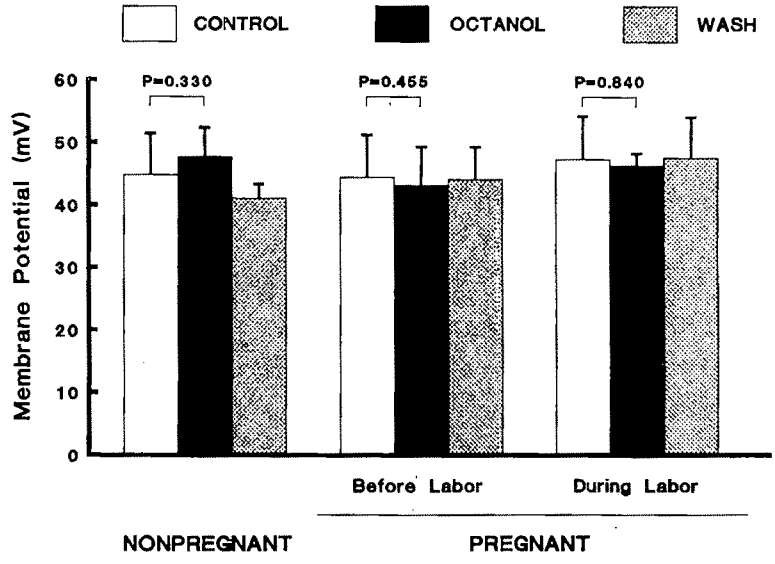

Fig. 3. Effect of octanol (1.2 mmol/L) on the membrane potential in myometrial preparations from nonpregnant and pregnant women. *Bars,* Mean values ± SEM obtained from impaled cells of preparations in various groups.

similarly shaped cells gradually became visible within a minute after the illumination of the source cell (Fig. 5, *A* and *B*). On the other hand, myometrial preparations from nonpregnant women[5] showed little or no spread of Lucifer yellow between the cells (Fig. 5, *C*). Only the injected source cell was illuminated, and Lucifer yellow was undetectable in adjacent cells even more than 10 minutes after injection, indicating that there was no Lucifer yellow transfer in nonpregnant myometrium. In the preparations from pregnant women before labor (14 cases), most injections (10 cases) showed good spread of Lucifer yellow similar to those during labor (Fig. 5, *D*), whereas some (4 cases) showed that although Lucifer yellow was detectable in adjacent cells, the spread was poorer (Fig. 5, *E*). In the pregnant preparations the result of Lucifer yellow injection during application of octanol was strikingly different from that before its application, with a marked decrease in transfer noted. As found in the nonpregnant controls, only the injected cell remained illuminated without spread to any other adjacent cells, indicating the Lucifer yellow transfer was blocked by octanol application (Fig. 5, *F*).

To determine whether elevated intracellular 3′,5′-cyclic monophosphate concentration had an influence on junctional communication between the myometrial cells, the preparations from nonpregnant women or pregnant women before labor were examined in the presence of 10^{-6} mol/L isoproterenol or 5×10^{-4} mol/L dibutyryl adenosine 3′,5′-cyclic monophosphate. In the pregnant group both of these two agents significantly (isoproterenol $p = 0.007$, dibutyryl adenosine 3′,5′-cyclic monophosphate $p < 0.001$ by Student t test) hyperpolarized values of membrane potential (isoproterenol 52.8 ± 4.65 mV, dibutyryl adenosine 3′,5′-cyclic monophosphate 54.6 ± 8.26 mV) from the control value (Fig. 6). These hyperpolarized values of membrane potential values rapidly returned to the control values after washing (isoproterenol 38.8 ± 3.46 mV, dibutyryl adenosine 3′,5′-cyclic monophosphate 44.3 ± 5.69 mV). In contrast, values of membrane potential in nonpregnant group was not significantly (isoproterenol $p = 0.937$, dibutyryl adenosine 3′,5′-cyclic monophosphate $p = 0.697$ by analysis of variance) changed during isoproterenol (45.9 ± 3.01 mV) or dibutyryl adenosine 3′,5′-cyclic monophosphate (43.2 ± 6.26 mV) application and after washing. Input resistance of myometrial cells of the pregnant group was significantly (isoproterenol $p < 0.001$, dibutyryl adenosine 3′,5′-cyclic monophosphate $p < 0.001$ by Student t test) increased by application of either of these two agents (isoproterenol 42.9 ± 7.17 MΩ, dibutyryl adenosine 3′,5′-cyclic monophosphate 39.7 ± 6.78 MΩ) (Fig. 7). These high input resistance values returned to control values after washing. However, the already high input resistance of the nonpregnant group was not significantly (isoproterenol $p = 0.931$, dibutyryl adenosine 3′,5′-cyclic monophosphate $p = 0.666$ by analysis of variance) changed either during isoproterenol (42.8 ± 5.21 MΩ) or dibutyryl adenosine 3′,5′-cyclic monophosphate (39.5 ± 2.12 MΩ) application and after washing. Therefore the effects of these two agents on input resistance (i.e., electric coupling), only found in pregnant but not in nonpregnant groups, are similar to those of octanol. Again, Lucifer yellow transfer between the pregnant myometrial cells was blocked by application of either of these agents (data not shown).

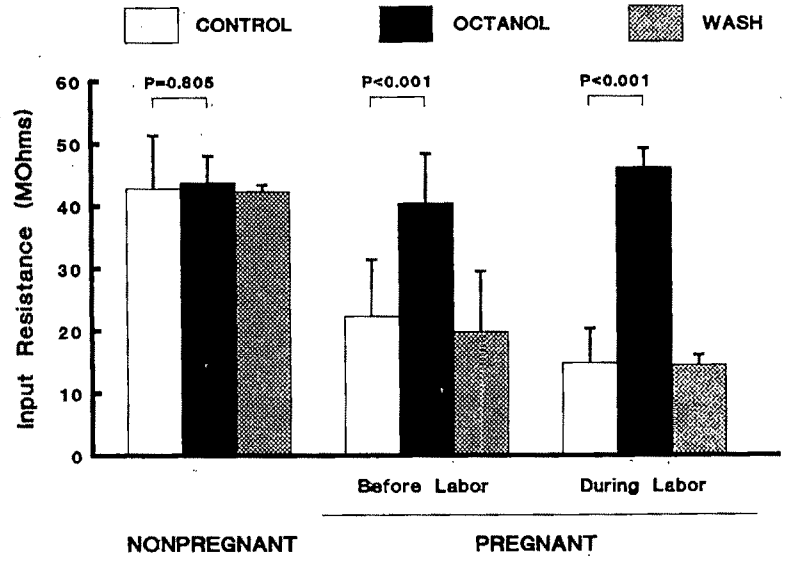

Fig. 4. Effect of octanol on the input resistance in myometrial preparations from nonpregnant and pregnant women. *Bars,* Mean values ± SEM obtained from impaled cells.

Comment

Direct measurement of the electric resistance (input resistance) between human myometrial cells shows a large decrease during pregnancy and a further decrease after the onset of labor. Intracellular injection of the fluorescent molecule Lucifer yellow demonstrates rapid and extensive spread from an injected cell to neighboring cells in the myometrial tissues from pregnant women but not in those from nonpregnant women. Moreover, octanol, isoproterenol, and dibutyryl adenosine 3′,5′-cyclic monophosphate indicate the rapid and reversible decrease in input resistance and Lucifer yellow transfer with changes requiring seconds to minutes. These results provide evidence that electric and metabolic coupling between human myometrial cells is dramatically increased during pregnancy, reaching a maximum at term during labor, and that this coupling is rapidly and reversibly decreased after specific forms of drug treatment. These results suggest two modes of modulation of gap junction coupling between smooth muscle cells of human myometrium during pregnancy, one regulating their presence and the other their permeability.

In rats and guinea pigs, morphologic studies have shown that gap junctions increased in number and size between myometrial cells at parturition, although somewhat higher numbers were present before parturition in the latter species.[1, 2, 4] On the other hand, recent studies of determination of input resistance and Lucifer yellow spread have demonstrated that electric and metabolic coupling was improved between myometrial cells in these species during periods of term labor.[10-12] In both species, because the improvement of the coupling was well correlated with development of gap junctions, it was concluded that the site of coupling and low electric resistance was the gap junctions and that the alteration in the coupling was based on the change in number of gap junctions between myometrial cells.

This study evaluated the change in gap junction number by showing the difference in electric and metabolic coupling between myometria from nonpregnant and pregnant women. The improved cell-to-cell coupling observed in pregnant groups provides evidence that gap junctions increase in myometrium from women undergoing cesarean section, although gap junction profiles in women during early pregnancy and normal, spontaneous vaginal delivery are not known. Furthermore, myometrial cells were found to be relatively well coupled in pregnant women even before labor, suggesting that the number of gap junction in pregnant human myometrium are already numerous before labor. This pattern of change in gap junction number is similar to that in guinea pigs and sheep[3, 4] but appear to be different from that in rats, where gap junctions increased dramatically about 24 to 36 hours before the onset of labor.[1, 2] The different patterns of change in structural coupling may be dependent on the changing hormonal environment in each species.

Because gap junctions are thought to provide a pathway for the flow of electrolytes and small molecules between cells,[13] the appearance of gap junctions would promote electrical and contractile synchrony in the myometrium, resulting in coordinated contractions of the uterus. Therefore their appearance between myometrial cells in human preceding or during labor is necessary for the generation of powerful contractions of the uterus and termination of pregnancy.

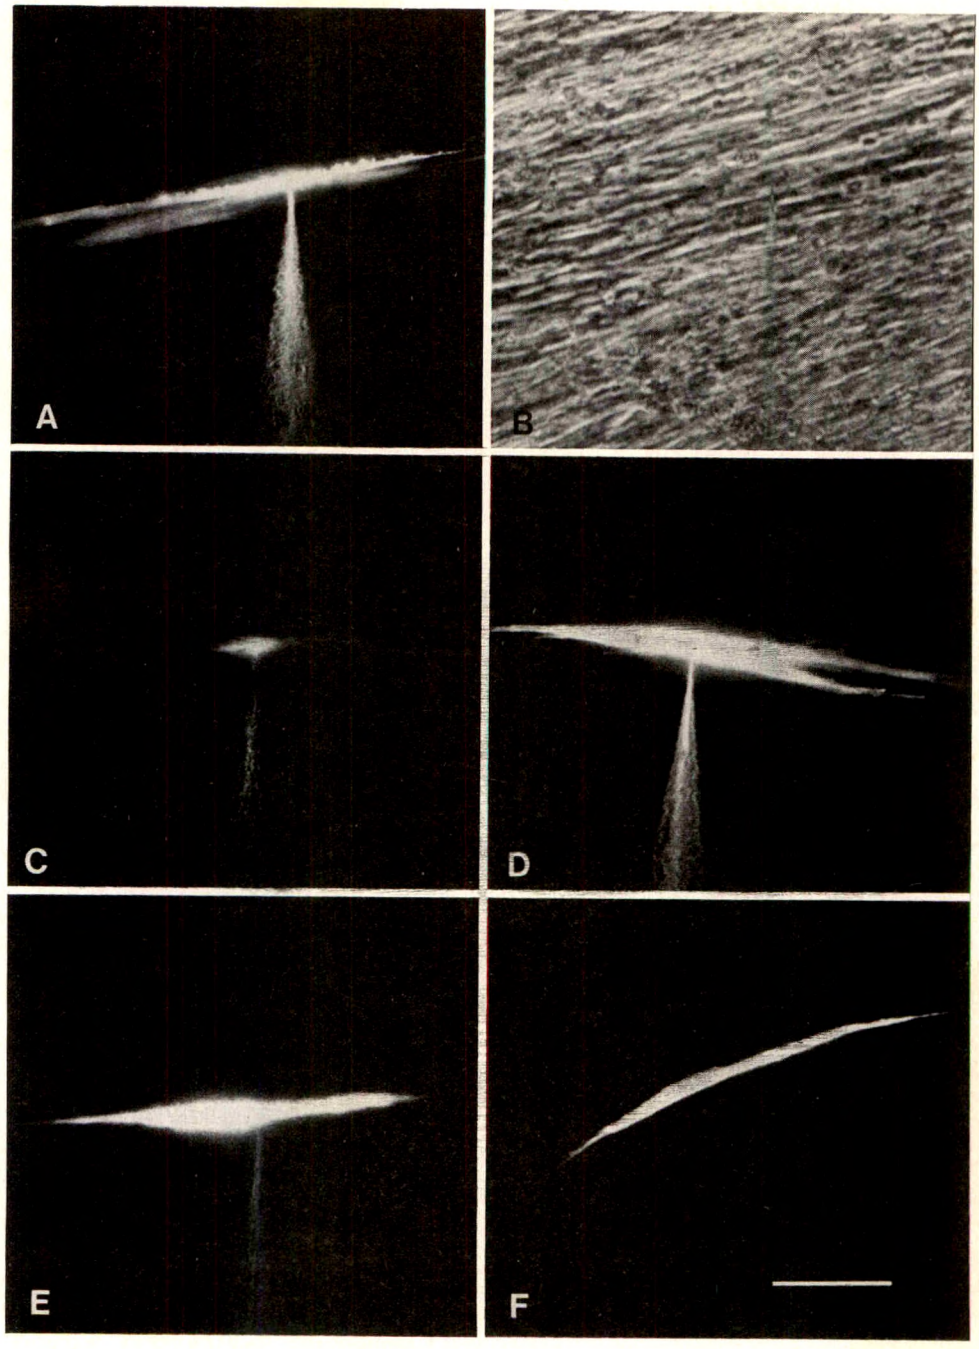

Fig. 5. Fluorescence photomicrographs after injecting the fluorescent probe Lucifer yellow into cells in myometrial preparations from women. *Scale bar* (in **F**) represents 100 μm. All six figures (**A** to **F**) are same magnification. **A,** Two minutes after injection of Lucifer yellow into cell in tissue from woman during labor. Lucifer yellow fluorescence is visible in several neighboring cells. **B,** Phase-contrast photomicrograph of field in **A. C,** Five minutes after injection of Lucifer yellow into cell in tissue from nonpregnant woman. Only injected cell is illuminated, and Lucifer yellow is undetectable in adjacent cells. **D,** Three minutes after injection of Lucifer yellow into cell in tissue from woman before labor. As found in tissue from woman during labor **(A),** Lucifer yellow spreads well to neighboring cells. **E,** Five minutes after injection of Lucifer yellow into cell in tissue from another woman before labor. Lucifer yellow is detectable in adjacent cells, but spread of Lucifer yellow is poorer than that found in **D. F,** Ten minutes after injection of Lucifer yellow into cell in 1.2 mmol/L octanol-applied tissue from woman during labor. Microelectrode was removed from cell at 5 minutes after injection. Lucifer yellow is detectable in only injected cell.

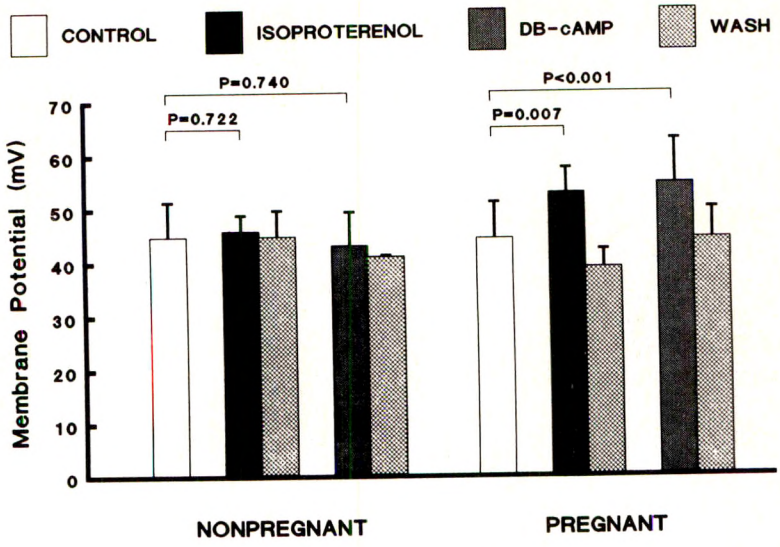

Fig. 6. Effect of isoproterenol (10^{-6} mol/L) or dibutyryl adenosine 3′,5′-cyclic monophosphate (5×10^{-4} mol/L) on the membrane potential in myometrial preparations from nonpregnant and pregnant women. *Bars*, Mean values ± SEM from impaled cells.

Not only is the presence of gap junctions necessary for cell-to-cell coupling, but openness of the channels is also required for electrolytes and metabolites to pass between myometrial cells. Experimentally, cell-to-cell coupling can be reversibly changed by the alteration of permeability of gap junctions, according to changes in intracellular Ca^{2+}, intracellular pH, intracellular 3′,5′-cyclic monophosphate, and many pharmacologic agents such as long-chain alcohols.[14-16] Opened (functionally well-coupled) gap junctions would be expected to promote greater electrical and contractile synchrony in the myometrium and lead to more forceful and frequent contractions and more effective labor. Alternatively, closed (functionally uncoupled) gap junctions would reduce the synchrony and lead to ineffective labor and a prolongation of pregnancy (i.e., the same condition existing in the absence of the junctions). The possible significant role of modulation of gap junction permeability in the myometrial contractility was observed in this study after the application of the agents (octanol, isoproterenol, and dibutyryl adenosine 3′,5′-cyclic monophosphate) that close gap junctions (Figs. 4 and 7).

Octanol is reported to decrease junctional permeability by decreasing the pore size of gap junctions, thereby resulting in uncoupling between cells.[16] This study has shown that octanol rapidly (≤60 seconds) increased input resistance and blocked dye spread after application to myometrial preparations from pregnant women, where gap junctions are numerous and input resistance was initially low before treatment. Furthermore, input resistance returned to pretreatment values immediately after washing out octanol from the preparations. These quick changes in input resistance at both application of and recovery from octanol indicate that this alcohol rapidly and reversibly regulates gap junction permeability, because such a rapidity cannot be explained by changes in gap junction numbers. On the other hand, octanol affected neither input resistance nor dye spread in preparations from nonpregnant women, indicating that octanol has little effect on tissues with no or few gap junctions between cells.

As found during application, octanol, isoproterenol, and dibutyryl adenosine 3′,5′-cyclic monophosphate in myometrial preparations from pregnant women increased input resistance and blocked dye spread with changes requiring similar time scales. The decreased coupling by these agents results from the decrease in junctional permeability, because their changes and predominant effects on the pregnant tissue are identical to those observed during application of octanol (Fig. 4 vs Fig. 7). Although the sites on which these two agents act are different, both of them are well known to elevate 3′,5′-cyclic monophosphate in the myometrial cells.[17, 18] This implies that, regardless of the sites, the uniform consequence of elevated 3′,5′-cyclic monophosphate is the reduction in permeability of gap junctions. Similar effects of elevated 3′,5′-cyclic monophosphate on junctional permeability has been shown in rat myometrium,[19] but the mechanisms by which 3′,5′-cyclic monophosphate reduces the permeability of myometrial gap junctions is unclear. Recently it has been proposed that activation of protein kinase by 3′,5′-cyclic monophosphate with consequent phosphorylation of junctional

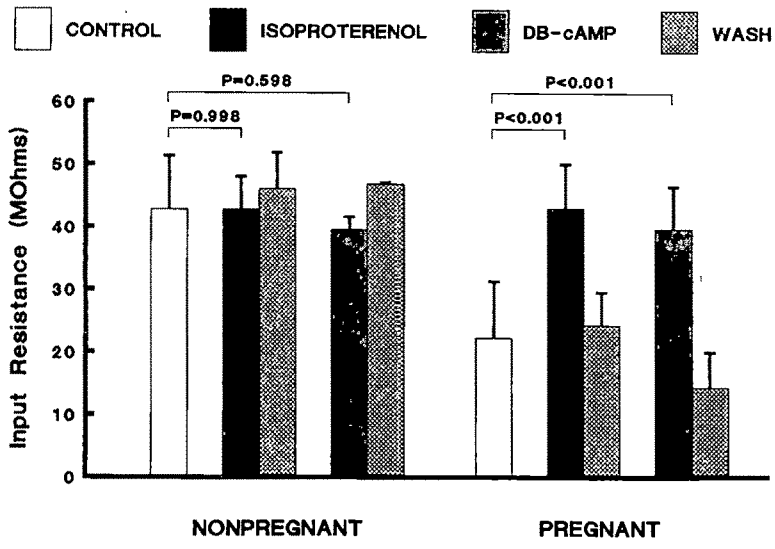

Fig. 7. Effect of isoproterenol or dibutyryl adenosine 3′,5′-cyclic monophosphate on input resistance in myometrial preparations from nonpregnant and pregnant women. *Bars*, Mean values ± SEM from impaled cells.

protein is necessary for the change in gap junction permeability in rat heart and liver,[20, 21] but the functional significance of this remains to be clearly identified.

Isoproterenol is one of the nonselective β-adrenergic receptor agonists. In clinical treatment other β-adrenergic receptor agonists with fewer side effects (primarily β_2-adrenoceptor agonists) are most widely used as tocolytic drugs.[22] They are reported to stimulate adenylate cyclase and thereby indirectly elevate 3′,5′-cyclic monophosphate in the myometrial cell.[23] Therefore 3′,5′-cyclic monophosphate is thought to play an important role in the modulation of uterine contractility. However, the exact mechanisms by which it inhibits spontaneous activity in the myometrium is poorly understood and remains controversial. It has been suggested to reduce intracellular Ca^{2+} concentration either by stimulating Ca^{2+} uptake into storage sites[24] or by increasing Ca^{2+} efflux across the plasma membrane.[25] However, the closure of gap junctions could produce more profound effects on relaxation than its direct action on Ca^{2+}. Closure of the junctions would prevent exitation by inhibiting the spread of action potentials and also thereby indirectly inhibit Ca^{2+} entry. One of the primary sites of action for agents that stimulate 3′,5′-cyclic monophosphate in myometrial cells may be the closure of gap junctions and the promotion of the ineffective spread of electrical activity between myometrial cells. In addition, drugs such as the β-adrenergic receptor agonists hyperpolarize the values of membrane potential (Fig. 6), thus further reducing excitability. However, hyperpolarization is clearly not a requirement for decreased excitability, because octanol produces uncoupling independent of any change in values of membrane potential (Fig. 3).

We found that spontaneous contractile activity in the pregnant myometrial preparations was completely prevented by application of either octanol, isoproterenol, or dibutyryl adenosine 3′,5′-cyclic monophosphate. The drug-induced quiescence in vitro may be indirect evidence that increased permeability of gap junctions is necessary for improvement of coupling and propagation of activity. These data are further interpreted to mean that the modulation of junctional permeability may be an important mechanism, both physiologically and pharmacologically, for regulation of myometrial contraction, especially in species where a relatively high number of gap junctions exist before labor. The present study demonstrates that input resistance in myometrial tissues from women before labor is already low and indicates that gap junctions exist even before labor. However, this low value of input resistance in the nonlabor group may be an artificially low in vitro. There might be some endogenous substance that keeps the junctions in the closed configuration until just before labor in vivo. This substance may not be present in vitro, and thus most gap junctions may be in open state.

The findings of these studies suggest that cell-to-cell coupling between human myometrial cells is regulated by both the presence and the permeability of gap junctions and that these two methods of modulation of GJs may be major mechanisms for control of myometrial contractile activity in the human uterus during pregnancy. Further studies are needed to clarify the role of gap junctions in human labor, especially normal vaginal

deliveries, and to assess clinical treatment with excitants and inhibitors of uterine contractions in relation to modulation of gap junctions.

We thank Ms. Debbie Merrett for technical assistance.

OBJECTIVE: We attempted to evaluate the effects of danazol on autoantibodies, in particular, to phospholipids, and on the immune system in patients with adenomyosis.

STUDY DESIGN: Forty-two patients with adenomyosis who had high titers of autoantibodies were randomly chosen, and they received 400 mg/day of danazol for 4 months (n = 22) or underwent hysterectomy (n = 20).

RESULTS: Among the six autoantibodies we investigated, the incidence of antiphosphatidylinositol immunoglobulin G was the highest (42.9%), followed by antiphosphatidylglycerol immunoglobulin G (38.1%). The autoantibody titers decreased with time and were comparable to the control values 16 weeks after treatment in both groups. Total serum levels of immunoglobulin G and M were high before treatment, but immunoglobulin M levels decreased significantly in week 8 during treatment with danazol, whereas C4 levels increased and C3 levels decreased with danazol.

CONCLUSION: Danazol has an inhibitory effect on the autoimmunologic response associated with adenomyosis. (Am J Obstet Gynecol 1992;167:481-6.)

Key words: Adenomyosis, endometriosis, autoantibody, autoimmunity, danazol

Endometriosis is associated with immunologic abnormalities such as increases in the number[1] and activity[2] of macrophages in peritoneal fluid and secretion of cytokines such as interleukin-1 and tumor necrosis factor by these cells.[3, 4] In addition, autoantibodies, in particular, antiphospholipid antibodies, are often detected in peripheral blood samples obtained from patients with endometriosis.[5-7] Antiphospholipid antibodies, which are found in many patients with endometriosis, are often detected in patients with autoimmune diseases such as systemic lupus erythematosus[8] and rheumatoid arthritis.[9] More recently, autoantibodies have also been demonstrated in women with repeated spontaneous abortion.[10, 11]

Danazol, a drug commonly used for the treatment of endometriosis, exerts a direct effect on endometriosis,[12] reduces autoantibodies, and normalizes the immunologic abnormalities associated with it.[13] In a previous study we reported that autoantibodies, in particular, antiphospholipid antibodies, are also often detected in peripheral blood samples obtained from patients with adenomyosis.[6, 7] In the current study we administered danazol to patients with adenomyosis who were positive for autoantibodies to evaluate its effects on autoantibodies and the immune system.

Material and methods

Subjects. Fifty-nine patients with adenomyosis diagnosed by bimanual examination, ultrasonography, hysteroscopy,[14] serum CA 125 levels, or autoantibody levels were included in this study. Bimanual examination and ultrasonography were performed to ascertain the size of the uterus and to detect adenomyoma. In a previous study a retrospective analysis revealed that 93.8% of the patients who underwent hysterectomy and in whom the presence of adenomyosis was histologically confirmed had elevated levels of autoantibodies and/or CA 125 in peripheral blood.[7] Further, hysteroscopy revealed that 31 (77.5%) of the 40 patients with adenomyosis had characteristic findings such as a persistent large glandular ostium and/or network of dilated vessels throughout the menstrual cycle.[14]

Autoantibody levels were increased in 42 cases that were divided into two groups in a randomized fashion: 22 patients received danazol (400 mg/day) for 16 weeks and 20 underwent total hysterectomy (Table I). There

were 19 patients with an enlarged uterus (>165 gm) in the surgery group and 17 in the danazol group (calculated from ultrasonography). Postoperative histologic examinations confirmed the presence of ectopic endometrial tissues in the myometrium in all cases from the surgery group. The histologic diagnosis of adenomyosis was based chiefly on the finding of endometrial islands deep beneath the mucous surface, within the myometrium; that is, when the endometrial tissue was at least the distance of one high-power field below the basal endometrium. The diagnosis of endometriosis was established by laparoscopy or laparotomy. Sixty-six normal women who had ligation of fallopian tubes for contraception purposes at laparoscopy and who were without adenomyoma or inflammation of pelvic tissues served as controls. Women without adenomyosis and patients with adenomyosis and a history of repeated spontaneous abortion, thrombosis, or autoimmune diseases or who were receiving medication were excluded.

Assay methods. Blood samples were collected before treatment and 8 and 16 weeks after operation in one group and during treatment in the danazol group for immunologic evaluation. Antibodies to the following phospholipids were determined by enzyme-linked immunosorbent assay[6,7]: anticardiolipin immunoglobulin (Ig) G and IgM (CL-G and CL-M), anti–phosphatidic acid IgG (PA-G), antiphosphatidylinositol IgG (PI-G), antiphosphatidylserine IgG (PS-G), and antiphosphatidylglycerol IgG (PG-G). Briefly, 20 μg/ml of each phospholipid (Sigma Chemical Co., St. Louis) was allowed to adsorb after immobilizing protamine sulfate (5 μg/ml, Sigma) on microplates. Fiftyfold diluted sera were then added and allowed to react with peroxidase-labeled antihuman IgG and IgM antibodies (Dako, Denmark). After coloration with o-phenylenediamine

dihydrochloride (Sigma), reaction was stopped by adding 100 μl of 2.5 mol/L sulfuric acid and absorbance was determined at 490 nm. Standard sera supplied by Harris[15] were used for quantitative determination. IgG and IgM levels were expressed in GPL and MPL units per milliliter, respectively. Values exceeding mean + 2 SD of normal were regarded as abnormally high.

Immunoglobulins (IgG, IgM, and IgA) and components C3 and C4 of complement in serum were determined by latex agglutination photometric assay.[16] The fully automatic immunochemical analyzer used to process the samples (laser nephelometry, LX-3000; Eiken Chemical Co., Ltd., Tokyo) can perform all procedures from imputing of parameters to data printout completely automatically. However, dilution of the samples before the analysis was done manually with a special diluter. Absorbance was determined at 660 nm, 6 and 33 seconds after the diluted test sera were mixed with antiserum (Eiken) in cells for reaction, and the difference between the two measurements was calculated. Concentrations were calculated from the standard curve.

Lymphocyte subsets were determined by two-color flow cytometry.[17] Monoclonal antibodies CD4-FITC (Becton Dickinson Immunocytometry Systems, San Jose, Calif.), 4B4-RD1 (Coulter Electronics, Hialeah, Fla.), CD11-FITC (Coulter), and CD8-PE (Becton Dickinson) were used to determine lymphocyte subsets with a laser flow cytometer (FCM-1D; Nihon Bunko, Tokyo): $CD4^+4B4^+$ (helper T cells), $CD4^+4B4^-$ (suppressor/inducer T cells), $CD11^-CD8^+$ (cytotoxic T cells), $CD11^+CD8^-$ (natural killer T cells), and $CD11^+CD8^+$ (suppressor T cells).

Serum CA125 levels were determined with radioimmunoassay kits (Centocor, Tokyo). Radioimmunoassay kits for serum estradiol and free testosterone levels were purchased from DPC Japan (Tokyo).

Statistical analyses. The results were expressed as mean ± SD. Statistical analyses of the immunoglobulins, complement components, and serum steroid hormone levels were performed with the one-way analysis of variance, and the levels of lymphocyte subsets were determined with the Kruskal-Wallis test. Differences were regarded as significant if $p < 0.05$.

Results

The incidences of each autoantibody in the control ($n = 66$) and adenomyosis ($n = 42$) groups are shown in Fig. 1. The incidence of autoantibody in the control group ranged between 2.5% and 6.7%; among them, that for PA-G was the highest. In the adenomyosis group the incidence was highest for PI-G (18 patients, 42.9%), followed by PG-G (38.1%) and PS-G (31.1%), and then by CL-M, PA-G, and CL-G. The number of types of autoantibodies per patient was 1 for the majority of patients (21 patients, 50.0%), followed by 2 in 10 patients (23.8%) and 3 in 6 patients (14.3%).

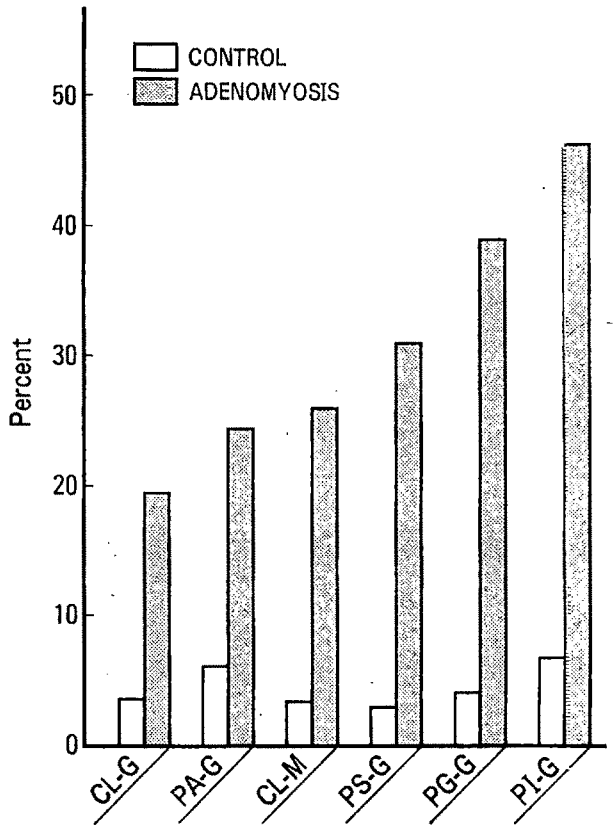

Fig. 1. Incidence of different types of autoantibodies in control and adenomyosis groups.

Fig. 2 illustrates the changes in individual autoantibodies during medical treatment and after surgery. The levels of autoantibodies in the control group were as follows: 0.97 ± 0.37 GPL U/ml for CL-G, 1.92 ± 1.89 MPL U/ml for CL-M, 1.37 ± 0.09 GPL U/ml for PA-G, 1.09 ± 0.39 GPL U/ml for PI-G, 0.70 ± 0.51 GPL U/ml for PS-G, and 1.25 ± 0.13 GPL U/ml for PG-G. The overall mean ± SD of autoantibodies in all patients with adenomyosis (surgery and danazol groups combined) before treatment was as follows: 6.27 ± 3.96 GPL U/ml for CL-G, 12.48 ± 5.07 MPL U/ml for CL-M, 8.42 ± 7.37 GPL U/ml for PA-G, 5.85 ± 2.55 GPL U/ml for PI-G, 9.71 ± 8.56 GPL U/ml for PS-G, and 4.48 ± 0.67 GPL U/ml for PG-G. All values had decreased at week 8 of treatment in both groups and were very close to control values by week 16. At week 8 the number of patients with high titers of autoantibodies was 12 in each group, that is, 60.0% in the surgery group and 54.5% in the danazol group (Fig. 3). At week 16 it had decreased to 6 (30.0%) in the surgery group and only 3 (13.6%) in the danazol group. The number of patients with high titers of autoantibodies thus markedly decreased with time.

Table II shows the changes in lymphocytes subsets observed after treatment. Levels of helper T cells, which were higher than the upper control limit before

treatment in both groups, tended to decrease; however, the difference at week 16 was not significant. In contrast, suppressor T cells, which showed slightly low values compared with control before treatment, tended to increase with time. The helper/suppressor T-cell ratio decreased linearly to values that were slightly lower than those of the control population. Cytotoxic, suppressor/inducer, and natural killer T cells remained almost unchanged in both groups.

Table III shows changes in values of immunoglobulin and complement components C3 and C4 after treatment. Pretreatment IgG levels were significantly higher in the surgery and danazol groups than in the control group ($p < 0.05$ and $p < 0.01$). However, no apparent change was seen after treatment in either group. Pretreatment IgM values were also significantly higher in both groups than in the control ($p < 0.001$). In the danazol group at week 8 these values had significantly decreased as compared with pretreatment values ($p < 0.05$) and were almost at control levels at week 16. IgA values were close to the control upper limit before treatment in both groups. Slight decreases were seen after treatment in both groups.

C3 levels were comparable to those in the controls in both groups before treatment. In the danazol group they had significantly decreased compared with the pretreatment values at week 8 ($p < 0.01$). C4 levels were also comparable to those in the controls in both

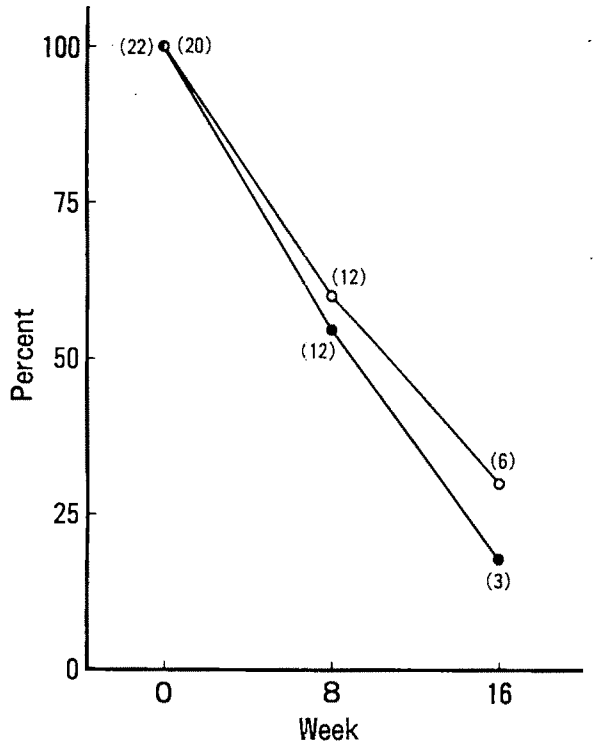

Fig. 3. Percentage of patients with high titers of autoantibody in surgery (○) and danazol (●) groups. *Figures in parentheses* indicate number of patients.

groups before treatment. However, in contrast to C3 levels, C4 significantly increased compared with the control values at weeks 8 and 16 in the danazol group ($p < 0.001$).

Serum estradiol and free testosterone levels were 32 ± 16 and 1.1 ± 0.9 pg/ml, respectively, in the control group (Table IV). Estradiol levels tended to decrease during treatment with danazol, but the difference was not significant. In contrast, free testosterone levels markedly increased during treatment, showing 31- and 34-fold increases over pretreatment levels at weeks 8 and 16, respectively ($p < 0.001$).

Comment

Endometriosis is associated with immunologic abnormalities, and high titers of autoantibodies have often been detected in serum obtained from patients with this condition,[5-7] suggesting that an autoimmune process is involved in endometriosis. El-Roeiy et al.[18] administered danazol to patients with endometriosis and high autoantibody titers and observed a decrease of autoantibodies and immunologic improvement with time during treatment. In a previous study we reported that high titers of autoantibodies were detected in patients with adenomyosis as often as in those with endometriosis.[6, 7] In this study in patients with adenomyosis we show that autoantibody levels decreased with time during treatment and reached almost control values after 16 weeks of treatment. This effect of danazol

is similar to that reported in patients with endometriosis.[18]

Findings obtained in the current study show that danazol has an effect on immunoglobulin concentrations, which were higher before treatment in patients with adenomyosis than in the controls. According to El-Roeiy et al.,[18] IgG and IgM levels are higher in autoantibody-positive patients with endometriosis than in those who are autoantibody negative. In the current study IgG and IgM levels tended to increase in the surgery group: in particular, increases in IgM levels were statistically significant compared with pretreatment values, 8 weeks after surgery. In contrast, immunoglobulin levels decreased after treatment in the danazol group. Especially, decreases in IgM levels were statistically significant compared with pretreatment values at week 8 during treatment. These findings corroborate in part those of El-Roeiy et al.[18] and indicate that danazol inhibits the production of immunoglobulins.

Only a few studies have been conducted on the effect of danazol on complement components in endometriosis. According to Agnello et al.,[19] C4 levels had increased in a patient with systemic lupus erythematosus during treatment with danazol. In the current study serum C3 and C4 levels responded differently to danazol therapy, with C3 levels decreasing significantly at week 8 during treatment compared with pretreatment levels and C4 levels increasing during treatment. Increases in C4 levels were not significant compared with pretreatment levels but were significant compared with controls. There are reports that C3 levels decrease in patients with autoimmune hemolytic anemia[20] and increase in those with hereditary angioedema[21] during treatment with danazol. Danazol has already been shown to affect immunocytes.[22, 23] C3 and C4 are produced by hepatocytes and immunocompetent cells such as monocytes and macrophages.[24] The fact that these complement components were affected differently by danazol in the current study suggests that danazol may act differently on those cells.

The fact that immunocompetent cells are under the influence of various hormones, in particular, steroid hormones, has been reported.[25] In fact, steroid

hormones such as estrogen,[26] androgen,[27] and glucocorticoids[28] have direct effects on T cells in vitro. In addition, estrogen increases helper T-cell activity and decreases suppressor T-cell activity[29] while androgen increases suppressor T-cell activity. These sex steroids also have direct effects on B cells.[30] In the current study estradiol levels decreased slightly on administration of danazol, while free testosterone levels markedly increased. However, the helper/suppressor T-cell ratio tended to normalize. Therefore it is uncertain if the changes in sex steroids may have affected the lymphocyte subsets.

It would be very interesting to know the mechanisms by which danazol affects the autoimmune response in patients with adenomyosis. The putative mechanisms of action of danazol include a direct effect on endometriosis tissues in addition to inhibitory effects on the hypothalamus, pituitary, and ovaries,[12, 31] resulting in regression of the endometriotic lesions. IgG and complement components C3 and C4 are very often deposited in ectopic endometriosis tissues in the tunica muscularis in patients with adenomyosis,[32] a finding that suggests that strong local immunologic reactions take place in these patients. It is therefore tempting to say that danazol might also have a direct inhibitory effect on the local immune response in patients with endometriosis and adenomyosis. Further studies on the mechanisms by which danazol affects the immune response are needed to provide an answer to these questions.

Serial measurements of platelet angiotensin II binding in two patients with hypertension in pregnancy: Case reports

Philip N. Baker, DM, and Fiona Broughton Pipkin, DPhil
Nottingham, England

Serial estimations of platelet angiotensin II binding were made in two patients with hypertension developing in the third trimester of pregnancy. The fall in platelet angiotensin II binding that is seen in normotensive pregnancy did not occur in these two patients. (AM J OBSTET GYNECOL 1992;167:487-8.)

Key words: Angiotensin II, platelet membrane glycoproteins, pregnancy toxemia, renin-angiotensin system

Two patients were recruited to a longitudinal study ($n = 30$) of platelet angiotensin II binding in normotensive pregnancy. In one of these patients platelet angiotensin II binding was measured before conception. Hypertension developed subsequently, and thus they were excluded from the original study. Neither woman was known to have renal, metabolic, or cardiovascular disease. Both patients were receiving unrestricted sodium intake and on recruitment to the study had normal serum urea, creatinine, and electrolyte values. In both patients serial platelet counts and plasma creatinine and urate levels were measured, with serial estimations of platelet angiotensin II binding and plasma angiotensin II concentration being performed, as previously described.[1]

Case reports

Case 1. A 28-year-old normotensive nulliparous woman was initially studied on day 6 of the menstrual cycle. She conceived 3 months later and was then studied at intervals during her pregnancy. She remained normotensive (diastolic blood pressure <80 mm Hg, Korotkoff phase 4) until 32 weeks' gestation, when a blood pressure recording of 140/95 (Korotkoff phase 4) mm Hg was noted. The blood pressure subsequently stabilized; however, at 37 weeks' gestation it was recorded as 145/100 (Korotkoff phase 4) mm Hg and proteinuria (2+) was noted on dipstick testing for the first time. After hospital admission, the blood pressure remained elevated and significant proteinuria was confirmed (0.63 gm per 24-hour specimen). Labor was induced. Eight hours after artificial rupture of membranes and commencement of oxytocin infusion, the cervix remained only 2 cm dilated. A cesarean section was performed and a male infant weighing 2.64 kg was delivered. She recovered well postoperatively, and at 12 weeks post partum she was normotensive, with no proteinuria on dipstick testing (<0.1 gm per 24-hour specimen).

Case 2. A 26-year-old primiparous woman was initially studied at 11 weeks' gestation, at which time the blood pressure was 110/65 (Korotkoff phase 4) mm Hg. She remained normotensive (diastolic blood pressure <80 [Korotkoff phase 4] mm Hg) until 38 weeks' gestation, when the blood pressure was recorded as 140/100 (Korotkoff phase 4) mm Hg. No proteinuria was present. At 36 hours after hospital admission, the blood pressure remained elevated, and she went into spontaneous labor. A male infant weighing 3.02 kg was delivered vaginally. At 12 weeks post partum the blood pressure was 120/60 (Korotkoff phase 4) mm Hg.

Fig. 1 illustrates the serial values of platelet angiotensin II binding in both patients, for comparison with the median values that were found in a longitudinal study of normotensive pregnancy.[1] When the serial estimations of platelet count, plasma urate and creatinine concentrations, and plasma angiotensin II concentration were considered, no value of either patient was outside the interquartile range established for normotensive pregnancy.[1]

Comment

In normotensive pregnancy there is a diminution in platelet angiotensin II binding, with a significant reduction being apparent by the first trimester, which parallels the pregnancy-induced decrease in pressor responsiveness to infused angiotensin II.[1] In women with established hypertension in pregnancy, the increased levels of platelet angiotensin II binding, in comparison with levels in normotensive primigravid women, also parallels the increased angiotensin II pressor responsiveness found in hypertension in pregnancy.[2]

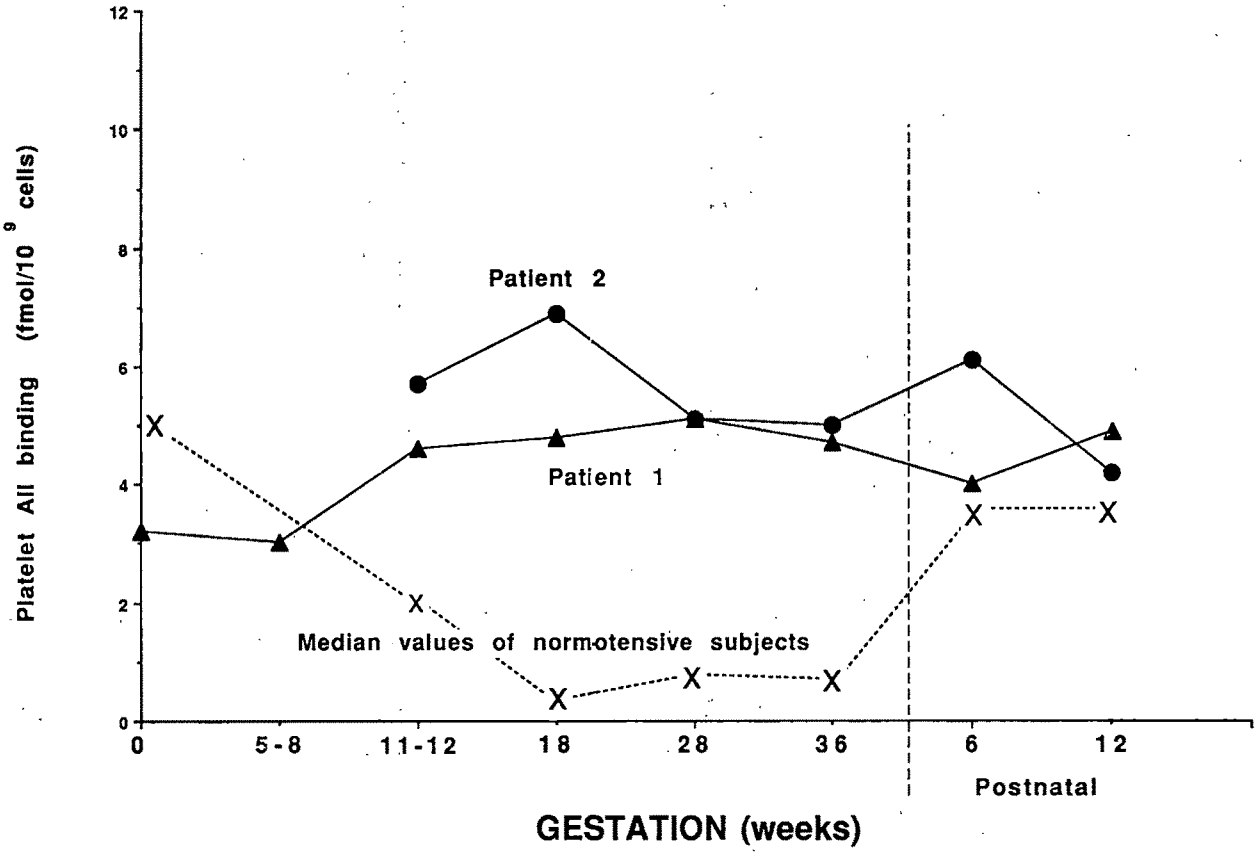

Fig. 1. Platelet angiotensin II binding in two patients in whom hypertension developed in pregnancy. Median values of platelet angiotensin II binding determined from a longitudinal study of normotensive pregnancy[1] are also shown.

The results from the two cases described support the hypothesis that the elevated levels of platelet angiotensin II binding in women with hypertension in pregnancy, as compared with those in normotensive primigravid women, are not due to an increase in binding toward the end of pregnancy in hypertensive patients but instead are due to absence of the early pregnancy decrease in platelet angiotensin II binding found in normotensive pregnancy. The use of platelet angiotensin II binding as a less invasive alternative to the angiotensin II sensitivity test in screening for hypertension in pregnancy has previously been suggested.[2] If the hypothesis above is correct, it should be possible to identify patients at risk of hypertension as early as the antenatal clinic booking visit.

Down-regulation by plasma angiotensin II concentration has been suggested as a mechanism controlling platelet angiotensin II binding in normotensive pregnancy.[1] The results of these two cases, in which platelet angiotensin II binding appeared to be unrelated to plasma angiotensin II concentration, suggest that a more complex mechanism regulates platelet angiotensin II binding in pregnancies complicated by hypertension.

Ifosfamide alone and in combination in the treatment of refractory malignant gestational trophoblastic disease

Gregory P. Sutton, MD,[a] John T. Soper, MD,[b] John A. Blessing, PhD,[c] Kenneth D. Hatch, MD,[d] and Danny R. Barnhill, MD[e]

Indianapolis, Indiana, Durham, North Carolina, Buffalo, New York, Tucson, Arizona, and Washington, D.C.

OBJECTIVE: We attempted to evaluate the use of ifosfamide either alone or in combination in patients with refractory malignant gestational trophoblastic disease.

STUDY DESIGN: Our study comprised, in part, a phase II multiinstitutional trial of ifosfamide in refractory gynecologic malignancies and, in part, a review of institutional experience with ifosfamide in combination chemotherapy.

RESULTS: Single-agent ifosfamide produced a significant response in titer in one of two patients with refractory choriocarcinoma. Ifosfamide with etoposide and cisplatin (also known as VIP) resulted in significant response in human chorionic gonadotropin titers in three patients with highly refractory metastatic gestational trophoblastic disease and one cure in this group of patients.

CONCLUSION: Ifosfamide has activity in refractory choriocarcinoma and, when combined with etoposide and cisplatin (VIP), may be curative. (Am J Obstet Gynecol 1992;167:489-95.)

Key words: Ifosfamide, refractory gestational trophoblastic disease

Metastatic gestational trophoblastic disease that carries a poor prognosis is cured in approximately 80% of patients receiving chemotherapy with drug combinations such as MAC (methotrexate, dactinomycin, and chlorambucil)[1] or EMACO (etoposide, methotrexate, dactinomycin, cyclophosphamide, and vincristine).[2] However, the development of drug resistance still accounts for a large proportion of the deaths from this illness.[3]

Ifosfamide, a congener of cyclophosphamide, has a broad spectrum of activity against tumors such as ovarian and cervical carcinomas and uterine sarcomas. Prohibitive urothelial toxicity requires the concurrent administration of mercaptoethane sodium sulfonate (mesna). In 1989, ifosfamide and mesna received Food and Drug Administration approval for use in refractory testicular carcinoma. This approval was based mainly on the work of Loehrer et al.[4] who reported sustained remissions in 7 of 48 men with such malignancies after treatment with etoposide, ifosfamide, and cisplatin (also known as VIP).

In a Gynecologic Oncology Group phase II study of ifosfamide, highly resistant malignant trophoblastic disease was treated in two patients. A favorable response in one of these patients led to the use of VIP in three additional women with refractory trophoblastic disease. These four cases are summarized here and in Figs. 1 through 4.

Case reports

Case 1. A 27-year-old black woman underwent craniotomy for evaluation of a mass in March 1986, 5 months after the delivery of a viable preterm infant. Metastatic gestational choriocarcinoma was identified at the time of surgery. Staging studies indicated the presence of pulmonary metastases and an elevated serum human chorionic gonadotropin (hCG) level. She received chemotherapy with MAC over the next 8 months until the level failed to respond. She underwent two thoracotomies in December 1986 and a hysterectomy in January 1987. From this time until January 1988 she received chemotherapy with cisplatin and etoposide and then with methotrexate, hydroxyurea, vincristine, cyclophosphamide, and 5-fluorouracil. The hCG level rose to 5079 mIU/ml, and computerized tomography disclosed multiple new hepatic metastases. She received ifosfamide, 1.2 gm/m^2 intravenously daily for 5 days with mesna, 240 mg/m^2 intravenously im-

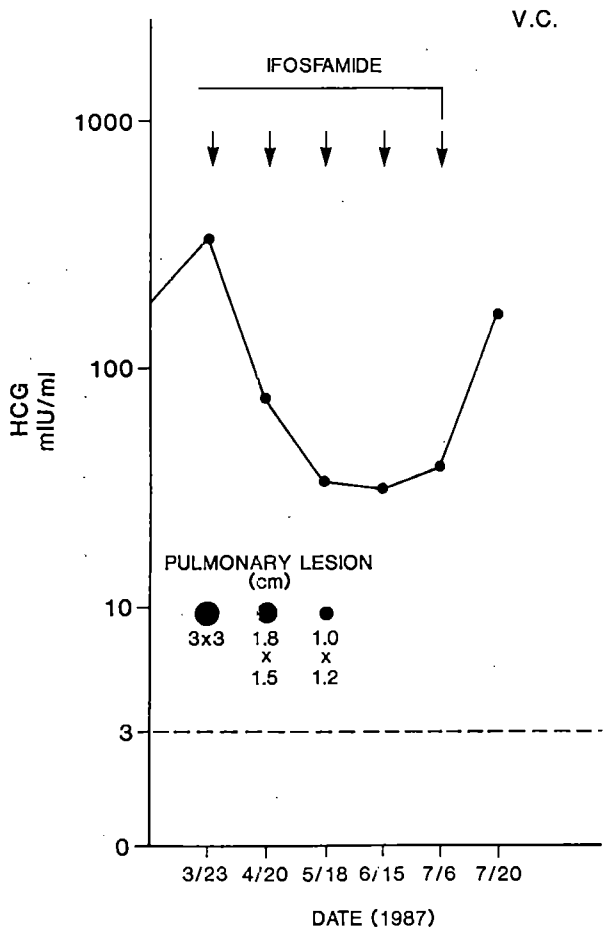

Fig. 1. hCG level and lesion response to ifosfamide alone in case 2.

mediately and 4 and 8 hours after each ifosfamide dose. The white blood cell count fell to 2300/mm³ and there was no other toxicity, but the hCG level rose to 49,690 mIU/ml within 4 weeks. This patient died 2 months later of respiratory failure.

Case 2. In a 30-year-old white woman, hemoptysis and vaginal bleeding developed about 4 months after the delivery of her second child by cesarean section. A curettage was done in July 1986 and choriocarcinoma was identified. Diffuse nodularity was observed on a chest radiograph. She received a single course of MAC, and the hCG level rose from 4786 to 7400 mIU/ml. She then was treated with eight courses of dactinomycin, etoposide, and methotrexate. This resulted in a fall in the hCG level to a nadir of 83 mIU/ml before it rose to 126 mIU/ml. She received two cycles of vinblastine, bleomycin, and cisplatin in November and December of 1986 and had a transient response in hCG. She underwent left thoracotomy and resection of pulmonary nodules and excision of vaginal metastases and then received dactinomycin and etoposide without response. She then received high-dose methotrexate and folinic acid without response before being referred for ifosfamide therapy. At the outset of treatment with this agent, the hCG level was 342 mIU/ml and there was a 3.0 × 3.0 cm nodule in the right lower lung field on radiograph.

She received a total of five courses of ifosfamide and mesna. The starting dose of ifosfamide was 1.2 gm/m², but this was escalated to 1.5 gm/m² because of lack of hematologic toxicity. With treatment every 4 weeks, this patient had a measurable partial response in the pulmonary nodule and a titer response to 32 mIU/ml before brain metastases developed. She died 6 months later (Fig. 1).

Case 3. An 18-year-old black woman, para 2-1-1, underwent suction curettage in December 1984 for a hydatidiform mole. Before evacuation, the hCG level was 167,000 mIU/ml. Within 10 weeks the hCG level was undetectable; however, in January 1986 the hCG value was 52 mIU/ml. Physical and ultrasonographic examination of the pelvis, as well as abdominal and cranial computerized tomograms, all gave normal results. A curettage yielded secretory endometrium, and the uterine cavity was sounded to 7.5 cm. She received four courses of chemotherapy with methotrexate with little drop in the hCG level, so dactinomycin and chlorambucil were added. Seven courses of MAC were administered, and in August 1986 a 1 cm nodule was noted on a chest radiograph. A fine-needle aspiration confirmed the diagnosis of metastatic choriocarcinoma, but the patient refused surgical resection of this mass and was transiently lost to follow-up.

In 1987 she received four courses of chemotherapy with bleomycin, etoposide, and cisplatin, and the disease was believed to be in remission. On June 10, 1988, she presented with an hCG level of 141,000 mIU/ml and a 3 cm left breast mass. Another curettage was performed and scanty tissue was obtained. On Aug. 8, 1988, the breast mass was 7 cm in diameter, and a biopsy confirmed the presence of metastatic choriocarcinoma. The hCG level was then 926,130 mIU/ML, and a large pleural effusion and multiple pulmonary nodules were present on a chest radiograph. She was referred to Indiana University Medical Center. Computerized tomography of the head demonstrated five discrete metastatic lesions that were enhanced with contrast. There was a right-to-left shift of the midline structures. On abdominal tomography, there were bilateral renal metastases, a nonfunctioning right kidney, and no apparent pelvic disease. She was treated with dexamethasone, dilantin, and 3000 cGy whole-brain radiotherapy in 300 cGY fractions with cobalt 60. Chemotherapy was initiated. She received 14 courses of EMACO (Fig. 2), consisting of etoposide 100 mg/m², dactinomycin 500 μg, vincristine 1.0 mg/m², and cyclophosphamide 600 mg/m². Methotrexate 100 mg/m² as an intravenous bolus and 200 mg/m² infused over 12 hours was given with intramuscular folinic acid rescue 15 mg every 12 hours times four. The hCG level decreased but began to rise in June 1989. After the rise was confirmed, therapy with etoposide, ifosfamide, and cisplatin was started. She received etoposide 75 mg/m², ifosfamide 1.2 gm/m², and cisplatin 30 mg/m² daily for 2 days

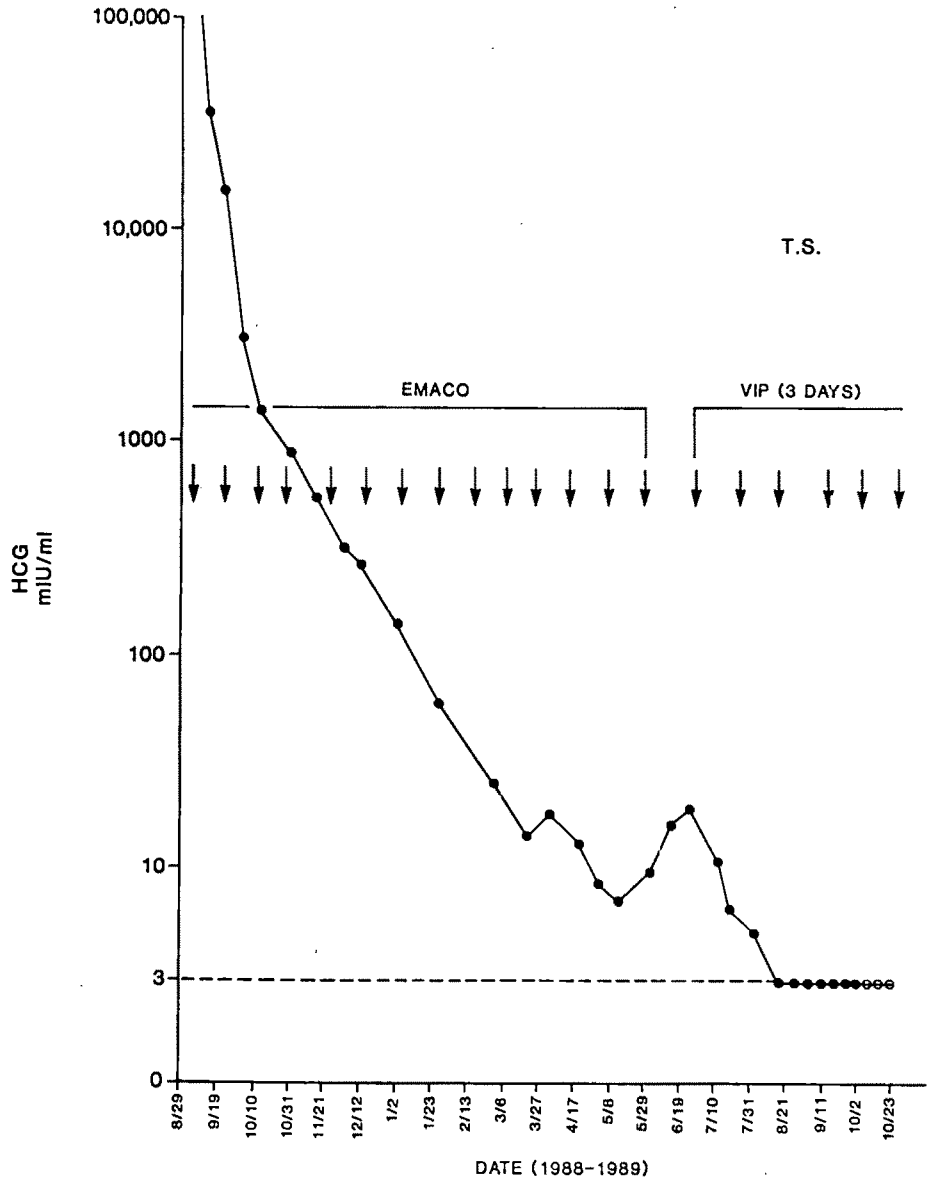

Fig. 2. Permanent remission induced with repeated 3-day courses of VIP therapy in EMACO-resistant patient (case 3).

during the first course and for 3 days during subsequent courses. Mesna was given in a 120 mg/m² intravenous bolus followed by 1.2 gm/m² intravenous infusion. Courses were repeated as often as counts permitted, about every 21 days. The hCG level was undetectable after the third course, and four additional courses were given. She was hospitalized twice for febrile neutropenia, which responded to parenteral antibiotics. The hCG values have remained <3.0 for 34 months since the first undetectable level and she is without symptoms.

Case 4. A 52-year-old white woman was referred to Duke University Medical Center in March 1988. She had had a term vaginal delivery 29 years before admission and a spontaneous abortion in 1982. She underwent an abdominal hysterectomy for bleeding in 1983 with no cancer seen histologically. She presented with a thyroid mass, numerous pulmonary metastases, and mediastinal lymphadenopathy. The initial hCG level was 30,000 mIU/ml. An open biopsy of the thyroid mass demonstrated choriocarcinoma of unknown origin, and abdominal computerized tomograms revealed multicystic enlargement of the ovaries. Shortly after admission, she underwent bilateral salpingo-oophorectomy; theca-lutein cysts were confirmed histologically. She received seven cycles of EMACO chemotherapy ending in June 1988. An hCG nadir of 20 mIU/ml was attained before a rise into the 70 to 100 mIU/ml range. She was treated with cisplatin 20 mg/m² and etoposide 100 mg/m² intravenously daily times five. Remission was attained after the first course of therapy, and she received three additional cycles. In

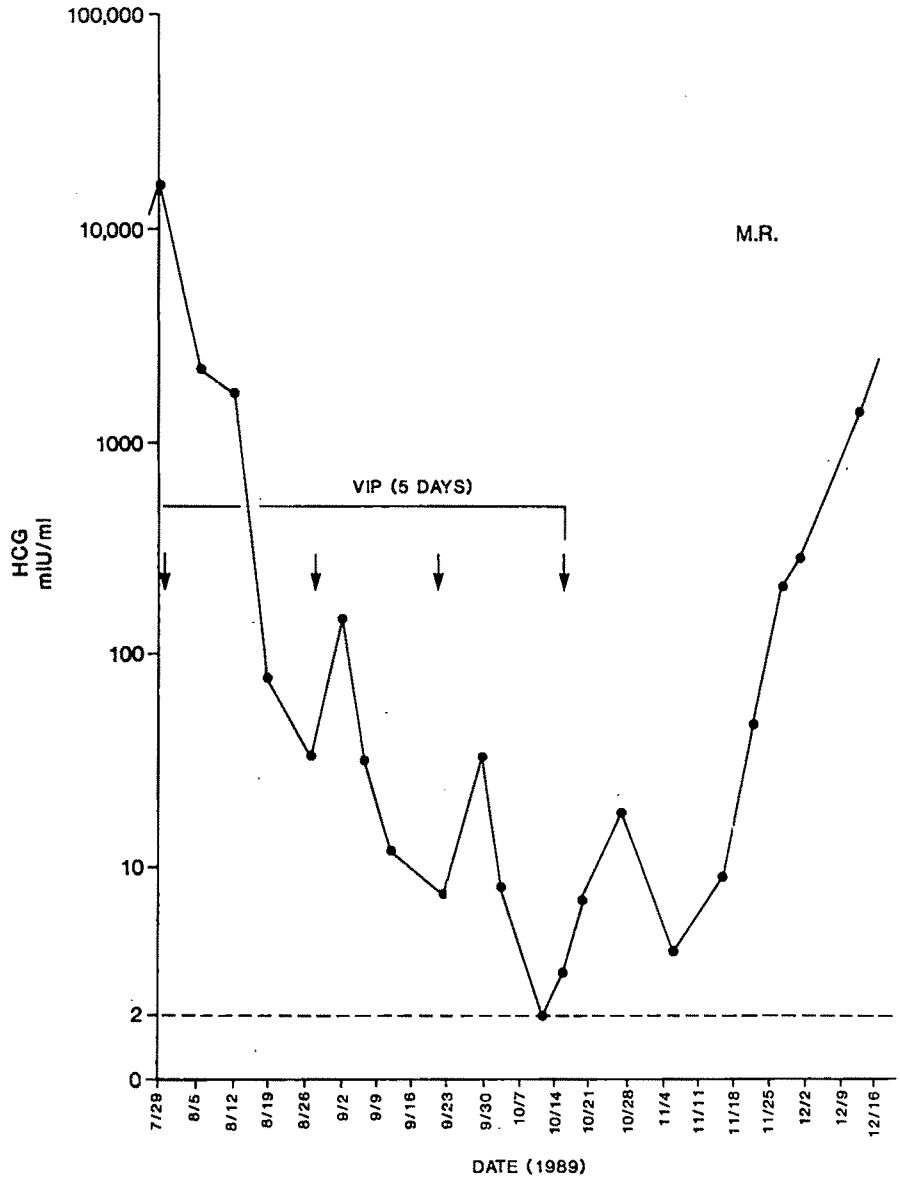

Fig. 3. Transient remission induced with 5-day courses of VIP in case 4. Myelotoxicity precluded rapid recycling of VIP.

October 1988 the hCG level again became elevated into the 70 to 100 mIU/ml range, and two additional cycles of cisplatin and etoposide were given. Bleomycin was added concurrently. The nadir attained after this treatment was 15 mIU/ml. Etoposide, dactinomycin (500 μg intravenous per day), and cyclophosphamide (200 mg/m²) were given for 5 days. She experienced neutropenia and sepsis, and there was no additional fall in hCG response. Two more courses of etoposide as a single agent were given. New pulmonary nodules developed, and the hCG level rose to 134 to 150 mIU/ml.

She next received three cycles of alternating etoposide, methotrexate, and dactinomycin (EMA) and etoposide-cisplatin, but the hCG level remained above 75 mIU/ml. Chest tomography demonstrated persistent small pulmonary nodules, and she received 3150 cGY to the mediastinum and 1575 cGY to whole-lung fields. An hCG nadir of 734 mIU/ml was attained, but the level quickly rose to 15,000 to 17,000 mIU/ml and radiotherapy was abandoned.

VIP therapy was started on July 29, 1989 (Fig. 3). Etoposide 75 mg, cisplatin 20 mg, and ifosfamide 1.2 gm/m² were given intraveous daily times five. Mesna was given as a constant infusion (see case 3). Toxicity of the first course included an increase in creatinine level from 1.6 to 2.3 mg/dl, a nadir hematocrit of 22%, neutropenia of 200 cells/mm³, and thrombocytopenia of 15,000 cells/mm³. Although each of the four courses of VIP was associated with similar toxicity, negative

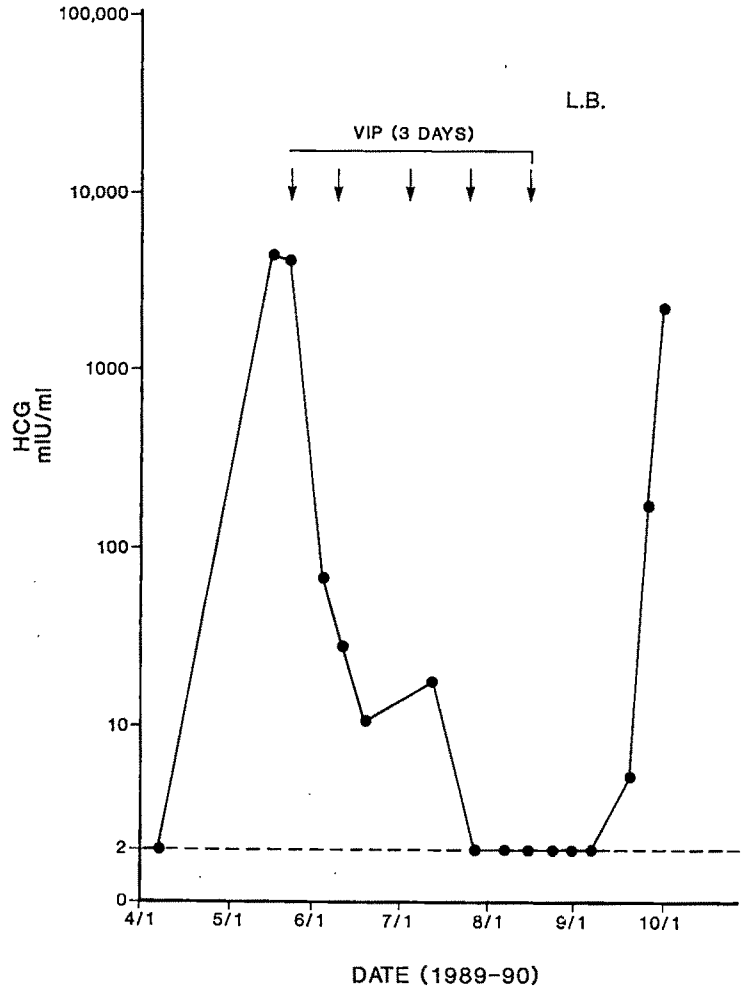

Fig. 4. Remission induced with 3-day courses of VIP in case 5. Relapse followed discontinuation of therapy after only two consolidation cycles.

hCG levels were attained after the third course of therapy. Because of neutropenia, treatment could not be given more frequently than every 24 days. She refused further chemotherapy after a rise in hCG level during the fourth course of treatment and died of respiratory failure in December 1989.

Case 5. A 38-year-old white woman, para 1-0-0-1, underwent evacuation of a hydatidiform mole in 1986. She was treated with two cycles of methotrexate and folinic acid when hCG levels plateaued after the suction procedure. In July 1989 the patient apparently had a missed abortion; curettage and laparoscopy were performed and no pregnancy tissue was demonstrated. In October 1989 abdominal hysterectomy and bilateral salpingo-oophorectomy were performed because of a persistent hCG value in the 600 mIU/ml range. No evidence of choriocarcinoma of ovarian abnormality was identified. The hCG level rose to the 1000 mIU/ml range in spite of two further courses of methotrexate and folinic acid. Five courses of EMACO therapy were given starting in November 1989. By December 1989 hCG levels were undetectable. The last EMACO was given on Feb. 1, 1990. In April 1990 the hCG level was normal, but on May 14, 1990, it had risen to 4400 mIU/ml. She was admitted to Duke University Medical Center where physical examination findings and hematologic parameters were normal. The quantitative hCG value ws 4200 mIU/ml, and computerized tomograms of the brain, chest, abdomen, and pelvis gave normal results except for the absence of gynecologic organs. Cisplatin 30 mg/m^2, ifosfamide-mesna 1.2 gm/m^2, and etoposide 100 mg/m^2 were given daily for 3 days (Fig. 4). The granulocyte count fell to 1200/mm^3, the platelet count to 96,000/mm^3, and the hematocrit to 28%. She experienced nausea and vomiting, which were treated with transdermal scopolamine and lorazepam. The hCG level fell to 68.5 mIU/ml 17 days after the chemotherapy was started. She received a second course of VIP chemotherapy while hospitalized and three additional courses at the referring in-

stitution. The hCG value was <5 mIU/ml at the beginning of the fourth course of chemotherapy. She experienced Gynecologic Oncology Group grade 3 nausea and vomiting in the last three cycles of therapy, as well as grade 3 myelosuppression, leading to a 20% reduction in the doses of etoposide and ifosfamide. The serum creatinine value was unaffected by therapy. Because of gastrointestinal toxicity, this patient declined therapy after the second consolidation course. After 2 months in remission, the hCG level once again was elevated to 5.6 mIU/ml and then 2200 mIU/ml by Oct. 2, 1990. Chemotherapy with etoposide, dactinomycin, methotrexate, and cisplatin was introduced, but the patient ultimately died.

Comment

The aggressive use of multidrug chemotherapy in patients with metastatic gestational trophoblastic disease having a poor prognosis has resulted in permanent remission rates of about 80%. Li et al.[5] introduced the use of "triple" therapy (methotrexate, dactinomycin, and chlorambucil) in patients with testicular cancer in 1960. Hammond et al.[6] demonstrated the advantage of this combination when compared with single-drug therapy at the time of diagnosis in patients with high-risk metastatic disease in 1973.

Bagshawe[7] advocated the use of a seven-drug, 9-day combination called CHAMOMA, and this combination was modified slightly by Surwit et al.[8] when it was introduced in this country. The Gynecologic Oncology Group[1] found that a modified CHAMOMA combination was significantly more toxic and perhaps less effective ($p > 0.05$) than MAC in a prospective randomized two-arm multiinstitution study.

When the activity of a new drug can be demonstrated in patients with chemotherapy-resistant tumors, this agent may be incorporated into a new first-line combination. The alternating, non-cross-resistant (EMA-CO) combination introduced by Bagshawe[2] in 1984 included etoposide because of its marked activity in both previously treated and untreated patients. The therapeutic value and low toxicity of this now popular combination have been corroborated by others.[9]

In 1979, Newlands and Bagshawe[10] reported that cisplatin, either alone or in combination with methotrexate and vincristine, produced responses in patients with refractory trophoblastic disease. Einhorn[11] found that the combination of cisplatin, bleomycin, and vinblastine was highly active in malignant testicular germ cell tumors. Although the initial reports of Schlaerth et al.[12] and Hainsworth et al.[13] suggested a role for this combination in gestational trophoblastic disease, Gordon et al.[14] and DuBeshter et al.[15] failed to achieve sustained remissions with this combination in the majority of patients.

Etoposide and cisplatin were combined with or without dactinomycin in 22 patients reported on by Theodore et al.[16] Long-term remission was induced in all eight patients receiving this regimen without prior therapy and in 11 of 14 patients (78%) with disease refractory to the initial chemotherapy regimens.

The Gynecologic Oncology Group has exhaustively studied ifosfamide as a single agent in patients with gynecologic malignancies. Response rates of 20% and 11.1% have been observed in previously treated ovarian epithelial cancer and squamous carcinoma of the cervix. Uterine sarcomas are very sensitive to this agent; 14.3% of untreated leiomyosarcomas and 30.7% of mixed müllerian tumors responded to therapy.[17]

When the response to ifosfamide described in case 2 was observed, it seemed logical to combine this drug with cisplatin and etoposide in subsequent cases. Loehrer et al.[4] demonstrated the efficacy of this three-drug combination in refractory testicular cancer and initiated a phase III study comparing VIP with cisplatin, etoposide, and bleomycin in patients with untreated testicular germ cell neoplasms. Because of the extent of prior drug exposure, the patient described in case 3 was given just 2 days and then 3 days of VIP, normally a 5-day regimen. The 5-day administration of VIP proved to be prohibitively toxic in untreated patients with small-cell carcinoma of the lung, but this combination could be given safely when the dose was reduced by 20% and given over 4 days.[18] The 3-day course of administration allowed relatively rapid recycling of therapy in case 3 whereas administration of the full 5-day course resulted in toxicity-related treatment delays, which may have allowed "escape" of the tumor in case 4. Case 5 underscores the need to continue therapy for more than one or two "maintenance" courses before the first negative hCG value.[19]

For those few patients with trophoblastic disease resistant to regimens such as MAC and EMACO, further evaluation of ifosfamide-containing regimens seems warranted; earlier use of this agent would also be of interest.

Circulating concentrations of fetal fibronectin do not reflect reduced trophoblastic invasion in preeclamptic pregnancies

Steven A. Friedman, MD, Christianne J.M. de Groot, MD, Robert N. Taylor, MD, PhD, and James M. Roberts, MD

San Francisco, California

This prospective, nested, case-control study investigated whether maternal plasma fetal fibronectin reflects reduced trophoblastic invasion at 16 to 20 weeks in women who later have preeclampsia. Concentrations of fetal fibronectin were 8.7 ± 2.6 μg/ml in women with preeclampsia and 8.1 ± 2.5 μg/ml in matched controls ($p > 0.5$). These results are discussed. (AM J OBSTET GYNECOL 1992;167: 496-7.)

Key words: Fetal fibronectin, preeclampsia, implantation, trophoblastic invasion

The cause of preeclampsia remains unknown, but there is evidence that impaired trophoblastic invasion into maternal spiral arterioles plays an important pathogenetic role.[1] This incomplete remodeling of the spiral arteriolar wall occurs at 16 to 20 weeks' gestation, as a result of the failure of the second wave of trophoblastic invasion. Invading cytotrophoblasts in the decidua are surrounded by extracellular matrix, which stains heavily for fetal fibronectin.[2] During pregnancy fetal fibronectin, presumably of trophoblastic origin, can be detected in maternal plasma in concentrations that increase with the duration of pregnancy.[2] We hypothesized that circulating concentrations of fetal fibronectin would be reduced at 16 to 20 weeks' gestation in women who subsequently have preeclampsia, when compared with matched controls who subsequently carry a normal pregnancy.

Material and methods

A prospective, nested, case-control study design was used. Blood collected in 5 mmol/L ethylene diaminetetraacetic acid was drawn at 16 to 20 weeks' gestation and stored as plasma at −70° C. After pregnancy women were identified as preeclamptic if they met strict criteria, namely, late-pregnancy hypertension (an absolute blood pressure ≥140/90 mm Hg, or a rise of ≥30 mm Hg systolic or ≥15 mm Hg diastolic over values in the first 20 weeks), proteinuria (≥1+ in a catheterized specimen or ≥2+ in a voided specimen), and hyperuricemia (serum uric acid ≥1 SD above normal for gestational age) in a nulliparous woman whose clinical and laboratory findings resolved by 12 weeks post partum. Controls, also nulliparous, were matched for maternal age, gestational age, and race. All patients were delivered at term. This study was approved by the university's Committee on Human Research.

Fetal fibronectin was measured in triplicate by a sensitive and specific enzyme-linked immunosorbent assay that used the FDC-6 antibody (ROMCheck, Adeza Biomedical, Sunnyvale, Calif.). This antibody recognizes a glycosylated hexapeptide located in the IIICS region that is unique to the fetal isoform of fibronectin.

Results were compared with paired, two-tailed t tests and are reported as means ± SD, with a $p < 0.05$ considered significant.

Table I. Maternal and neonatal clinical characteristics and plasma fetal fibronectin concentrations

	Preeclamptic	*Control*	*p Value*
No.	10	10	
Age (yr)	24.1 ± 4.6	23.8 ± 4.8	NS
Gestational age (wk)	17.2 ± 1.1	17.2 ± 1.2	NS
Maternal weight (kg)	63.0 ± 13.4	59.0 ± 10.6	NS
Neonatal weight (kg)	3.17 ± 0.72	3.43 ± 0.39	NS
Maternal serum α-fetoprotein (ng/ml)	54.4 ± 30.0	55.3 ± 39.9	NS
Plasma fetal fibronectin (μg/ml)	8.7 ± 2.6	8.1 ± 2.5	NS

NS, Not significant.

Results

There were no significant differences between preeclamptic and matched control patients in maternal

age, gestational age, maternal weight, infant weight, maternal serum α-fetoprotein levels, or fetal fibronectin concentrations (Table I). The values for all comparisons were $p > 0.3$.

Comment

Immunohistochemical studies demonstrate the presence of fetal fibronectin in the extracellular matrix of the decidua, amnion, and chorion but not in the cytoplasm of trophoblastic or decidual cells.[2] When designing this study, we posited that fetal fibronectin enters the maternal circulation as a consequence of trophoblastic invasion of maternal spiral arteriolar walls. We further hypothesized that the degree of invasion, which should be decreased in pregnancies complicated by preeclampsia, would correlate roughly with maternal plasma fetal fibronectin levels.

There are several possible explanations for the absence of such a correlation in this carefully matched cohort of preeclamptic and control patients. First, in spite of its high molecular weight, the entry of fetal fibronectin into the maternal circulation may not require gross invasion of the spiral arteriolar wall and thus may not correlate well with the characteristic histologic findings in the placental bed of preeclamptic patients. It is possible that in all pregnancies there is sufficient disruption of the spiral arteriolar basement membrane to allow the passage of fetal fibronectin.

Second, extravillous trophoblast may not be the primary source of maternal plasma fetal fibronectin. For example, fetal hepatocytes and renal tubular cells contain fetal fibronectin,[2] and the transplacental transfer of this protein from fetal blood or amniotic fluid as with α-fetoprotein, is possible. However, we found a poor correlation between fetal fibronectin levels and α-fetoprotein levels in these patients ($r = 0.257$, data not shown).

Third, data suggesting reduced trophoblastic invasion in preeclampsia are based on placental bed biopsies obtained after the development of clinical disease. Although these findings have been interpreted as a failure of normal invasion early in pregnancy, another interpretation is that initial invasion is normal in preeclamptic women and regresses later in gestation.

Further studies are required to elucidate the possible role of fetal fibronectin in the pathogenesis of preeclampsia.

Resident research in obstetrics and gynecology: Development of a program with comparison to a national survey of residency programs

Patricia J. Sulak, MD,[a] Julie A. Croop, RN,[a] Argye Hillis, PhD,[b] and Thomas J. Kuehl, PhD[a]

Temple, Texas

OBJECTIVE: The objective of this report is to describe our recently established resident research program and to compare this program with those of other obstetrics and gynecology residency training programs in the United States.

STUDY DESIGN: The components of our program are described. Data for comparison from other programs were obtained from questionnaires, phone follow-up and the *Directory of Obstetrics and Gynecology Residency Programs* of the Council on Resident Education in Obstetrics and Gynecology.

RESULTS: We initiated a residency research program in 1987 with acceptable projects defined, a time for completion of manuscripts established, and a Resident Research Day organized with presentation of articles, critique by a guest speaker, and an awards banquet. Nationally, <60% of residency programs have research requirements. Of the 208 programs responding to the written questionnaire 86% of programs associated with a university required research compared with 10% of community-based residency programs.

CONCLUSION: While more than a third of residency programs in obstetrics and gynecology do not have resident research programs, the trend is for programs to establish research as a required portion of training. An outline of a recently established program is provided. (AM J OBSTET GYNECOL 1992;167: 498-502.)

Key words: Resident research, resident training, program accreditation, obstetrics and gynecology residency programs

Many residency programs in obstetrics and gynecology require the involvement of their residents in research, but the actual number of programs providing research training and the nature of these programs are not available. Resident research activities can encourage critical thinking, stimulate self-learning, and promote exploration and assessment of career opportunities, as well as provide significant contributions to the literature.[1-4] Research projects provide experience in the review and evaluation of scientific literature, training in the conduct of research projects and preparation of manuscripts, and opportunities for training and experience in public speaking. Because our department recognized a deficiency in these opportunities for our residents, we formally initiated resident research in 1987 and a Resident Research Day in 1988.[5] Guidelines and a timetable were established to assist the residents in planning and completing projects and in preparing subsequent formal presentations. To compare our residency research training program with other programs, we initiated a national survey of obstetrics and gynecology programs in May 1990.

Material and methods

Development of a resident research program. A plan for ongoing resident research projects culminating in an annual Resident Research Day was initiated at our institution in 1987. The purposes of establishing resident research projects were as follows: (1) to teach residents to critically review the medical literature, to organize and conduct a research project with an appropriate understanding of all aspects of experimental design and statistical analysis, and to prepare a manuscript; (2) to teach residents to organize a formal presentation including the preparation of visual aids and to present formally to an audience of their peers; (3) to promote research, formal presentations, and the publication of manuscripts as essential components of an academic residency training program and of a career in obstetrics and gynecology.

Guidelines for annual resident research projects were established, including definitions of acceptable projects, a time line for completion of each phase of each project, faculty supervision of projects, a faculty coordinator

Table I. Response to resident research survey of 280 obstetrics and gynecology residency programs

	No.	*% of responders*	*% of all programs*
Written responders			
"Yes" responses	142	68	51
"No" responses	66	32	23
Subtotal	208	100	74
Phone responders			
"Yes" responses	6	26	2
"No" responses	17	74	6
Subtotal	23	100	8
TOTAL RESPONDING	231		82

Table II. Relationship of program size and university connection to the proportion of obstetrics and gynecology residency programs requiring research

Total No. of residency positions	*Programs associated with a university*		*Community-based programs*	
	No.	*% with Research*	*No.*	*% with Research*
≤10	33	82	15	13
11-20	81	86	31	10
≥21	45	89	3	0
TOTAL*	159	86	49	10

*Of 208 programs responding to written questionnaire, proportions requiring research are significantly different ($p < 0.0001$) between programs associated with a university and those that are community based.

for the overall Resident Research Day, and formal presentation of projects at the annual Resident Research Day. A format was proposed for printing of all manuscripts in a booklet, presentation of articles to the faculty and resident staff, critique of presentations by a guest faculty, judging of research projects and formal presentations, presentation of awards at an annual Resident Research Day Banquet, and submission of manuscripts to scientific journals for formal publication. To compare our resident research program with others, a national survey of all accredited obstetrics and gynecology programs was conducted.

Resident research questionnaire. A questionnaire was sent to 280 accredited obstetrics and gynecology programs. Each program director was asked, "Does your residency program have a formal resident research program that is required for completion of the residency?" If the response was "yes," then the year in which the program was initiated, the number of research projects required during the residency, and specific questions about the research were asked, including criteria for acceptable projects, research guidance available to residents, and means of presentation of projects made available to residents. If the response was "no," then the percentage of residents electively doing research, the reasons for not requiring resident research, and whether a formal program was contemplated within the next 2 years were surveyed.

Results

Resident research questionnaire: "Yes" responders. Of the 280 questionnaires that were mailed, 208 were returned, for a written response rate of 74% (Table I). Seventy-two of the 280 programs surveyed did not return the questionnaire. Twenty-five of these nonresponders to the written questionnaire were randomly chosen for phone follow-up and were asked if they require residency research for the completion of the residency program. Twenty-three of 25 programs were reached by phone, and their response to the question of having a research requirement is shown in Table I. Programs that require residency research were more inclined to respond to the written questionnaire than were programs that do not require research. Sixty-eight percent of the 208 programs that returned the questionnaire reported that research is required and 26% of the 23 programs polled by phone reported that residency research is a requirement. The difference was statistically significant by χ^2 analysis ($p < 0.0001$). To verify the written responses, we randomly chose for phone follow-up 20 residency programs that had responded "yes" on the written questionnaire. Nineteen of these 20 confirmed that resident research is a requirement for the completion of the residency. One program indicated that resident research was a requirement on the written form but did not confirm that research was required to complete residency on phone follow-up for a 5% error rate. Of the total 231 respondents, 148 (64%) require their residents to complete a structured research program whereas 83 (36%) do not. Table II shows the relationship of program size as measured by the total number of approved residency positions and of university connections to the proportion of programs requiring research.

Format for resident research. The design and requirements of our residency research training program were compared with those of other programs. When our program was initiated in 1987, a Director of Resident Research was appointed to coordinate resident research activities and Resident Research Day. Each second-, third-, and fourth-year resident is required to complete a yearly project under the supervision and with the approval of a faculty advisor. To complete each project satisfactorily, a manuscript of the work, written by the resident and approved by the faculty advisor, is formally presented by the resident on Resident Research Day. Thus, for completion of our residency research requirements, a resident must complete three projects

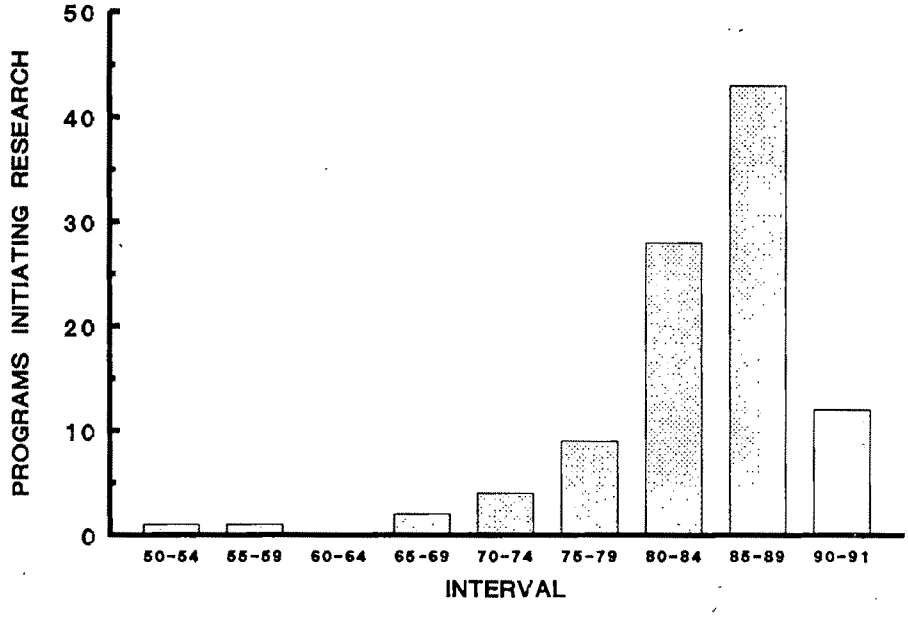

Fig. 1. Year resident research initiated in obstetrics and gynecology program requiring resident research.

culminating in written manuscripts with each formally presented. This format was compared to the responses from the 142 programs with a research requirement that completed the written questionnaire. Fig. 1 shows the year in which residency programs initiated formalized research requirements. Whereas we require the completion of three projects, 79% of the programs require only one project during the entire residency. Twelve percent require two projects, 8% require three projects, and only 1% require yearly projects.

Our residency research program outlines specific guidelines for acceptable projects. The annual projects may consist of basic or clinical research, including prospective studies, retrospective studies, and case studies. Each resident is to complete at least one prospective study during the residency, which should be planned during the first or second year to ensure completion by spring of the fourth year of residency. The remaining two projects can include a case study or retrospective studies. Only one case study or case series is allowed. Our guidelines are similar to those of other residency programs that require residency research in that the majority require retrospective or prospective studies (Fig. 2).

Resident research instruction. Realizing that resident research adds to the demands already placed on our residents but recognizing the benefits to the residents, we take several measures to assist them. A faculty adviser supervises each project throughout its many phases, from developing the idea to practicing the presentation. We also establish a 1-month resident research rotation with the Research Director of the Department of Obstetrics and Gynecology. The residents receive instruction in research philosophy, literature review, experimental design, research methods, and statistics. Additionally, each month a 1-hour research conference is conducted for the residents and staff with topics focusing on the mechanics of developing a research proposal, experimental design, computer use, literature review, record keeping, statistical methods, analysis of results, writing abstracts and manuscripts, and public speaking. Our monthly journal club also supports resident instruction in research by critically evaluating recently published articles and classic articles from the past. Of the 142 responding programs that require residency research, 96% indicated that residents have a faculty advisor for each project although only 48% of these programs have formal instruction for residents on how to conduct research.

Presentations and manuscripts. A formal Resident Research Day was established at our institution as an annual departmental event held each April. The day includes the residents' presentations of their annual research projects, critique of the projects by a guest reviewer, resident awards, and an evening banquet. A booklet of the residents' final manuscripts is prepared for distribution on Resident Research Day. The manuscripts are sent to the guest reviewer at least 1 week in advance. Each resident is allotted 15 minutes to present a retrospective or prospective study or 10 minutes to present a case report or series. The guest reviewer critiques each presentation and a question-and-answer session follows. An Awards Committee, comprising the guest reviewer and four faculty members, is appointed

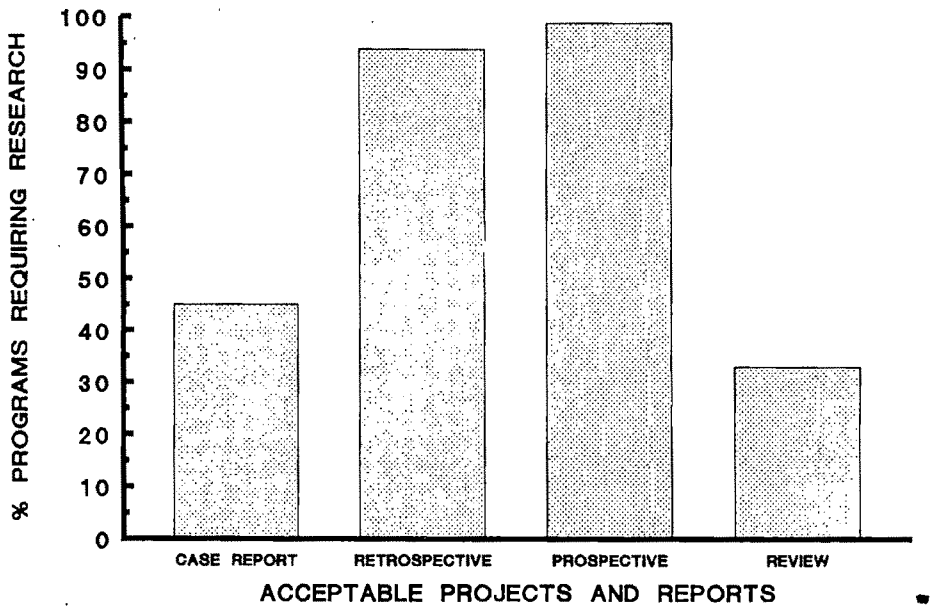

Fig. 2. Acceptable projects and reports for obstetrics and gynecology programs requiring resident research.

by the department chairman to select a "best paper" and a "best presentation." These awards are presented at a banquet the evening of Resident Research Day. Of the 142 programs that require resident research, 94% reported that the resident projects are presented in a formal manner, similar to our annual resident research day. Seventy-seven percent said that residents are required to submit a formal manuscript of their research while for 23% this is not a requirement.

In developing our residency research program, publication of a manuscript was not set as a requirement. We have completed 4 years of residency research, and to date 10 of the projects have been published or have been accepted for publication in the scientific literature and five are currently submitted or are in preparation for submission. In response to the questionnaire, only 15% of the programs that require residency research require that project manuscripts be submitted for publication. We have not made publication in the medical literature a requirement, but we have been very pleased with the quality of the projects presented thus far.

Resident research questionnaire: "No" responders. Sixty-six programs that responded to the written questionnaire said they do not require research and many cited more than one reason for not doing so. The predominant reasons expressed were that the residents were too busy (52%), that the staff was too busy to assist the residents (28%), and that research should not be a requirement during residency training (46%). Of the programs that do not require residents to perform research, most have ≤25% of their residents electively doing research. Of the programs not requiring research, 42% do not contemplate initiating a formal residency research program within the next 2 years, while 43% do plan to initiate one. Fifteen percent did not respond to this question.

Comment

We had a very good response to our questionnaire. Of 280 programs surveyed, 208 returned the questionnaire with 142 of these requiring resident research for completion of training. Of the 72 nonresponders to the written questionnaire, 23 were contacted by phone with 26% of this study group stating that they do require research. If we apply the 26% figure to all 72 nonresponders, then we can estimate that approximately 19 of these programs require research, for a total of 161 (142 + 19) programs (58%) among the entire 280 in the United States. Ninety-five percent of programs confirmed their written response in telephone follow-up. From our survey we found that most resident research programs have been initiated since 1980 and many programs plan to initiate a research requirement for completion of residency training within the next 2 years.

The residency review council and boards require residency programs to integrate research into residency training, but the structure and supervision of this aspect of residency are left up to each residency director. The information obtained from our survey of obstetrics and gynecology residency programs should be of interest to all those participating in residency training. It is noteworthy that programs directly associated with a university or medical school more frequently had a re-

search requirement than did programs that are community based. The size of residency programs did not seem to be related to whether the program required research (Table II). Other aspects of the influence of a research requirement on the nature and academic rank of applicants to programs or the career choices and opportunities of graduating residents were not dealt with in our survey. A survey of candidates applying to programs and of physicians a few years after completing an obstetrics and gynecology residency would be needed to see if a resident research requirement influences program choices by medical students and career choices by graduates. The results of that survey will be important in assessing the impact of research requirements.

Our resident research program was comparable to those of other institutions requiring residents to perform research. We require a greater number of projects than do most programs, but we have also incorporated research time and instruction in residency training. Our director of departmental research plays an active role in assisting residents in projects and research instruction.

Since we initiated this program in 1987, our residents have achieved the Clinical Scholar Award for the best resident research at our hospital 4 years in a row. Two projects have been selected by the Southern Medical Association as Best Resident Presentations at their annual meetings in 1988 and 1989. Two projects have won the Pritchard Prize for Best Resident Paper at the Texas Association of Obstetrics and Gynecology Annual Meetings in 1989 and 1991. Several articles have also been presented at other meetings, including the Society for Perinatal Obstetricians in 1990 and the Central Association of Obstetrians and Gynecologists in 1990.

Many of the program directors surveyed responded that they do not require resident research because they feel the quality of articles would be poor if residents were forced to do research; however, we have not found this to be so at our institution. We have been delighted by our residents' enthusiasm and efforts in planning and conducting their projects and in submitting their manuscripts for publication in journals and for presentation at scientific meetings. Before the initiation of a formal residency research program and Resident Research Day, no research presentations or publications were made by the residents in our department. Residents now routinely discuss research activities, willingly pursue potential research projects, and, when confronted by new or interesting clinical problems, are more likely to search the literature and do so with more ease and confidence. A formal resident research program contributes significantly to the overall education of obstetrics and gynecology residents. At the same time the resident research program will enable compliance with Accreditation Counsel for Graduate Medical Education Guidelines for Residency Programs as evaluated by our residency review committee. Our residents have developed a foundation on which to build and pursue research endeavors, whether in private practice or in academic medicine.

We thank Janice E. Hudgins for manuscript preparation.

Nonimmune fetal hydrops caused by bilateral type III congenital cystic adenomatoid malformation of the lung at 17 weeks' gestation

David M. Sherer, MD,[a] Jacques S. Abramowicz, MD,[a] Leon A. Metlay, MD,[b] Michele Roberts, MD, PhD,[b] and James R. Woods, Jr., MD[a]

Rochester, New York

Type III congenital cystic malformation of the lung with nonimmune hydrops and oligohydramnios was diagnosed at 17 weeks by ultrasonography. Massive fetal cardiac compression with probable associated left- and right-sided failure causing both the oligohydramnios and the ascites, respectively, was thought to be the underlying pathophysiologic mechanism of this unusual clinical presentation. Pathologic examination after termination of the pregnancy confirmed the prenatal diagnosis. (AM J OBSTET GYNECOL 1992;167:503-5.)

Key words: Prenatal ultrasonography, nonimmune hydrops, congenital cystic adenomatoid malformation of the lung

Congenital cystic adenomatoid malformation of the lung is a rare form of congenital lung disease. The cause and heredity are unknown.[1] This hamartomatous lesion resulting from cessation of bronchiolar maturation with an overgrowth of mesenchymal elements and proliferation of polypoid glandular tissue in the absence of normal alveolar differentiation creates the "adenomatoid" histologic appearance. These structures are lined by cuboidal or ciliated columnar epithelium. Congenital cystic adenomatoid malformation has been classified into three types that differ primarily in the size of the cysts along with other histologic and clinical features.[1] Type I lesion has some large cysts and type II has multiple evenly sized cysts, whereas type III consists of a firm bulky mass, uniformly formed by small cysts that usually involve an entire lobe. Type III is the rarest, with bilateral involvement being reported six times previously.[1] We present a case in which bilateral type III congenital cystic adenomatoid malformation of the lung was associated with nonimmune fetal hydrops and oligohydramnios at 17 weeks.

Case report

A 28-year-old woman, gravida 3, para 0, aborta 2, was referred to Strong Memorial Hospital, the regional perinatal referral center, at 17 weeks' gestation for consultation because of an increased risk for trisomy 21. Her medical history was unremarkable, and the current gestation was uneventful with ultrasonographic confirmation of dates at 7 weeks. At 17 weeks' gestation, maternal serum α-fetoprotein level was 1.83 multiples of the median (normal) and the serum human chorionic gonadotropin level was elevated at 3.87 multiples of the median (77,533 mIU/ml). She was counseled as to the increased risk of trisomy 21 calculated at 1:228 (vs 1:755 for age only); she elected to undergo genetic amniocentesis. Ultrasonography before this procedure revealed a singleton, vertex-presenting fetus with markedly decreased amniotic fluid. Examination of the fetal chest disclosed an abundant amount of hyperechoic tissue representing the fetal lungs. This condition was bilateral and continuous throughout the chest. Massive compression of the fetal heart was noted with the fetal heart occupying a relatively small portion of the chest (<10%) (Fig. 1, *a*). Although a detailed echocardiographic examination was not technically possible, ultrasonographic evaluation at the four-chamber level revealed two ventricles, an intraventricular septum, two atria, and two atrioventricular valves. A large amount of ascitic fluid was noted in the fetal abdomen with an increased abdominal circumference consistent with 25 weeks' gestation (Fig. 1, *b*).

These ultrasonographic findings were interpreted as consistent with bilateral type III congenital cystic adenomatoid malformation of the lung. Because of the poor prognosis associated with the extensive bilateral condition, the parents elected to terminate the preg-

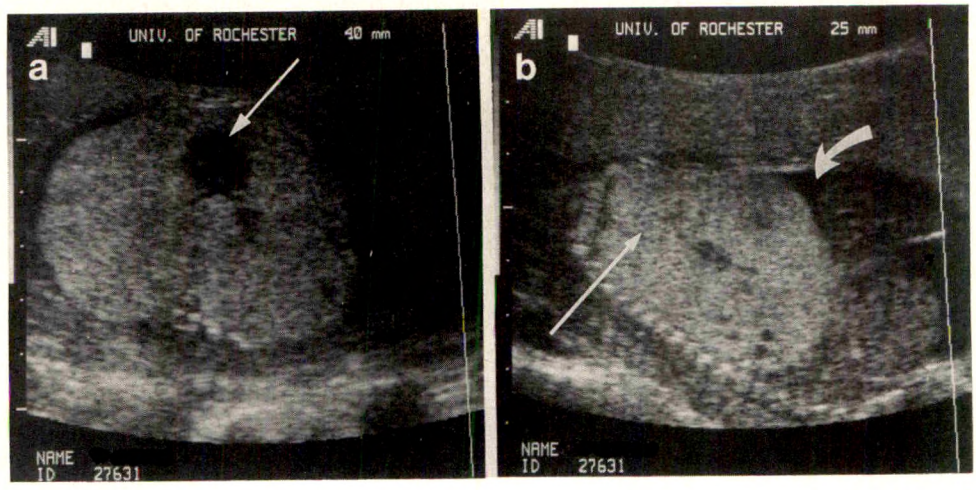

Fig. 1. Prenatal ultrasonographic views at 17 weeks' gestation. **a,** Transverse view of fetal chest. *Arrow,* Fetal heart compressed by abundant lung tissue. **b,** Longitudinal view of fetal chest and abdomen. *Arrow,* Hyperechogenic lung tissue; *curved arrow,* ascites.

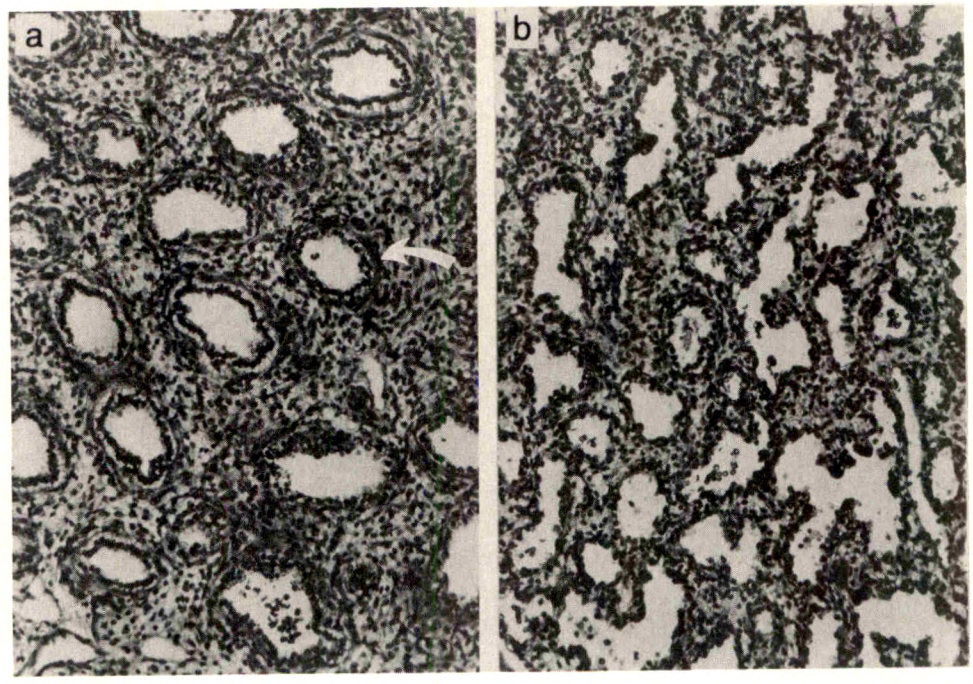

Fig. 2. a, Histopathologic section of lung tissue of described fetus. Note decreased terminal air spaces surrounded by increased smooth muscle *(arrow)* consistent with type III congenital cystic adenomatoid malformation of lung. (Original magnification ×20.) **b,** Normal lung of gestational age–matched control. (Original magnification ×20.)

nancy without an amniocentesis. At the parents' request, an evacuation was performed while the patient was under general anesthesia. Pathologic examination revealed abnormally large fetal lungs (weighing 25 gm, >97.5th percentile for gestational age). Multiple grooves were noted on the outer aspects of the fetal lungs and were identified as rib impressions caused by increased intrathoracic pressure. Histopathologic studies throughout four random sections of fetal lung disclosed notably decreased terminal air spaces and increased smooth muscle, consistent with bilateral type III congenital cystic adenomatoid malformation of the lungs (Fig. 2, *a*). Histopathologic studies of a gestational age–matched control are shown for comparison (Fig.

2, *b*). Fetal kidneys and liver were normal. The fetal head was traumatized during the evacuation and thus was not available for evaluation. The placenta and umbilical cord were normal. Karyotyping was obtained at the time of the evacuation and subsequently revealed a 46,XX karyotype.

Comment

Neonatal outcome of fetuses with congenital cystic adenomatoid malformation of the lung depends on the type of lesion and, as with all intrathoracic space–occupying lesions, on the presence or absence of pulmonary hypoplasia (dependent on the extent of pulmonary involvement). Although the prognosis for a unilateral type I lesion is excellent after resection, type II lesions are associated with a high incidence of structural and chromosomal abnormalities and an overall poor prognosis. Fetuses with type III lesions have a poor outcome on the basis of pulmonary hypoplasia or hydrops.

Spontaneous improvement in utero has been reported in cases of fetuses with unilateral involvement of both type I and type II lesions. Approximately two thirds of fetuses with antenatal diagnosis of this condition will have hydropic changes with either polyhydramnios or oligohydramnios.[2] Although polyhydramnios noted to be associated with this anomaly is attributed to esophageal compression with subsequent impaired fetal swallowing, it is interesting to note similar cases (as ours) where nonimmune fetal hydrops existed with severe oligohydramnios. Our case and three previously published cases of fetuses with bilateral type III congenital cystic adenomatoid malformation of the lung[1,2] suggest that, at least in these cases, combined right- and left-sided cardiac failure caused by cardiac compression may be the underlying pathophysiologic mechanism behind the associated nonimmune hydrops and oligohydramnios.

Case Reports

Pregnancy complicated by chronic cardiomyopathy and an automatic implantable cardioverter defibrillator

Jeanna M. Piper, MD, Michael Berkus, MD, and Louis E. Ridgway III, MD
San Antonio, Texas

The dismal prognosis of dilated cardiomyopathy and its resulting tachyarrhythmias has recently been improved by technical advances such as the automatic implantable cardioverter defibrillator. We report a successful pregnancy in a patient with chronic cardiomyopathy and malignant tachyarrhythmias necessitating use of this device, with a documented defibrillator discharge and monitored fetal response. (Am J Obstet Gynecol 1992;167:506-7.)

Key words: Cardiomyopathy in pregnancy, cardiac arrhythmias, automatic implantable cardioverter defibrillator

Chronic dilated cardiomyopathy complicated by cardiac arrhythmias has been variously reported to have a 5-year mortality rate of 50% to 60%. Poor prognostic factors include tachyarrhythmias, left ventricular ejection fraction <35%, myocardial ischemia, and left ventricular dilation sufficient to make the cardiothoracic ratio >0.55 on chest x-ray film.[1] Recent advances in antiarrhythmic medications and technical advances, such as the automatic implantable cardioverter defibrillator, have markedly improved long-term survival.[2] The automatic implantable cardioverter defibrillator was introduced in 1980 for the treatment of malignant ventricular arrhythmias unresponsive to antiarrhythmic medications or surgical ablation.[2] It uses two epicardial defibrillating patches and can be programmed for triggering rate criteria (126 to 208 beats/min) and strength of discharge (1 to 40 J). (Because of direct epicardial application, 8 to 30 J is adequate for cardioversion or defibrillation.) The extended life span afforded by the automatic implantable cardioverter defibrillator and other advances has allowed women with cardiomyopathy to consider pregnancy. Thus the effect of pregnancy on cardiac dysfunction and its effects on the fetus must be considered. To our knowledge, this is the first report of a successful pregnancy complicated by dilated cardiomyopathy and an automatic implantable cardioverter defibrillator.

Case report

This 22-year-old primigravid woman had viral myocarditis in January 1987 that resulted in a severe chronic cardiomyopathy. The initial left ventricular ejection fraction was 15%, and the left ventricular diastolic diameter was 6.4 cm (normal <5.6 cm). After initial recovery tachyarrhythmias occurred, including ventricular fibrillation in October 1989. Electrophysiologic testing indicated that antiarrhythmic medications could not adequately control the arrhythmias. Thus an automatic implantable cardioverter defibrillator (Ventak 1550 AICD, Cardiac Pacemakers, St. Paul, Minn.) was placed in February 1990. At the time of surgery the ejection fraction was 55%, and she could maintain daily activity without symptoms.

She subsequently became pregnant in May 1990, against the advice of her cardiologist. Her medications included digoxin, metoprolol, furosemide, potassium, and subcutaneous heparin. The first two trimesters were without complications. At 28 weeks' gestation she began to have episodic dyspnea and tachycardia that responsed to bed rest; ejection fraction remained 45% to 50%. At 33 weeks' gestation she experienced a tachyarrhythmia that triggered automatic implantable cardioverter defibrillator discharge. A single 30 J shock resulted in conversion to a normal sinus rhythm and a normal rate. She was monitored, and stable vital signs, a normal electrocardiogram, and a reactive fetal heart tracing were seen.

The patient was placed at bed rest, and both she and her fetus underwent extensive surveillance for the final

month of pregnancy because of increasing fatigue, dyspnea, and activity intolerance. Ejection fraction fell to 35% before delivery. At 37 weeks 3 days' gestation spontaneous rupture of membranes occurred, followed by labor. An introducer sheath (cordus) was placed to monitor central venous pressure and to facilitate rapid introduction of a pulmonary artery catheter, should it be needed. Intrathecal narcotics were used for pain management. An uncomplicated labor resulted in delivery of a viable male infant (Apgar scores of 8 and 9 at 1 and 5 minutes, birth weight 3001 gm), with outlet forceps. Central venous pressure monitoring remained stable for 24 hours post partum, with uneventful recovery. By 6 weeks post partum the patient had returned to full daily activity without symptoms, and ejection fraction had returned to 48%. The infant is doing well.

Comment

Viral myocarditis may occur at any age and generally has no long-term sequelae. Dilated cardiomyopathy is an uncommon but severe potential complication. Historically, dilated cardiomyopathy has had a dismal prognosis, with progressive deterioration, congestive failure, and malignant arrhythmias. Recent advances in medical management and invasive technology have allowed some patients to have a relatively normal lifestyle and to consider reproduction.

Because of the historically poor prognosis, there is no body of literature addressing the effects of pregnancy on chronic dilated cardiomyopathy. The pregnancy reported here was complicated by increasing tachyarrhythmias and decreasing ejection fraction (particularly during the third trimester), which resolved rapidly post partum. The physiologic volume expansion of pregnancy is normally associated with a progressive increase in cardiac output, through increased stroke volume, which peaks at term.[3] In this patient with dilated cardiomyopathy the further increase in left ventricular size necessary to accommodate the excess volume resulted in decreased efficiency (reduced ejection fraction) and increased arrhythmogenic potential. Because this patient was relatively compensated before pregnancy, she progressed beyond the initial volume expansion (24 weeks) before having symptoms.

Tachyarrhythmias are a primary cause of sudden death in chronic dilated cardiomyopathy.[2] The increased tachyarrhythmias experienced in this pregnancy included one of sufficient rate and duration to necessitate cardioversion by automatic implantable cardioverter defibrillator.

No adverse effects on the fetus were noted from the worsening maternal cardiac function or from the automatic implantable cardioverter defibrillator discharge for cardioversion.

Repeated external cephalic version at term

Doron J.D. Rosen, MD, Jeffrey S. Illeck, MD, and Jeffrey S. Greenspoon, MD
Los Angeles, California

External version was performed three times in a patient at term because of spontaneous reversion to breech presentation. She was then delivered vaginally. Spontaneous reversion to breech presentation can be managed with additional external cephalic version procedures. (AM J OBSTET GYNECOL 1992;167:508-9.)

Key words: Breech, external cephalic version

External cephalic version has been reintroduced to modern obstetrics as a safe and effective alternative for delivery of the fetus in a breech presentation.[1] In cases in which immediate induction of labor does not follow successful version, there is a risk of 6% to 7% that the fetus will spontaneously return to a breech or transverse lie.[1] We present a case in which external cephalic version was successfully performed three times at term before a successful vaginal delivery occurred. We discuss the management of breech presentation that reverts before delivery.

Case report

A 37-year-old woman, gravida 2, para 1, was seen at 38 weeks' gestation with a breech presentation. The obstetric and medical history was unremarkable. She had a spontaneous vaginal delivery of a 4025 gm infant 4 years previously. During that pregnancy the fetus remained in a breech presentation until the day of delivery, when spontaneous version to cephalic presentation occurred. The current pregnancy course was uneventful. Dating was confirmed by early second-trimester ultrasonography; genetic amniocentesis was normal. A 1-hour glucose screen after 50 gm of glucola resulted in a blood glucose level 143 mg/dl. A 3-hour oral glucose tolerance test gave a normal result (fasting, 79 mg/dl; 1 hour, 151 mg/dl; 2 hours, 129 mg/dl; 3 hours, 116 mg/dl). Complete breech presentation was diagnosed at 38 weeks' gestation. The estimated fetal weight was 3600 gm; the amniotic fluid index was 20 cm. The patient was counseled regarding the options for delivery. She consented to have external cephalic version, which was easily performed with magnesium sulfate tocolysis. An hour later, during continuous external monitoring, the fetus spontaneously reverted to a breech position. After undergoing counseling regarding her options, the patient agreed to undergo another external cephalic version on the next day to be followed by immediate induction of labor. The second external cephalic version was successful. Cervical ripening with prostaglandin E_2 gel and oxytocin induction of labor were initiated. A serial 3-day induction was attempted with oxytocin infusion for a total of 34 hours. There was no cervical change. The patient requested expectant management rather than cesarean delivery for failed induction. The patient declined further induction attempts for 3 weeks. Antepartum testing was done twice weekly and remained reassuring. At 41 weeks' gestation a breech presentation was diagnosed for the third time. The estimated fetal weight by ultrasonography was 3900 gm with adequate amniotic fluid. After receiving further counseling regarding options, the patient requested cesarean delivery for breech presentation if labor ensued, or if delivery had not occurred in 1 week, she would undergo a third external cephalic version followed by induction of labor. At 42 weeks, external cephalic version was successfully done, and ripening with prostaglandin E_2 and oxytocin induction of labor were accomplished. After a 15-hour labor, a 4140 gm infant was delivered vaginally. Apgar score was 9 at both 1 and 5 minutes.

Comment

Breech presentation at term is associated with a cesarean section rate approaching 90%.[1, 2] External cephalic version reduces the number of breech deliveries and therefore decreases the cesarean section rate. The success rate of external cephalic version at term is approximately 75% while the spontaneous version rate at the same gestational age is only 12% to 17%.[1, 2] After a successful external cephalic version, patients are often permitted to await the spontaneous onset of labor. During this waiting period, 7% of the fetuses revert to breech presentation.[1] There are no established guidelines regarding the management of these patients.

Although external cephalic version is associated with small risks, including fetal distress, abruptio placentae, and fetomaternal transfusion, these risks are acceptably infrequent and manageable with careful patient selection, tocolysis during the procedure, gentle technique, and continuous fetal monitoring during and after the procedure.[1, 2]

External cephalic version is routinely offered to patients with breech presentation at term in many hospitals in the United States. In our case the first and

6/1/39005

second versions were done for the patient's benefaction in view of the higher complication rate of cesarean sections. It seemed prudent to induce labor after the second version, because the fetus quickly reverted to a breech position after the first external cephalic version. When induction failed, the patient was offered a cesarean section, but she declined. Because there was no immediate danger to either mother or fetus, the patient's request for expectant management with careful surveillance was honored according to the principle of patient autonomy. This patient had been carefully counseled on multiple occasions by several physicians regarding her options, risks, and benefits, and she made fully informed decisions. The third external cephalic version was done at the patient's request to employ reasonable options to avoid a cesarean delivery or breech vaginal birth.

We believe that patients who require a second version usually should have labor induced. This case suggests that when induction of labor is unsuccessful, expectant management rather than cesarean section is a reasonable option. It demonstrates that a fetus may spontaneously revert to a breech position twice at term and that external cephalic version may be done three times successfully and safely in selected cases to avoid unnecessary cesarean delivery.

Congenital deficiency of α-fetoprotein

Frank Greenberg, MD,[a] Andrew Faucett, MS,[a] Esmie Rose, PhD,[b] Lisa Bancalari, MS,[c] Nataline B. Kardon, MD,[c] Gerald Mizejewski, PhD,[d] James E. Haddow, MD,[e] and Elliot Alpert, MD[b]

Houston, Texas, Flushing and Albany, New York, and Scarborough, Maine

Although α-fetoprotein may play a role in fetal immune function or in maintenance of osmotic pressure, its exact function is unknown. We report two infants documented to have congenital deficiency of α-fetoprotein. One infant had cord blood levels <0.5 ng/ml. The second infant had a neonatal level of 120 ng/ml, which is about 2% of the usual concentration for a term newborn. These infants document the existence of congenital deficiency of serum α-fetoprotein. Because it is homologous to albumin, congenital deficiency of α-fetoprotein may be analogous to analbuminemia, a benign genetic trait. (AM J OBSTET GYNECOL 1992;167:509-11.)

Key words: α-Fetoprotein, gene regulation, analbuminemia

The exact function of α-fetoprotein (AFP) is currently unknown.[1] AFP has been suggested to play a role in growth regulation, immune function, and maintenance of osmotic pressure in fetal life.[1] We report two infants with congenital deficiency of AFP, both of whom appeared normal at birth, thereby not supporting the three suggested functions of AFP during intrauterine development. Because AFP is homologous to albumin, congenital deficiency may be analogous to analbuminemia, a benign genetic trait.

Case reports

Patient 1. A 36-year-old woman gravida 3, para 2, woman who had an amniocentesis at 14.5 weeks' gestation for advanced maternal age. The pregnancy was uncomplicated, and the family history was significant only for myopia in several family members and strabismus in a previous child. Ultrasonography revealed no fetal abnormalities. Amniocentesis was performed without complication. The amniotic fluid cells grew slowly. There was no measurable AFP by electroimmunodiffusion or by radioimmunoassay (<0.5 ng/ml). Because the amniotic fluid total protein concentration was low, the specimen was thought to be maternal urine. A repeat amniocentesis was performed at 17 weeks'

gestation. These amniotic fluid cells grew more rapidly and a 46,XX chromosome pattern was found in 20 cells from three primary cultures. There was still no measurable AFP, but the amniotic fluid total protein concentration was within the normal range. A maternal serum AFP level was obtained at 19 weeks' gestation; it showed a concentration of <0.5 IU/ml. This was determined in a more sensitive radioimmunoassay, obtained by changing the conditions of the assay to derive a standard curve from 0.5 ng/ml to 30 ng/ml. The intraassay and interassay coefficient of variation at this low level was <5%. Repeat fetal ultrasonographic studies at 24 and 32 weeks' gestation showed normal interim growth and no evidence of anomalies. A normal, healthy female infant was delivered vaginally at term with a birth weight of 3.8 kg. Cord blood serum AFP levels were undetectable (<0.5 ng/ml). Maternal serum AFP levels at delivery were also undetectable. Serum AFP levels in one older sibling were <0.5 ng/ml and were 1.0 ng/ml in another sibling and in the father. At age 1 year, this infant was doing well with no physical or developmental problems.

Patient 2. Amniocentesis was performed on a 26-year-old woman, gravida 1, para 0, at 21 weeks' gestation because of two previously undetectable maternal serum AFP levels with normal ultrasonography. Amniocyte chromosome analysis showed a 46,XY pattern. The amniotic fluid AFP concentration was <0.5 ng/ml. The amniotic fluid protein concentrations were within the normal range.

A healthy, normal-appearing term infant was delivered. Birth weight was 3.72 kg and Apgar scores were 9 and 9 at 1 and 5 minutes, respectively. The placenta appeared normal. No cord blood was obtained. About 6 to 8 months after delivery, the original heelstick blood spots from the neonatal screening program were retrieved and analyzed by previously published methods.[2] The AFP concentration was 120 ng/ml, which is about 2% of the usual concentration for a term newborn.

Comment

α-Fetoprotein is the major fetal serum protein and has genetic homology with albumin.[1] It is produced in early embryogenesis by the yolk sac and subsequently by the fetal liver, reaching a peak concentration at 12 weeks' gestation.[3] A small amount of AFP is excreted through the fetal kidney into the amniotic fluid, reaching peak concentrations at 13 weeks' gestation.[3] Smaller amounts cross the placenta into the maternal circulation, resulting in peak concentrations at about 28 to 32 weeks' gestation.[3] After delivery there is a rapid drop in AFP concentration, reaching adult concentration of <10 ng/ml by about 8 months of age.[2] The normal adult male and nonpregnant female level has recently been shown to be 3.04 ± 0.19 ng/ml.

The primary function of AFP in fetal life is unknown. On the basis of previous studies, several functions have been hypothesized.[1] These are: (1) osmotic pressure regulation, (2) carrier transport (steroids, lipids, metals, etc.), (3) growth regulation, (4) blood pH regulation, (5) immunoregulation, (6) hematopoiesis, (7) sexual differentiation (sex hormone binding), and (8) antiprotease activity.

The observation of two normal infants with documentation of congenital deficiency of AFP and presumed prenatal deficiency on the basis of maternal serum and amniotic fluid levels suggests that AFP may not have been obligatory for any of the above functions. However, some of these functions (i.e., growth regulation) require only picomolar or nanomolar amounts of AFP to be effective.

The basic defect in AFP production or regulation in our patients is currently unknown. However, the differences in the neonatal levels of AFP in these two infants suggest the possibility of at least two different mechanisms for this defect, namely gene deletion or decreased production. The latter may be related to defects in the two regulatory genes for AFP found in a mouse model, termed *raf* and *rif*. Defects in the *raf* gene have been suggested as a cause of hereditary persistence of AFP, a benign autosomal dominant trait. In mice, defects in the *rif* gene cause decreased induction of AFP after liver damage and are inherited in an autosomal dominant fashion. A putative *rif*-like gene may be involved in one or both of our patients. However, the exact defect will require further molecular studies.

In addition to the genetic and synthetic mechanisms discussed above, other possibilities for the lack of AFP could be considered. These might include the following: (1) the rapid vascular clearance of nonglycosylated AFP isoprotein variants, (2) glucocorticoid hormonal down-regulation of AFP synthesis at the transcriptional level (a premature extinction of AFP gene activity can be induced by the glucocorticoid hormone dexamethasone in the developing mammalian liver), (3) possible presence of antibodies to AFP, and (4) increased presence of a bound (nonimmunoreactive) form of AFP, noncovalently bound to a blood or tissue component, concomitant with a decrease in the free form. Neither of our patients were on corticosteroid medications or were known to be stressed, making the second possibility unlikely. Most of these situations would probably lead to lower, but detectable, AFP levels.

Given the lack of pregnancy, labor, or delivery complications and the absence of any neonatal problems, congenital deficiency of AFP is likely to be a benign trait, analogous to analbuminemia. From a clinical standpoint, congenital deficiency of AFP should be included in the differential diagnosis of low or absent maternal serum or amniotic fluid AFP levels.

We thank Heinrich Schettler, MD, for referral of patient 1.

Successful pregnancy outcomes after amniotic fluid embolism

Steven L. Clark, MD
Salt Lake City, Utah

Two patients who survived cardiorespiratory arrest occurring in association with amniotic fluid embolism syndrome were seen during the subsequent pregnancy. Both had uneventful pregnancies and delivered at term without complications. These are the only case reports of pregnancy after amniotic fluid embolism, and they support a model of amniotic fluid embolism involving chemically abnormal amniotic fluid rather than an unusual sensitivity to normal amniotic fluid. (AM J OBSTET GYNECOL 1992;167:511-2.)

Key word: Amniotic fluid embolism

Amniotic fluid embolism syndrome is an often devastating yet incompletely understood condition characterized in its complete form by dyspnea, hypotension, cardiovascular collapse, and coagulopathy. Reported mortality figures approach 80%.[1] Because of the clinical features, pregnancy subsequent to documented amniotic fluid embolism syndrome is uncommon and to date has not been reported. We report here the first recorded cases of successful pregnancy after documented amniotic fluid embolism syndrome.

Case report

Case 1. The patient, a 37-year-old woman, gravida 3, para 1, aborta 1, was referred for consultation. Her previous pregnancy 5 years before was complicated in the active phase of the first stage of labor by amniotic fluid embolism syndrome with cardiopulmonary arrest, disseminated intravascular coagulopathy, and cesarean delivery for fetal distress at term. The amniotic fluid was clear. The patient was one of the study subjects described in a prevoius manuscript detailing the hemodynamic findings of patients with amniotic fluid embolism syndrome.[2]

This patient desired an additional pregnancy and wanted information regarding risk of recurrence for amniotic fluid embolism syndrome and the optimal mode of delivery. No information was available with which to counsel the patient with respect to these questions, because pregnancy after amniotic fluid embolism syndrome had not been previously reported. The patient subsequently conceived, carried the pregnancy to term, and at her request underwent elective repeat cesarean delivery. Mother and infant did well without any clinical or laboratory evidence of recurrent amniotic fluid embolism syndrome.

Case 2. The patient, a 25-year-old woman, gravida 2, para 1, was referred for care at 35 weeks of gestation after relocating from another area. She had undergone primary cesarean section while she was under spinal anesthesia before labor for breech presentation 2 years previously. As the abdomen was being closed, sudden cardiorespiratory arrest occurred with subsequent disseminated intravascular coagulation and adult respiratory distress syndrome. Squamous cells and fetal hair were recovered from her sputum. She was successfully resuscitated.

The patient desired a trial of labor. She entered the

6/1/38692

hospital in spontaneous labor at 39 weeks and underwent oxytocin augmentation for dysfunctional latent-phase contractions. Labor progressed rapidly and she underwent an outlet forceps delivery without complications. Her postpartum course was uneventful.

Comment

Although more data regarding pregnancy outcome subsequent to amniotic fluid embolism syndrome is desirable, these cases represent the only information currently available. In these two patients amniotic fluid embolism syndrome did not recur during either scheduled cesarean delivery or vaginal delivery after oxytocin-augmented labor.

Our understanding of the pathophysiologic characteristics of amniotic fluid embolism syndrome is incomplete. However, in the primate model the infusion of even large amounts of normal autologous amniotic fluid is clearly not pathologic; recently, an abnormal concentration of amniotic fluid leukotrienes has been implicated.[1] This report supports the role of a qualitatively abnormal amniotic fluid, which may be different in a subsequent pregnancy, as opposed to any unusual maternal sensitivity to amniotic fluid per se in the genesis of this condition. Although any conclusions based on two cases must be regarded as tenuous, it appears that on a theoretic basis, supported by these two cases, repeat amniotic fluid embolism syndrome is probably unlikely.

Hepatotoxicity with the administration of nifedipine for treatment of preterm labor

George F. Sawaya, MD, and Patricia A. Robertson, MD

San Francisco, California

Nifedipine, a calcium channel blocker, is becoming increasingly popular as a tocolytic medication. Previous reports of hepatitis associated with nifedipine in the medical literature have been published. We present the first case reported of a patient with preterm labor treated with nifedipine who had development of a concurrent elevation in serum liver enzyme levels. (Am J Obstet Gynecol 1992;167:512-3.)

Key words: Hepatotoxicity, nifedipine, preterm labor

We report a case in which the patient had preterm labor treated with nifedipine and an elevation in serum liver enzyme levels occurred.

Case report

A 25-year-old primigravid white woman with a 30-week twin gestation was admitted to Long Hospital of the University of California Medical Center at San Franciso for management of preterm labor. Twin pregnancy was diagnosed at 8 weeks' gestation after ovulation induction with clomiphene citrate. Her prenatal course was complicated by frequent uterine contractions at 29 weeks, treated with oral terbutaline. Continued contractions with cervical change prompted admission to our hospital for tocolysis with intravenous magnesium sulfate and subcutaneous terbutaline. On the second hospital day indomethacin was added to her tocolytic regimen because of difficulty in controlling the preterm labor but was discontinued 5 days later because of oligohydramnios. At that time the patient was weaned from intravenous magnesium sulfate to the terbutaline pump. On the eighth hospital day, because of increasing uterine contractions with the terbutaline pump alone, nifedipine was added to the tocolytic regimen at a dose of 20 mg every 4 hours. Good tocolysis was achieved. Mildly consistent elevated blood pressures prompted laboratory tests to rule out preeclamp-

sia. Of significance, aspartate transaminase (AST) was elevated at 141 U/L (normal 7 to 39 U/L); alanine transaminase (ALT) was elevated at 343 U/L (normal 2 to 54 U/L). Complete blood cell count with differential, platelet count, uric acid, total bilirubin, fibrinogen, prothrombin time, and total urinary protein values were all normal. The patient felt well, denying headache, visual changes, abdominal pain, arthralgias, and pruritus. No fever, nausea, or vomiting occurred. Physical examination was unremarkable and revealed no peripheral edema, hepatomegaly, or right upper quadrant tenderness. She had no history of liver disease, alcohol use, substance abuse, or transfusion. The panel of hepatitis tests gave negative results. Blood pressures subsequent to these laboratory values normalized.

Consultation was obtained from the gastrointestinal service. Monitoring of the patient's bilirubin and prothrombin time for signs of hepatic failure was recommended, and the nifedipine was not to be discontinued unless either the bilirubin or the prothrombin time became elevated. Three weeks after admission the preterm labor could not be controlled with the terbutaline pump and nifedipine. Intravenous magnesium sulfate was restarted, and nifedipine was discontinued. The next day, serum aspartate transaminase peaked at 449 U/L and serum alanine transaminase peaked at 845 U/L. Without nifedipine, titers of both transaminases steadily fell until the patient was discharged 5 days later at 34 weeks' gestation; she was receiving only terbutaline pump therapy after again being weaned from intravenous magnesium sulfate. At that time of discharge, aspartate transaminase and alanine transaminase had fallen to 136 and 378 U/L, respectively. Bilirubin levels and prothrombin time remained within the normal range.

The patient was delivered of healthy twins at 36 weeks' gestation, 48 hours after discontinuation of all tocolytics. At the time of delivery, the aspartate transaminase (AST) level was normal at 37 U/L, and at 4 months postpartum the aspartate transaminase level was normal at 20 U/L.

Comment

Drug-induced hepatotoxicity is not uncommon. The clinical implications are variable, ranging from asymptomatic elevations in transaminase levels to fulminant hepatitis with hepatic failure. Diagnosis is one of exclusion and is supported by rapid resolution of signs and symptoms after drug withdrawal. Rechallenging the patient with the substance and subsequent reappearance of toxic manifestations provide further confirmatory evidence.

Two major mechanisms, hypersensitivity and direct toxicity, have been implicated for the development of hepatotoxicity. Hypersensitivity reactions typically appear 1 to 5 weeks after exposure to the agent and are frequently accompanied by fever, rash, and eosinophilia. The reaction is unrelated to dose and is thought to be a secondary effect of antibodies directed against the drug-hapten complex. Direct hepatotoxicity is often dose-related and is mediated by cryptogenic mechanisms. There is an enhanced female susceptibility to hepatic insults in association with drugs that act by this mechanism.

A review of the literature reveals six publications detailing seven case reports of hepatitis as a result of nifedipine use.[1] All were patients taking the drug for indications of hypertension or angina pectoris. The patients described had signs and symptoms associated with allergic hypersensitivity. Conversely, our patient was asymptomatic; the elevation in transaminase levels was found on screening for preeclampsia. It is unclear whether a more classic picture of allergic hypersensitivity would have developed had she been continued on a regimen of nifedipine for a longer period of time.

Our experience with calcium channel blockers for tocolysis is limited. Recently, Feguson et al.[2] reported cardiovascular and metabolic effects of nifedipine in 27 pregnant patients treated for preterm labor. In this study no elevations in maternal serum transaminase levels were reported after 24 hours of treatment with nifedipine. The transaminase values in these patients were not studied on a long-term basis. In a chart review of 12 patients at our hospital treated with nifedipine (1986 to 1991) for preterm labor, 66% were not screened on a periodic basis for liver function abnormalities in spite of prolonged courses of treatment (up to 68 days of nifedipine, average number of days on nifedipine 19.6).

The safety of drugs that cause only a transient rise in transaminase levels is unclear. Because nifedipine has been implicated in frank hepatitis, the current case serves as a reminder of this potential significant side effect associated with its use. It is our contention that baseline and periodic liver function tests are indicated in the patient on a regimen of nifedipine for the treatment of preterm labor.

Vaginal foreign body extraction by forceps: A case report

Kevin R. Emge, DO
Chicago, Illinois

Cases in which foreign bodies have been inserted into the vagina are uncommon but do occur. The technique and use of obstetric forceps for the extraction of an orange as a vaginal foreign body is described in this case report. Tucker-McLane forceps are the forceps of choice for this technique in this case. (AM J OBSTET GYNECOL 1992;167:514-5.)

Key words: Obstetric forceps, vaginal foreign bodies, foreign body extraction

Vaginal foreign bodies are not common but are seen in the practice of obstetrics and gynecology. Foreign objects may be inserted into the vagina as an aid to masturbation, sexual intercourse, or sexual assault. They may be inserted by the patient or a sexual partner. Many different objects have been used, including bones, tampons, billiard balls, thermometers, swizzle sticks, bottles of all types, drinking glasses, salt cellars, television tubes, wooden shoetrees, pencils, vibrators and other sexual devices, and vegetables and fruits of all varieties.[1] The sequelae of intravaginal foreign bodies includes traumatic lesions to the vagina, rectum, urethra or bladder; infection; stenosis; and vesicovaginal, rectovaginal, or urethrovaginal fistulas. Many different techniques have been used in foreign body extraction from the vagina and rectum. Obstetric forceps were used for extraction of a vaginal foreign body in the case presented here.

Case report

The patient, a 25-year-old white woman, gravida 4, para 3-0-0-3, presented with a viable intrauterine pregnancy at 28 weeks 3 days' gestation. At approximately 4 AM on the day of admission the patient and her intoxicated husband had been engaging in sexual activity when he placed an orange at the perineum and subsequently in the vagina. Neither the patient nor her husband could remove the orange. Later the same morning they were seen by the patient's family practitioner, who was likewise unable to remove the orange. The physician then contacted the labor and delivery triage unit at the hospital for referral. On arrival at the hospital the patient was placed on a monitor to evaluate fetal well-being and to rule out any contractions. Screening ultrasonography revealed a viable fetus in a cephalic position at 28 weeks' gestation. Also noted in the longitudinal plane was the rounded vaginal foreign body. On pelvic examination the perineum was minimally ecchymotic, no abrasions or lacerations were noted, and speculum examination revealed an orange in the proximal vagina. Manual extraction was attempted but was abandoned because of discomfort and inability to apply proper traction in the needed plane. Because of the similar size of the orange and a small fetal head at term, obstetric forceps were considered as a possible extraction method. After signing an informed consent, the patient was taken to the delivery room, placed in a dorsal lithotomy position, prepped, and draped as for a vaginal delivery. The patient was given 50 mg of meperidine hydrochloride by slow intravenous push and a pudendal block of 1% lidocaine for discomfort and to relax the perineum. The bladder was drained with a catheter, as is standard for all forceps procedures. Standard flat-blade Tucker-McLane forceps were lubricated copiously with gel and applied to the orange in a fashion similar to a direct occipitoanterior fetal head. Gentle traction was applied, and the orange was extracted without discomfort to the patient. Careful examination of the cervix, vagina, and perineum revealed no abrasions or lacerations. The patient was taken to the recovery room for maternal and fetal monitoring and subsequently discharged home. The orange had a circumference of 25 cm and a diameter of 7.8 cm.

Comment

Because the patient was multiparous, she had a relatively lax perineum, and the foreign body was round and smooth, similar to a fetal head, she was an ideal candidate for this type of foreign body extraction. The Tucker-McLane forceps was selected for the following reasons. First, the shanks of Tucker-McLane forceps are overlapping and thus cause less perineal stretching or trauma than Simpson forceps. This would be especially important in using this technique in a nulliparous patient. An alternate type might be Elliott forceps. Next, the shanks of the Tucker-McLane forceps are extended, making it easier to reach and apply to a higher, more proximal foreign body. As opposed to standard Simpson or Elliott forceps, the Tucker-

McLane forceps has solid, nonfenestrated blades that help protect the vaginal sidewalls and perineum during extraction.[2] As with all forceps procedures, the bladder should be empty and appropriate analgesia should be used. The pudendal block worked well in this case, but alternatives include regional or general anesthesia. General anesthesia may be more appropriate if there is suspicion of trauma and a more extensive repair may be needed, especially if there is extension into the bladder, rectum, or peritoneum.

In conclusion, this case represents the use of a common instrument of the obstetrician-gynecologist for use in an uncommon situation. This technique can be added to other techniques for vaginal foreign body extraction. In selected cases it may make extraction easier, with less associated morbidity.

Leiomyomatosis peritonealis disseminata treated with a gonadotropin-releasing hormone agonist

A case report

Holly Ann Hales, BS,[a] C. Matthew Peterson, MD,[a] Kirtly P. Jones, MD,[a] and Jeffrey D. Quinn, MD
Salt Lake City, Utah

To our knowledge, this is the first report of documented growth regression of leiomyomatosis peritonei while the patient was receiving a gonadotropin-releasing hormone agonist. This further documents the role of gonadal steroids in the growth of this tumor. (Am J Obstet Gynecol 1992;167:515-6.)

Key words: Leiomyomatosis peritonealis disseminata, gonadotropin-releasing hormone, tumor regression

Leiomyomatosis peritonealis disseminata is a rare condition in which multiple small nodules consisting of benign smooth muscle are found throughout the abdominopelvic viscera and peritoneum. Only two malignant cases have been reported.[1] This is the first report documenting decreased nodule growth with a gonadotropin-releasing hormone (GnRH) agonist.

Case report

A 29-year-old woman, gravida 1, para 0-0-1-0, presented with an 8-year history of intermittent and increasing left lower abdominal pain. The pain was colicky in nature and had no notable aggravating or alleviating factors. The patient did not have nausea, vomiting, or abnormal weight loss. She did report previous irregular bleeding and had been taking oral contraceptives since 1981. In 1983 she had a cervical fibroid removed by curettage. Pathologic studies confirmed a pedunculated leiomyoma. Because of persistent abdominal complaints, the patient underwent laparoscopy in 1989, which revealed disseminated peritoneal leiomyomatosis (Fig. 1). Multiple small smooth muscle tumors measuring 0.5 to 2 cm in diameter were noted on the ovaries, oviducts, anterior and posterior cul-de-sac, sigmoid colon, round ligaments, uterus, small intestines, and pelvic side walls. Biopsies showed the tumors to be benign.

Because of the known association between estrogen and progression of this disorder, the patient was placed on a regimen of leuprolide acetate (Lupron), a GnRH agonist, 0.5 ml subcutaneously daily to shrink tumor implants by decreasing estrogen production. Lupron

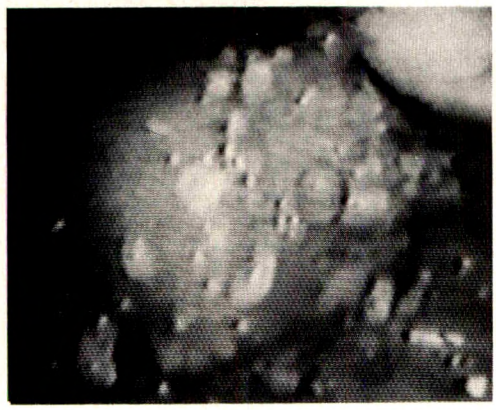

Fig. 1. Disseminated peritoneal leiomyomatosis in case 1.

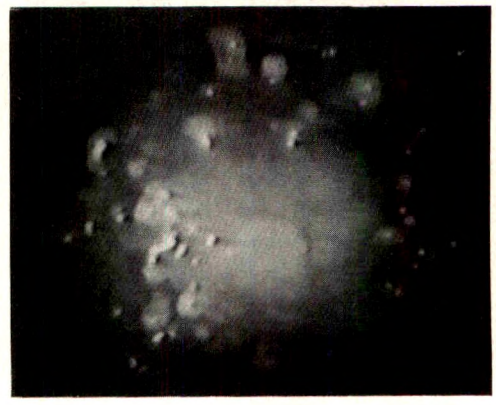

Fig. 2. Decreased leiomyomatosis after therapy in case 2.

therapy was administered for 6 months with notable hot flashes and persistent abdominal discomfort. A second laparoscopy was performed in June 1990. The lesions were significantly smaller in size; however, they were still present. Implants were no larger than 1 cm. Biopsies were performed and the tumors were found to be benign.

Other forms of ovarian suppression medroxyprogesterone acetate (Depo-Provera), megestrol acetate (Megace), and norethindrone (Micronor) were all tried over the next 6 months with notable side effects and continued discomfort.

In November 1990 total abdominal hysterectomy, bilateral salpingo-oophorectomy, and appendectomy were performed. At surgery a return to the pre-GnRH appearance was noted, with multiple 0.5 to 2 cm leiomyomas throughout the pelvis. Pathologic sections revealed virtually identical microscopic findings with discrete nodular proliferation of relatively hypocellular smooth muscle. No nuclear pleiomorphism was noted, and there was no evidence of significant mitotic activity. Two months after operation the patient was reinitiated on a regimen of low-dose estrogen therapy. In June 1991 a repeat laparoscopy was performed, revealing persistent leiomyomatosis in the pelvis, although greatly decreased from the time of hysterectomy, with leiomyomas measuring only 3 to 4 mm in diameter (Fig. 2). In September 1991 the patient returned for follow-up and reported occasional right lower-quadrant pain but normal bowel function. A pelvic examination showed significant improvement from prior examinations.

Comment

This case report further confirms the association of estrogen with the progression of disseminated leiomyomatosis peritonei. This condition is believed to be a hormonally stimulated disease process that is usually found in women who are either pregnant or using hormonal contraception. Oral contraception was discontinued and Lupron, a GnRH agonist, was administered to decrease gonadal steroid production. In this case regression of tumor volume was noted while the patient was receiving the GnRH agonist; however, no significant subjective improvement in the patient's symptoms was noted. This condition has been reported 43 times with only two of the incidents ($p = 0.05$) demonstrating malignant degeneration.[1] This case represents the first documented case of regression of tumor mass by a GnRH agonist.

A case of hidradenitis suppurativa treated with gonadotropin-releasing hormone agonist and by total abdominal hysterectomy with bilateral salpingo-oophorectomy

Jan-Willem Bogers, MD, Willy Minderhoud-Bassie, MD, and Frans J.M. Huikeshoven, MD, PhD

Rotterdam, The Netherlands

We report on a patient with hidradenitis suppurativa with premenstrual exacerbations, who was treated successfully with total abdominal hysterectomy and bilateral salpingo-oophorectomy combined with estrogen substitution. As a trial, she was initially treated successfully with a gonadotropin-releasing hormone agonist and subsequently a gonadotropin-releasing hormone agonist in combination with estrogen substitution. (AM J OBSTET GYNECOL 1992;167:517-8.)

Key words: Hidradenitis suppurativa, gonadotropin-releasing hormone, hysterectomy, salpingo-oophorectomy

Hidradenitis suppurativa is a chronic inflammatory disease of skin areas with apocrine sweat glands, especially the axilla and the anogenital region. It is characterized by deep abscesses, healing with scar and sinus tract formation. There is a female preponderance, and in women the axilla is the most involved area. In general, the disease has a postpubertal onset, and most of the patients with a regular menstrual cycle experience premenstrual flares. Treatment consists primarily of local and systemic antibacterial measures; however, additional surgery is often indicated. Sometimes even total excision of the apocrine sweat gland–bearing areas is warranted. However, this therapy fails in many cases. Treatment with isotretinoin, and hormonal treatment with cyproterone acetate is not entirely satisfactory. Treatment with oral contraceptives may benefit some patients; however, in some women the disease will develop while they are using the pill.[1] We present a case in which the patient, after a successful trial with the gonadotropin-releasing hormone (GnRH) agonist buserelin acetate, was finally treated by total abdominal hysterectomy and bilateral salpingo-oophorectomy in combination with estrogen replacement therapy.

Case report

A 30-year old woman, para 0, abortus 2, was referred to our clinic because of premenstrual exacerbations of hidradenitis suppurativa. She had hidradenitis suppurativa since age 16. Medical treatment with several local and systemic antibacterial drugs and isotretinoin were all without success. She underwent surgery, including full-thickness skin excision and skinning vulvectomy, without a satisfactory result 99 times. Hormonal therapy with oral contraceptives, cyproterone acetate, tamoxifen acetate, medroxyprogesteron acetate depot, and oral progestogens had been tried without success. To test the possible steroid dependency of the disease, we prescribed the GnRH agonist buserelin acetate in a dose of 0.21 mg three times daily. During 10 months of treatment the disease went into regression and disappeared completely. She experienced mild vasomotor symptoms and other signs of estrogen deprivation. To test the hypothesis that the hidradenitis suppurativa is steroid dependent but not estrogen dependent, we added estradiol valerate (2 mg daily) to the GnRH medication. The disease remained in remission during the 3 months of treatment. After this trial the buserelin medication was terminated, and we decided to treat the patient by a total abdominal hysterectomy and bilateral salpingo-oophorectomy combined with estrogen replacement therapy with estradiol valerate. The operation was uneventful. Six months after surgery the patient was without complaint.

Comment

To the best of our knowledge this is the first report of hidradenitis suppurativa treated by total abdominal hysterectomy and bilateral salpingo-oophorectomy. In one case a patient with hidradenitis suppurativa was reported as successfully treated with a combination of the GnRH agonist leuprolide acetate and dexamethasone.[2] The authors reported giving preference to leuprolide over oral contraceptives because their patient

6/1/37390

suffered from congenital heart disease and other systemic diseases. They did not mention the planned duration of the GnRH therapy, as will be important in view of osteoporosis, cardiovascular disease, and unknown sequels by long-term use of GnRH agonists. Oral contraceptives had been tried in our patient without success. In contrast with oral contraceptives, progestogens, or antiandrogens, GnRH agonists suppress the ovaries without inducing steroids. Therefore we used a GnRH agonist to temporarily treat the patient and to predict the possible effect of bilateral oophorectomy. A trial of GnRH in combination with estrogen predicted that, for this patient, hormonal replacement therapy after total abdominal hysterectomy and bilateral salpingo-oophorectomy was feasible. Further study is needed to find the place of GnRH or hysterectomy with bilateral salpingo-oophorectomy in patients with persistent hidradenitis suppurativa. Although not proved, our trials suggest that progesterone may be a major cause in the development of hidradenitis suppurativa. So, when available, antiprogesterones may play a role in the treatment of hidradenitis suppurativa.

Autonomic nervous system regulation of baseline heart rate in the fetal lamb

Akihiko Wakatsuki, MD, Yuji Murata, MD, Yuko Ninomiya, MD, Naoki Masaoka, MD, James G. Tyner, MD, and Krishna K. Kutty
Orange, California

OBJECTIVE: We examined 29 chronically instrumented fetal lambs from 125 to 143 days' gestation to investigate the effects of fetal behavioral states and autonomic nervous system maturation on baseline fetal heart rate.
STUDY DESIGN: Behavioral states were defined from electrocorticographic analysis as low-voltage fast activity or high-voltage slow activity. Decrease and increase in baseline fetal heart rate subsequent to administration of propranolol and methylatropine represented β-sympathetic and parasympathetic activity.
RESULTS: Baseline fetal heart rate decreased with gestation in both states, with steeper regression in low-voltage fast activity ($p < 0.001$). Positive correlation was noted between gestational age and percent decrease baseline fetal heart rate in both states with steeper regression in high-voltage slow activity ($p < 0.001$), and between gestational age and percent increase baseline fetal heart rate with steeper regression in low-voltage fast activity ($p < 0.001$). Fetal heart rate β-sympathetic and parasympathetic tones increased with age in both states, with elevation of β-sympathetic tone in high-voltage slow activity and parasympathetic tone in low-voltage fast activity.
CONCLUSION: Sympathetic and parasympathetic systems influence baseline fetal heart rate in these behavioral states and with age. (Am J Obstet Gynecol 1992;167:519-23.)

Key words: Baseline fetal heart rate, β-sympathetic tone, parasympathetic tone, fetal lamb, behavioral state, gestational age

Baseline fetal heart rate (FHR) declines with gestational age in the human fetus[1,2] and fetal lamb.[3] Schifferli and Caldeyro-Barcia[4] attribute this decline to maturing vagal parasympathetic functional control. Others report that baseline FHR is consistently higher in the high-voltage slow activity behavioral state than in the low-voltage fast activity state.[5-7] Using α-sympathetic and β-sympathetic blockades, Zhu and Szeto[8] concluded that the changes in baseline FHR relative to behavioral states were determined uniquely by sympathetic activity.[8] The regulation mechanisms of these fetal cardiovascular changes, especially the interaction of fetal behavioral states and autonomic nervous maturation on baseline FHR, remains unidentified. Our study investigated these control mechanisms at different gestational ages and behavioral states.

Material and methods

Surgical preparation. Twenty-nine chronically instrumented fetal lambs between 125 and 143 days' gestation from time-mated, cross-bred Columbia-Rambouillet ewes were used in this study. Sheep gestation averages 145 days. All animals were maintained in a facility approved by the American Association for the Accreditation of Laboratory Animal Care and in accordance with *Guide for the Care and Use of Laboratory Animals* and met the standards of care of the U.S. Department of Agriculture. Before implementation research protocols were approved by the Animal Research Committee at the University of California, Irvine.

After 24 hours of food and water withdrawal anesthesia was induced with xylazine (Rompun) 12 to 14 mg administered intramuscularly. Lidocaine 1% was used locally as needed. The uterus was exposed with a midline abdominal incision. The fetal head was delivered through a uterine myometrial incision and covered with a surgical glove filled with warm saline solution. Bilateral electrodes were sutured under the skin in the fetal chest wall for electrocardiography. Paired stainless steel electrodes (ethylcyanoacrilate, Loctite

Corp., Newington, Conn.) were placed and cemented bilaterally in the fetal parietal skull for electrocorticography. The instantaneous FHR was obtained from the R-R interval of the electrocardiogram. Polyvinyl catheters were inserted into the fetal carotid artery, jugular vein, and trachea. The procedures were performed carefully to avoid disturbing the fetal vagal nerve. An open-end catheter was retained in the amniotic cavity, and additional catheters were placed in the maternal femoral artery and vein. All electrodes and catheters were exteriorized to the flank of the ewe.

Experimental protocol. The animals were maintained in an air-conditioned room and given free access to food and water. For 3 to 4 days after surgery the mother and fetus received ampicillin (200 mg/kg/day intravenously) and gentamicin (6 mg/kg/day intravenously), and ampicillin (1 gm/day) was administered to the amniotic cavity. Maternal and fetal arterial pH, blood gases, and hematocrits were checked daily. For pH and gas determinations approximately 0.6 ml arterial blood was collected anaerobically and measured (Corning pH/Blood Gas Analyzer, Model 168 BGA, Ciba Corning Diagnostic Corp., Medfield, Mass.) at 37° C. Fetal well-being was determined by the following criteria: pH >7.30. Po_2 >16 mm Hg, hematocrit >30%. Fetal arterial blood pressure, FHR, electrocorticogram, tracheal pressure, intrauterine pressure, and maternal blood pressure were continuously monitored on an 8-channel rectilinear recorder (Beckman Model R612, Sensor Medics Corp., Anaheim, Calif.). Animals that demonstrated interpretable electrocorticogram were selected for this study. Fetal behavioral states were analyzed from the electrocorticogram for low-voltage fast activity and high-voltage slow activity. Experiments were performed after allowing ≥5 days of postoperative recovery. All experiments were carried out between 9 AM and 5 PM with the ewe standing or lying quietly.

In 10 fetal lambs between 125 and 143 days' gestation baseline FHR was assessed under normal physiologic conditions in the low-voltage fast activity and high-voltage slow activity behavioral states. Baseline FHR was measured after FHR was stable for at least 10 minutes in which uterine contractions were absent. A set of observations during adjacent low-voltage fast activity and high-voltage slow activity was obtained every day after fetal well-being was confirmed. The average duration of observation per fetus was 6.3 days and the average number of observations per animal was 12.6.

In 10 fetal lambs between 126 and 143 days' gestation saline solution was infused via the fetal jugular vein at 4.0 ml per hour for a 2-hour control period. The fetus then received an intravenous priming dose of propranolol (1.0 mg, 1 ml) followed by propranolol infusion (2.0 mg/hr, 4.0 ml/hr) for 2 hours to block β-sympathetic control of the heart rate. Baseline FHR was obtained in low-voltage fast activity and high-voltage slow activity states during control and propranolol periods. The percent decrease in baseline FHR between control and propranolol periods was calculated as an index of FHR β-sympathetic tone. Completeness of the β-blockade was indicated by the absence of cardiac acceleration response to an injected β-agonist (isoproterenol 2.0 μg/kg estimated fetal weight). The experiment was repeated on the same fetuses in 2 to 5 days, confirming complete recovery from the blockade. The average number of experiments per fetus was 4.5.

In nine fetal lambs between 127 and 143 days' gestation a 2-hour control period was followed by methylatropine (200 μg/kg estimated fetal weight intravenously) for blockage of the parasympathetic control of the heart rate. The methylatropine dose was determined in preliminary experiments. Baseline FHR was measured in the low-voltage fast activity and high-voltage slow activity states during the control period and subsequent to methylatropine administration. The percent increase of baseline FHR from control to methylatropine periods was taken as representing FHR parasympathetic tone. Completeness of methylatropine blockade was evidenced by the absence of deceleration response to norepinephrine (4 μg/kg estimated fetal weight). The effect of the blocking dose in our study lasted for ≥3 hours. The experiment was repeated on the same fetuses in 2 to 5 days, confirming complete recovery from the blockade. The average number of experiments per fetus was 4.5.

Data analysis. Regression lines were determined by the least squares method. The regression slopes were compared by t test regression analysis.[10] Statistical significance was accepted at $p < 0.05$.

Results

Figure 1 shows the normal physiologic relationship of fetal gestational age and baseline FHR in low-voltage fast activity (LVFA) and high-voltage slow activity (HVSA). Baseline FHR in both behavioral states decreased with gestational age. The regression equations for baseline FHR (BFHR) versus gestational age (GA) are as follows:

$$\text{LVFA:}\quad \text{BFHR} = -4.47(\text{GA}) + 745.97 \quad (r = 0.79,\ n = 126,\ p < 0.001)$$

$$\text{HVSA:}\quad \text{BFHR} = -2.44(\text{GA}) + 488.84 \quad (r = 0.47,\ n = 126,\ p < 0.001)$$

The low-voltage fast activity slope (−4.47) was significantly less ($p < 0.001$) than that of the high-voltage slow activity slope (−2.44).

Figure 2 shows the influence of gestational age on baseline FHR response to β-sympathetic blockade with propranolol infusion in the low-voltage fast activity and high-voltage slow activity states. A positive correlation was found between gestational age and percent de-

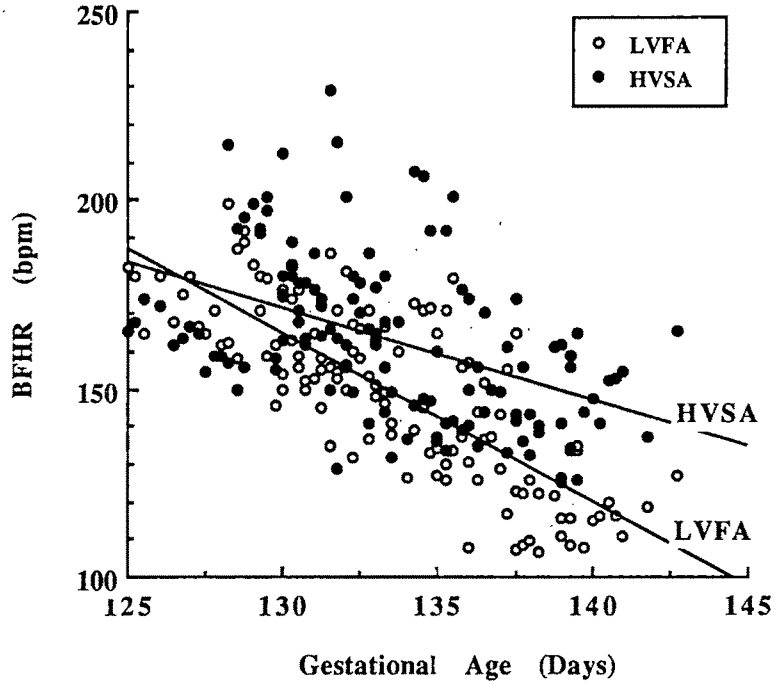

Fig. 1. Relationship between baseline FHR *(BFHR)* and gestational age in low-voltage fast activity *(LVFA)* and high-voltage slow activity *(HVSA)* states.

crease (% dec) in baseline FHR in both states. The regression equations follow:

LVFA: % dec BFHR = 0.54(GA) − 62.86 ($r = 0.50$, $n = 45$, $p < 0.001$)
HVSA: % dec BFHR = 0.97(GA) − 115.42 ($r = 0.65$, $n = 45$, $p < 0.001$)

The high-voltage slow activity slope (0.97) was significantly steeper than the low-voltage fast activity (0.54) ($p < 0.001$).

Figure 3 shows the relationship of gestational age and FHR response to parasympathetic blockade with methylatropine. The percent increase (% inc) in baseline FHR from control to methylatropine periods during low-voltage fast activity and high-voltage slow activity is illustrated. In both behavioral states the response increased with gestational age. The regression equations follow:

LVFA: % inc BFHR = 1.94(GA) − 243.28 ($r = 0.73$, $n = 30$, $p < 0.001$)
HVSA: % inc BFHR = 1.01(GA) − 129.59 ($r = 0.64$, $n = 30$, $p < 0.001$)

The low-voltage fast activity slope (1.94) was significantly steeper ($p < 0.001$) than the high-voltage slow activity (1.01).

Comment

Baseline FHR is regulated by the combined efforts of both intrinsic and extrinsic factors. The extrinsic factors are primarily the sympathetic and parasympathetic limbs of the autonomic nervous system.

The effects of the autonomic nervous system on baseline FHR in different behavioral states and gestational ages were assessed. Most previous studies used atropine sulfate to evaluate parasympathetic tone on FHR[11-13]; however, atropine sulfate has been reported to alter sleep behavior. Animals that received atropine sulfate did not show desynchronized sleep for several hours, and the desynchronized sleep that ultimately appeared was markedly modified.[14] For our study methylatropine was used as a parasympathetic blockade. This substance is much less lipid soluble and does not appear to act centrally.[15, 16] According to Guazzi et al.,[16] methylatropine (1 mg/kg) could be administered intravenously without any apparent sleep disturbance.[17]

In our study methylatropine 200 μg/kg estimated fetal weight was determined by prior experiments to be the appropriate dose. Complete parasympathetic block was obtained for ≥3 hours with no effect upon low-voltage fast activity– and high-voltage slow activity–cycling behavior. For the evaluation of autonomic nervous system effects on FHR, the sympathetic and parasympathetic blocking agents were not studied together. Twenty-four hours were allowed between tests for recovery of homeostasis. The percent decrease in baseline FHR subsequent to propranolol infusion and the percent increase in baseline FHR subsequent to methylatropine injection were calculated as representing FHR β-sympathetic and parasympathetic tone, re-

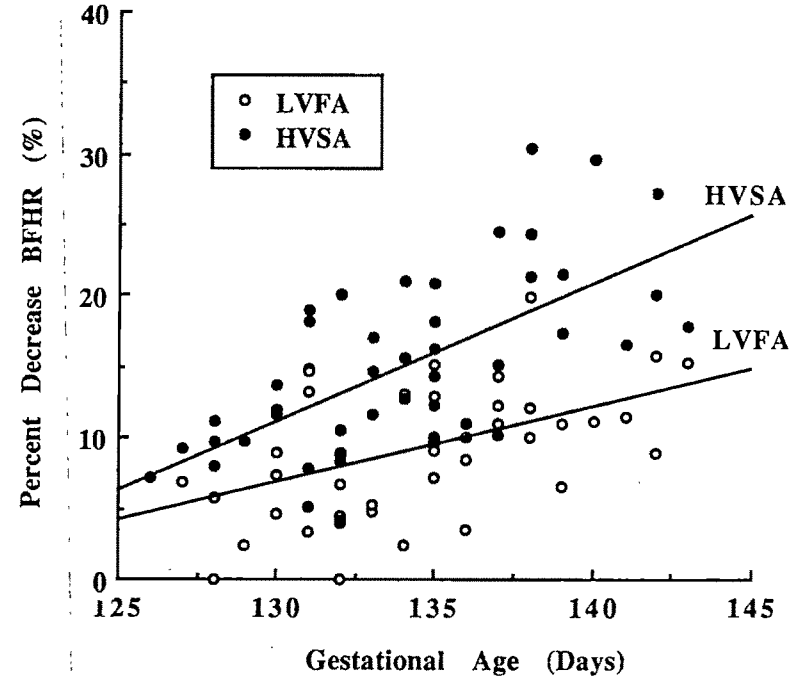

Fig. 2. Relationship between percent decrease in baseline FHR *(BFHR)* and in low-voltage fast activity *(LVFA)* and high-voltage slow activity *(HVSA)* states after propranolol.

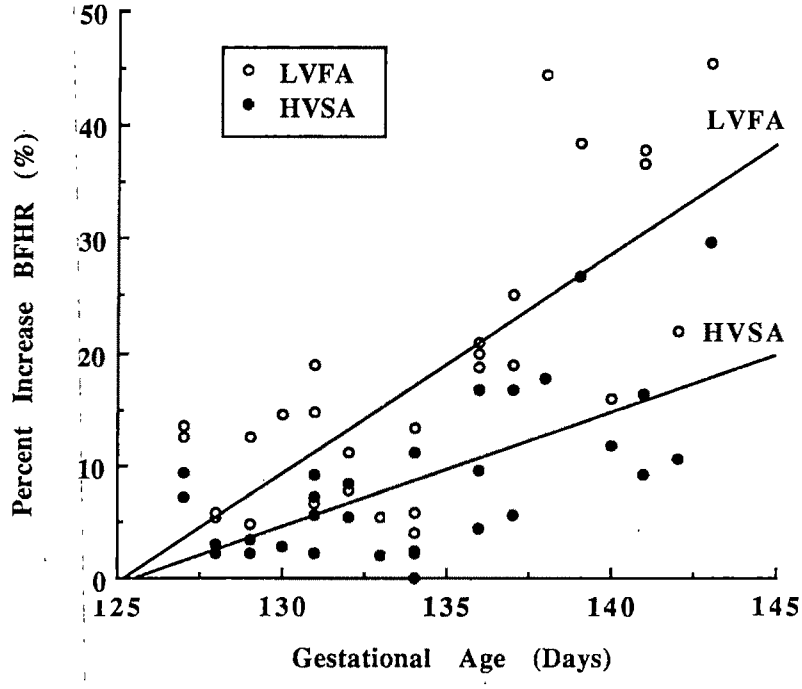

Fig. 3. Relationship between percent increase in baseline FHR *(BFHR)* and gestational age in low-voltage fast activity *(LVFA)* and high-voltage slow activity *(HVSA)* states after atropine.

spectively.[11-13] The percent decrease in baseline FHR increased with gestational age, and the slope of the regression line was steeper in the high-voltage slow activity state. These data indicate that FHR β-sympathetic tone increases with gestational age and is greater in the high-voltage slow activity state. The difference between low-voltage fast activity and high-voltage slow activity sympathetic tone also increased with gestational age.

The percent increase in baseline FHR rose with gestational age, and the regression line slope was steeper during the low-voltage fast activity state. These results

indicate that FHR parasympathetic tone increases with gestational age. FHR parasympathetic tone was higher in low-voltage fast activity, and the difference between states increased with gestational age.

A number of studies have reported conflicting results about the autonomic system influence on FHR. The existence of adrenergic cardiovascular function in the fetal lamb as early as 85 days' gestation was demonstrated by bradycardia response to propranolol.[13] Parasympathetic cardiac function in the fetal lamb at 60 days' gestation was shown by vagally driven heart rate slowing.[11] Nuwayhid et al.[12] reported that parasympathetic tone on resting heart rate in the fetal lamb was feeble at <130 days and sympathetic tone was constant throughout gestation. Walker et al.[3] found a progressive increase in parasympathetic tone and decrease in sympathetic tone toward term in the fetal lamb.[1] Vapaavouri et al.[13] reported that parasympathetic tone is fully developed by 120 days' gestation in the fetal lamb and that sympathetic tone increased from 101 days on. Other studies have reported that sympathetic influence upon FHR is significant[18] or minor.[19] In our study gestational age correlated positively with increased sympathetic and parasympathetic tone from 85% of gestational period to term. These results demonstrate that autonomic effects on FHR develop markedly during the last 15% of gestation in the fetal lamb. Assali et al.[11] concluded that sympathetic tone becomes active earlier than parasympathetic tone, and Walker et al.[3] showed a decrease of sympathetic influence toward term that resulted from a strong increase in parasympathetic activity. They did not, however, consider differences associated with behavioral states. In our study FHR sympathetic tone was more notable during high-voltage slow activity and parasympathetic tone more pronounced during low-voltage fast activity. Thus each behavioral state has unique autonomic effects upon FHR.

It would appear that FHR in the absence of autonomic effector action declines progressively with gestational age and that this may be a function of increased cardiac muscle mass and cardiac work. In our study we conclude that with behavioral state changes shifts in relative magnitudes of the simultaneous parasympathetic inhibitory and sympathetic acceleratory influences modulate the basal or intrinsic heart rate. During the low-voltage fast activity state increases in parasympathetic activity and decreases in sympathetic activity result in lower baseline FHR. On the other hand, during high-voltage slow activity state sympathetic activity increases and parasympathetic activity decreases so that baseline FHR rises.

We thank Lanie M. Adamson, MS, for editorial assistance in the preparation of the manuscript.

Interferon-γ receptors on human gestational choriocarcinoma cell lines: Quantitative and functional studies

Vilmos Fulop, MD, Michael A. Steller, MD, Ross S. Berkowitz, MD, and Deborah J. Anderson, PhD

Boston, Massachusetts

OBJECTIVES: This study was performed to further define the effects of interferon-γ on choriocarcinoma cell lines and to determine whether variations in response among cell lines are attributable to quantitative differences in interferon-γ receptors.

STUDY DESIGN: Interferon-γ receptors were quantified on BeWo, JEG-3 and Jar choriocarcinoma cell lines by a radiolabeled interferon-γ ligand binding assay. The response of these cell lines to interferon-γ was measured in two functional assays: a cell proliferation assay and a cell lysis assay after exposure to interferon-γ with and without actinomycin-D.

RESULTS: The number of interferon-γ receptors on BeWo, Jar, and JEG-3 cells did not differ significantly (650, 560, and 420 interferon-γ receptors per cell, respectively). Proliferation of all three choriocarcinoma cell lines was significantly inhibited to a similar extent by interferon-γ. After treatment with interferon-γ actinomycin-D, each choriocarcinoma cell line exhibited dose-dependent cell lysis; lysis of Jar was significantly less than that of either BeWo or JEG-3.

CONCLUSION: These data further document variations in the response of choriocarcinoma cell lines to interferon-γ and indicate that these differences are not the result of interferon-γ receptor number but of postreceptor mechanisms. (Am J Obstet Gynecol 1992;167:524-30.)

Key words: Interferon-γ, receptors, choriocarcinoma

Gestational choriocarcinoma is unique both clinically and biologically. Choriocarcinoma is remarkably curable with chemotherapy even in the presence of widespread metastases.[1, 2] Furthermore, because choriocarcinoma cells express genes of paternal origin, choriocarcinoma is at least a partial allograft. The dramatic curability of this tumor may be attributable in part to a host immunologic response. The presence of drug-resistant choriocarcinoma may be related to patient-partner histocompatibility.[3, 4] The prognosis of patients with choriocarcinoma has been correlated with the intensity of lymphocytic infiltration at the tumor-host interface.[5, 6]

Immunologically competent T lymphocytes secrete a variety of cytokines, including interferon-γ when antigenically stimulated. Interferon-γ has been previously demonstrated to enhance class I human leukocyte antigen expression in some choriocarcinoma cell lines and to inhibit choriocarcinoma cellular proliferation in vitro.[7-9] Interferon-γ may therefore be an important mediator of host immune defense against choriocarcinoma cells. Although interferon-γ enhanced expression of class I major histocompatibility complex in BeWo and JEG-3 choriocarcinoma cell lines, it did not in the Jar choriocarcinoma cell line.[7] Therefore choriocarcinoma cell lines may be heterogeneous in their response to interferon-γ.

Our study was undertaken to further document differences between the choriocarcinoma cell lines in their response to interferon-γ and to determine whether variations in responsiveness of choriocarcinoma cell lines are attributable to differences in interferon-γ receptor number or postreceptor mechanisms. Interferon-γ receptors were quantified on choriocarcinoma cell lines by radiolabeled ligand binding assay; physiologic responses to interferon-γ were determined by two assays: measurement of cell proliferation after exposure to interferon-γ and cell lysis after exposure to interferon-γ with and without the addition of actinomycin-D to block internal protein lytic defense mechanisms.[10]

Material and methods

Cell lines and growth conditions. WISH cells (a human amnion cell line) and choriocarcinoma cell lines (Jar, JEG-3, BeWo) were obtained (American Type Culture Collection, Rockville, Md.). NIH/3T3 cells (a mouse fibroblast cell line) were kindly provided by Dr.

From the Fearing Research Laboratory, Harvard Medical School, Department of Obstetrics and Gynecology, Brigham and Women's Hospital.

Timothy Bestor, Harvard Medical School. WISH cells were grown and maintained in tissue culture medium containing Eagle's minimal essential medium (GIBCO, Grand Island, N.Y.) supplemented with 15% heat-inactivated fetal calf serum, L-glutamine (2 mmol/L), penicillin G sodium (100 U/ml), streptomycin sulfate (100 μg/ml), and 0.25 μg/ml amphotericin B (minimal essential medium–tissue culture medium). Choriocarcinoma cells were maintained in tissue culture medium consisting of Roswell Park Memorial Institute (RPMI) 1640 medium (GIBCO) containing 10% fetal calf serum, L-glutamine, penicillin G, streptomycin, and amphotericin B in the above-mentioned concentrations (RPMI–tissue culture medium). NIH/3T3 cells were cultured in high glucose Dulbecco's modified Eagle medium with 10% fetal calf serum and antibiotics (Dulbecco's modified Eagle medium–tissue culture medium). Cells were maintained as exponentially growing monolayer cultures at 37° C in a humidified atmosphere of 5% CO_2 and 95% air. They were routinely split twice or three times a week and were free from contamination with *Mycoplasma* (Hoechst 33258 stain fluorescence negative).

Interferon γ. Recombinant human interferon-γ (specific activity: 2.5×10^7 half maximal U/mg protein) was obtained (Genzyme, Boston). The purity of this preparation was certified by the manufacturer to be 99%. It was reconstituted with RPMI 1640 medium (10^5 U/ml) and stored at −70° C. Interferon-γ was diluted in RPMI–tissue culture medium before its use in the cytolytic assay. Recombinant human interferon-γ (New England Nuclear, Boston)[11] was radioiodinated by the Bolton-Hunter technique to a specific activity of 70 μCi/μg.

Actinomycin-D. The stock solutions of actinomycin-D (Sigma Chemical Co., St. Louis), were prepared weekly in RPMI 1640 medium containing supplements and kept in the dark at 4° C.

IFN-γ cell binding experiments. Human gestational choriocarcinoma cells (Jar, JEG-3, BeWo), WISH cells (positive control cells), and mouse 3T3 cells (negative control cells) were seeded into 35 mm 6-well tissue culture plates (Corning, N.Y.) in 1 ml appropriate tissue culture medium ($0.7\text{-}1 \times 10^6$ cells/well) and allowed to grow 24 to 48 hours until the cultures reached confluence (approximately 1.5×10^6/well). For saturation-binding studies, monolayers were washed twice with appropriate cold tissue culture medium and then incubated for 4 hours at 4° C or for 1 hour at 37° C with increasing concentrations (0.0036 nmol/L to 0.118 nmol/L) of iodine 125–labeled interferon-γ in 1 ml tissue culture medium. After incubation the binding reaction was terminated by aspirating the tissue culture medium and washing the wells carefully six times with cold tissue culture medium. The cells were detached with trypsin and counted on a hemacytometer; their radioactivity was counted in a gamma counter (Pharmacia LKB Nuclear, Gaithersburg, Md.). Cell viability was assayed by the trypan blue exclusion test. The concentration of ligand necessary for receptor saturation for each cell line was determined. To assess binding specificity, competitive binding assays were performed by incubating the cells for 4 hours at 4° C with ^{125}I-interferon-γ (0.012 nmol/L in 1 ml tissue culture medium), together with various concentrations (0.012 nmol/L to 6.2 nmol/L) of cold interferon-γ. The cells were then washed with Roswell Park Memorial Institute, detached, and counted as above. Nonspecific binding, defined as counts remaining in the presence of 500-fold excess of unlabeled interferon-γ, was subtracted from all readings, and the remaining counts were defined as specific binding. Nonspecific binding was <10% of total binding. The affinity constant and the number of receptors were calculated from the binding curves by Scatchard analysis.[12]

The cytolytic assay. The cytolytic assay used in these experiments is a modification of the techniques previously described by Massad et al.[10] In these experiments 200 μl of choriocarcinoma cell suspension (5×10^4 cells/ml RPMI–tissue culture medium) were seeded in 96-well, flat-bottomed remove-a-cell plates (Dynatech Laboratories, Inc., Chantilly, Va.) that had been precoated with laminin (Sigma, St. Louis). Cells were allowed to adhere to culture wells for 18 to 20 hours. The tissue culture medium was aspirated, the wells were washed once in RPMI and then 100 μl of interferon-γ dilution (10 to 10,000 units in 1 ml of RPMI–tissue culture medium) were added in triplicate. Control triplicate wells were plated simultaneously and incubated in RPMI–tissue culture medium alone. After 16 hours of incubation at 37° C, in 5% carbon dioxide, the cells were labeled with 100 μl of RPMI–tissue culture medium containing 75 μCi/ml sodium chromate 51 (New England Nuclear) in each well. After an additional 8 to 10 hours of incubation in a humidified chamber at 37° C in 5% carbon dioxide, the supernatant was aspirated and each well was washed five times in RPMI. 100 μl of RPMI–tissue culture medium were then added to each well and another 100 μl of RPMI–tissue culture medium containing 2×10^{-6} mol/L actinomycin-D were added to the experimental wells. Control wells only received 100 μl of RPMI–tissue culture medium. After 24 hours of incubation at 37° C in a humidified atmosphere of 5% carbon dioxide and 95% air, the plates were centrifuged at 40*g* for 4 minutes, and a 100 μl aliquot of supernatant was removed from each well and counted in a gamma counter. Total incorporation was determined by counting the radioactivity of 2.5×10^4 cells cpm. Spontaneous ^{51}Cr release was measured in wells that were not pretreated with

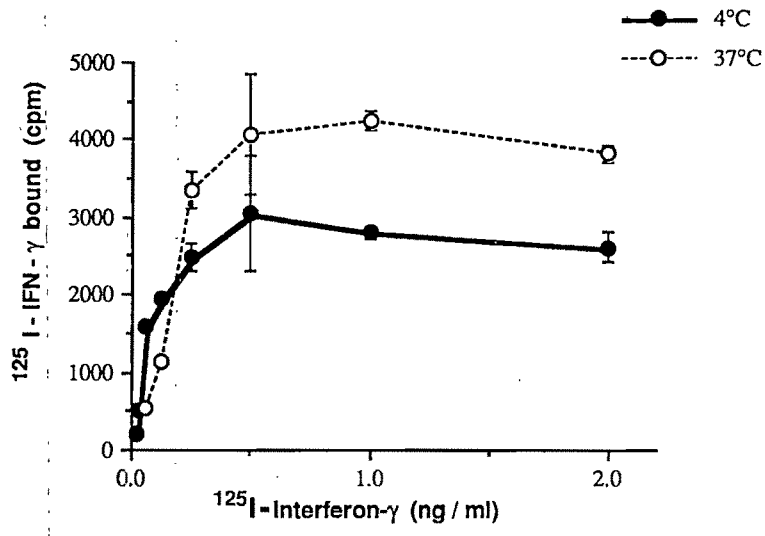

Fig. 1. Binding of ^{125}I-interferon-γ *(IFN-γ)* to Jar cells at 4° C and 37° C.

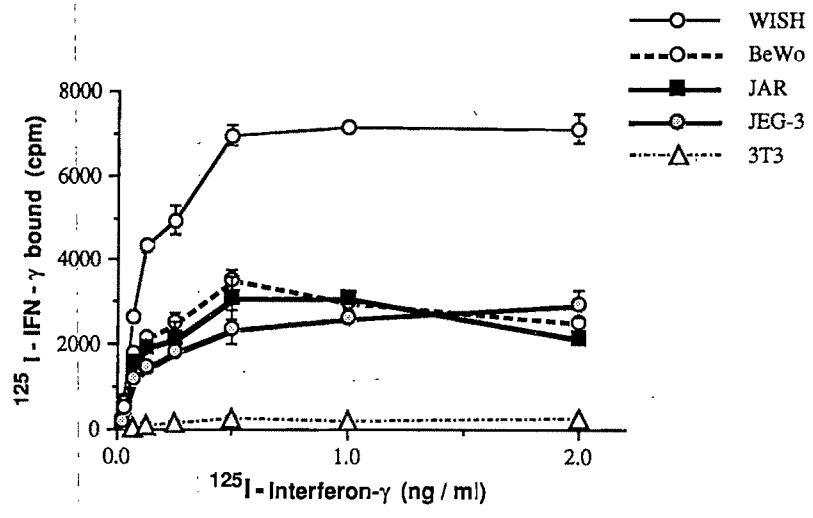

Fig. 2. Binding of ^{125}I-interferon-γ *(IFN-γ)* to WISH cells, gestational choriocarcinoma cells (Jar, JEG-3, BeWo), and mouse 3T3 cells at 4° C.

interferon-γ. Each assay was set up in triplicate, and the percentage of specific lysis (^{51}Cr release) was calculated as follows:

$$\text{Percent specific lysis} = \frac{\text{cpm } ^{51}\text{Cr (experimental)} - \text{cpm } ^{51}\text{Cr (spontaneous)}}{\text{cpm } ^{51}\text{Cr (total)} - \text{cpm } ^{51}\text{Cr (spontaneous)}}$$

The data were expressed as a mean percentage of specific lysis.

Tritiated thymidine incorporation assay. The tritiated thymidine incorporation assay with JAR and BeWo choriocarcinoma cell lines was performed as previously described from our laboratory.[8]

Statistical analysis. For radio-receptor and cytolytic assays, data were analyzed with Statview II statistical software on a Macintosh SE/30 computer. Differences among groups were determined by two-way analysis of variance followed by Fisher's protected least significant difference post-hoc testing.

Results

Characteristics of interferon-γ binding and binding-site competition. The binding of radiolabeled interferon-γ to Jar cells was dose-dependent and reached saturation by 4 hours at 4° C and by 1 hour at 37° C. The amount of cell-associated interferon-γ was greater ($p < 0.05$) at 37° C (Fig. 1), possibly because of internalization of ligand. To standardize the data, subsequent binding assays were performed at 4° C for 4 hours. The binding of ^{125}I-interferon-γ varied among the cell lines tested, with WISH cells binding the most interferon-γ ($p < 0.05$). The mouse 3T3 cells had no

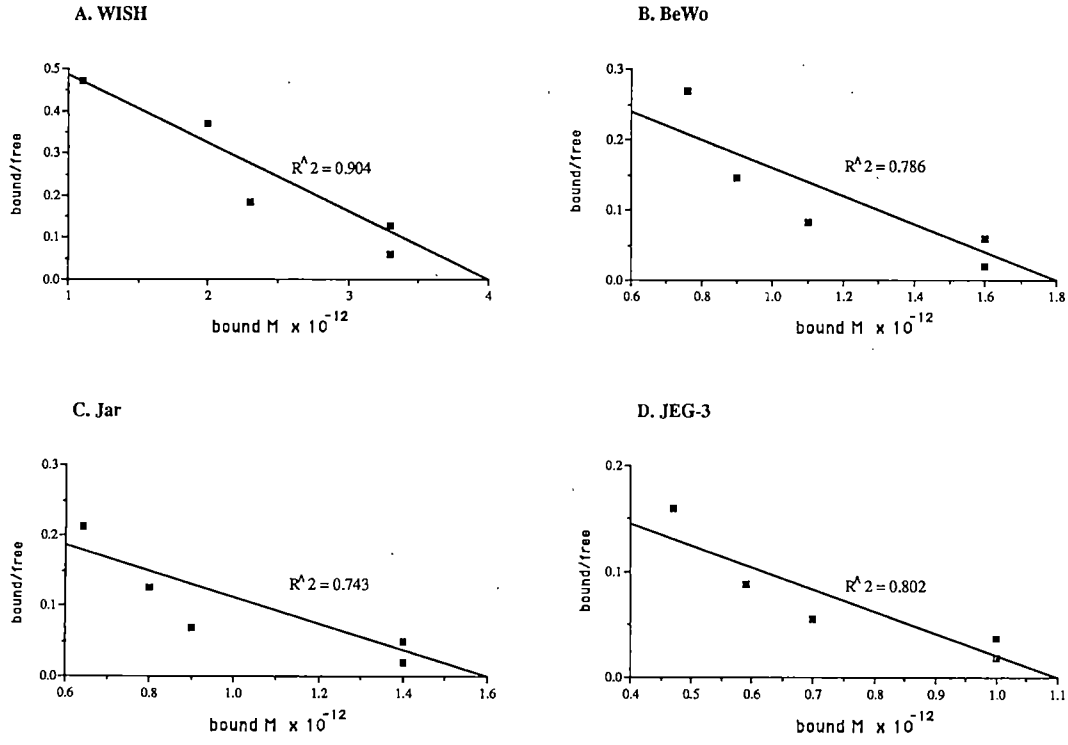

Fig. 3. Scatchard analysis of ^{125}I-interferon-γ binding to WISH and choriocarcinoma cell lines. *R^2*, Regression coefficient.

specific interferon-γ binding capacity, confirming the species specificity of this reaction (Fig. 2).

Scatchard analysis of the saturation curves showed a linear dependency (Fig. 3). These data indicate that there is a single type of high-affinity interferon-γ receptor on the human choriocarcinoma cell lines used in this study. Extrapolation toward the abscissa of the values at low interferon-γ concentrations gave a value of 1300 interferon-γ receptors per WISH cell with an affinity constant of 5.9×10^{-12} mol/L.[13] The same analysis revealed 650 interferon-γ receptors per BeWo cell, 560 interferon-γ receptors per Jar cell, and 420 interferon-γ receptors per JEG-3 cell, with affinity constants in the range of 3.3 to 4.9×10^{-12} mol/L. The differences in interferon-γ receptor numbers and affinity constants on the choriocarcinoma cell lines were not statistically significant ($p > 0.05$).

To establish the specificity of binding of ^{125}I-interferon-γ to choriocarcinoma cells a cold-competition assay was performed with the JEG-3 cell line. Unlabeled (cold) interferon-γ competitively inhibited the binding of ^{125}I-interferon-γ to JEG-3 cells in a dose-dependent manner, confirming binding specificity. The binding of ^{125}I-interferon-γ could be completely inhibited by a 50-fold excess of unlabeled interferon-γ (Fig. 4). The specific binding represented approximately 90% of the total counts bound.

Induction of lytic activity by interferon-γ on choriocarcinoma cell lines. The effects of various concentrations (10 to 10,000 U/ml) of interferon-γ alone, 10^{-6} mol/L actinomycin-D alone and the combination of interferon-γ and actinomycin-D were evaluated. The concentration of actinomycin-D was chosen based on prior reports describing the effect of actinomycin-D and interferon-γ on cervical carcinoma cell lines.[10] Spontaneous ^{51}Cr release was <14% for BeWo, <11% for Jar, and <6% for JEG-3 cells. No significant lysis was observed in response to interferon-γ alone at any concentration studied. The addition of actinomycin-D alone resulted in an increase in spontaneous chromium release with a low level of lysis. When interferon-γ was used in combination with actinomycin-D, marked enhancement of cell lysis was noted. This specific cell lysis was dependent on the concentration of interferon-γ used. Fig. 5 depicts a representative experiment where cells were pretreated for 24 hours with varying concentrations of interferon-γ. At interferon-γ ≥ 100 U/ml a dose-dependent increase in cell lysis was observed in the presence of 10^{-6} mol/L actinomycin-D in all three choriocarcinoma cell lines. However, the amount of cell lysis in the Jar cell line in the presence of actinomycin-D-interferon-γ was significantly less than that observed with the other choriocarcinoma cell lines ($p < 0.05$). Concentrations of interferon-γ <100 U/ml with 10^{-6} mol/L actinomycin-D caused the same low level of cell lysis as 10^{-6} mol/L actinomycin-D only.

Inhibition of proliferation of choriocarcinoma cell lines by interferon-γ. Proliferation in the Jar and

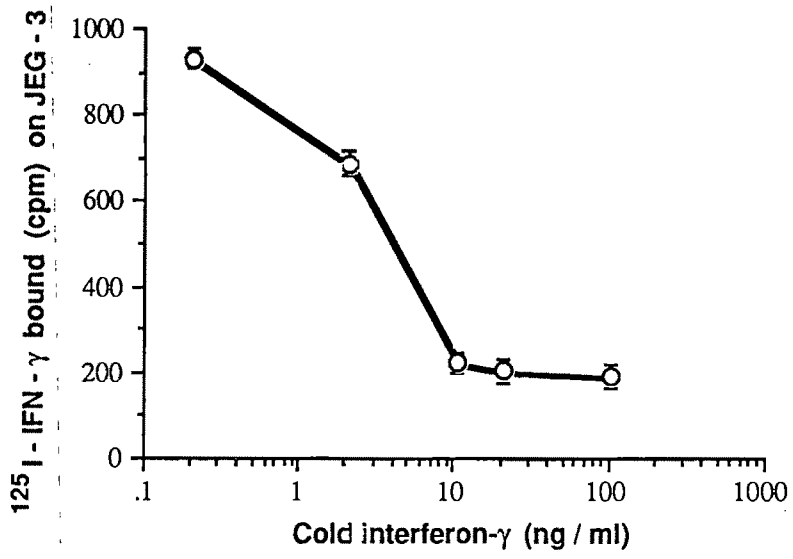

Fig. 4. Competitive inhibition of ^{125}I-interferon-γ *(IFN-γ)* (0.21 ng/ml) binding to JEG-3 choriocarcinoma cells by cold interferon-γ.

BeWo choriocarcinoma cell lines was significantly inhibited by interferon-γ (32% and 34% inhibition at 1000 U/ml, and 43% and 47% inhibition at 20,000 U/ml [$p < 0.05$]).

Comment

Interferon-γ is an important immunoregulatory cytokine produced by activated T cells and natural killer cells and plays an integral role in promoting specific mechanisms of host defense. Interferon-γ also regulates the production and activities of other immunomodulatory cytokines produced by macrophages and T cells such as tumor necrosis factor and certain interleukins.[14] In addition, interferon-γ produces antiproliferative effects in sensitive normal and neoplastic cells and is the major cytokine responsible for regulating expression of immunologically important cell surface determinants such as class I and II antigens of the major histocompatibility complex.[15]

We and others have previously demonstrated that class I human leukocyte antigen expression is up-regulated after exposure to interferon-γ in BeWo (the parent line of JEG-3[16]) and JEG-3 choriocarcinoma cell lines, but not Jar.[7, 9] This variation in response to interferon-γ may be attributable to differences in signal transduction pathways or other postreceptor mechanisms. To determine whether the variation in response to interferon-γ is unique to human leukocyte antigen expression, we used two different functional assays to further study the effects of interferon-γ in various choriocarcinoma cell lines. The interferon-γ cell lysis assay entailed the use of a protein synthesis inhibitor, actinomycin-D, which impairs a natural defense mechanism against cell lysis.[10] None of the choriocarcinoma cell lines demonstrated lysis in the presence of interferon-γ alone in concentrations ranging from 10 to 10,000 U/ml. In contrast, when incubated with actinomycin-D all three choriocarcinoma cell lines exhibited a dose-dependent increase in cell lysis with increasing concentrations of interferon-γ. However, the Jar cell line exhibited significantly less cell lysis with the actinomycin-D–interferon-γ combination than either BeWo or JEG-3 at concentrations of interferon-γ of ≥100 U/ml. The Jar cell line is therefore sensitive to lytic effects of interferon-γ but at a significantly lower level than the BeWo and JEG-3 cell lines. The tritiated thymidine incorporation studies performed in the current investigation and previously[8] indicated that proliferation is inhibited to a similar extent by interferon-γ in all three choriocarcinoma cell lines.

Interferon-γ induces its biologic effects by interacting with a specific interferon-γ receptor expressed at the target cell surface. The human interferon-γ receptor is an integral membrane glycoprotein with N-linked carbohydrates containing an extracellular ligand-binding domain with intramolecular disulfides necessary for ligand binding.[13] The amino acid sequence of the human interferon-γ receptor displays no resemblance to known proteins and does not belong to any of the known receptor families.[17] Unlike other inducible receptors for lymphokines, expression of interferon-γ receptors appears to be constitutive and is not influenced by agents inducing differentiation or by activation of cellular proliferation. Furthermore, receptor numbers do not substantially change during the cell cycle.[18] Under equilibrium conditions interferon-γ sensitive cells with high receptor numbers require proportionally lower interferon-γ concentrations to achieve sufficient

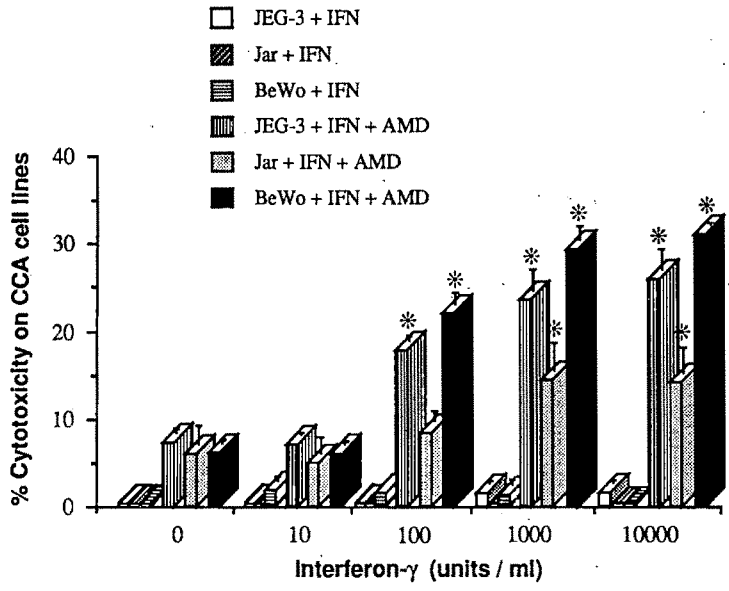

Fig. 5. Lytic effect of interferon-γ alone and in combination with actinomycin-D on three choriocarcinoma cell lines. *Asterisk,* Significantly greater percent cytotoxicity as compared with interferon-γ alone and actinomycin-D alone ($p < 0.05$).

receptor occupation-internalization for triggering a response as compared with cells with low receptor numbers. Together with the concentration of interferon-γ, the number of expressed receptors is critical for the induction of response. During the past few years a single class of high-affinity interferon-γ receptor has been demonstrated on a wide variety of cell types.[15] The mechanisms of postreceptor signal transduction by interferon-γ have not been clearly elucidated.

Human placenta is a rich source of interferon-γ receptor[19]; however, interferon-γ receptors have not previously been demonstrated on gestational choriocarcinoma cells. Using ^{125}I-interferon-γ with a high specific activity, we demonstrated that a receptor specific for human interferon-γ exists on gestational choriocarcinoma cells. The interferon-γ ligand bound with high affinity and in a highly specific and saturable manner to all three choriocarcinoma cell lines used in this study. The maximum binding capacity of ^{125}I-interferon-γ at 37° C was found to be nearly one and one half times more than measured at 4° C. The increased binding capacity at 37° C could be caused by de novo synthesis of additional interferon receptors; internalization of interferon receptors, or conformational changes of receptor or ligand molecules. There was no significant difference between the receptor numbers of BeWo, Jar, and JEG-3 lines; therefore the differing physiologic responses of choriocarcinoma cells to interferon-γ in human leukocyte antigen induction and lysis assays are not the result of quantitative differences in expression of the interferon-γ receptor.

The results of this study may have clinical relevance in the management of drug-resistant choriocarcinoma. Interferon-γ has antiproliferative and lytic effects on choriocarcinoma cells and also enhances their immunogenicity. Interferon-γ used alone or in conjunction wtih protein synthesis inhibitors such as actinomycin-D, a currently used agent in the treatment of choriocarcinoma, may play a role in the future therapy of this disease.

Effects of sustained hypoxemia on the sheep fetus at midgestation: Endocrine, cardiovascular, and biophysical responses

Yoshio Matsuda, MD,[a] John Patrick, MD,[b] Lesley Carmichael, BSc,[b] John Challis, PhD,[b] and Bryan Richardson, MD[b]

Kagoshima, Japan, and London, Ontario, Canada

OBJECTIVE: The purpose of our study was to examine the effects of induced hypoxia on endocrine, cardiovascular, and biophysical measurements of the ovine fetus at 0.6 (83 to 93 days) of gestation anc to compare the fetal responses at this earlier gestation with those reported near term.

STUDY DESIGN: Fourteen fetal sheep were studied (9 in the hypoxia group and 5 in the control group) at 0.6 of gestation during a 24-hour control period, 8 hours of either sustained hypoxemia or room air, and a 40-hour recovery period.

RESULTS: Induced fetal hypoxemia resulted in a progressive lactic metabolic acidosis; however, all fetuses had recovered within 24 hours. The fetal endocrine response was variable with norepinephrine, the only measured hormone showing a significant hypoxia-related increase ($p < 0.05$). Fetal heart rate and mean arterial blood pressure showed little hypoxia-induced change, although fetal heart rate was significantly increased over the first 2 hours ($p < 0.05$). The percent time fetal breathing movements, electroocular activity, and nuchal muscle activity likewise showed little hypoxia-induced change.

CONCLUSION: The cardiovascular and biophysical response of the preterm fetus to induced hypoxemia is thus much less pronounced than that of the older gestational-aged fetus; this difference may impact on survival and the success of antenatal assessment protocols. (Am J Obstet Gynecol 1992;167:531-40.)

Key words: Fetal biophysical activity, breathing movements, heart rate

The response of the ovine fetus to induced hypoxemia is well characterized near term with a decrease in both breathing[1-5] and body movements[6] when fetal oxygenation is sufficiently compromised. This response results in a protective decrease in oxygen requirements[7,8] and provides a physiologic basis for the use of biophysical parameters in monitoring the high-risk pregnant patient. However, controlled animal data for the preterm fetus is lacking in spite of the improved perinatal survival and associated need for antenatal assessment at younger gestational ages for human pregnancy. Therefore the purpose of our study was to examine the effects of induced hypoxia on biophysical and cardiovascular measurements of the ovine fetus at 0.6 (83 to 93 days) of gestation and to compare fetal responses at this earlier gestation with those reported near term.

Material and methods

Surgical procedures. Fourteen fetal lambs of mixed breed (nine in the hypoxia group; five in the control group) were surgically prepared for study between 78 and 87 days of gestation (term = 147 days). Ewes were given 600 mg of thiopental sodium intravenously; the ewes were intubated and maintained on a closed-circuit anesthesia system with 0.5 to 1.0% halothane (Abbott Laboratories, Montreal) and 67% oxygen–33% nitrous oxide at 6 L/min. Under sterile conditions a midline incision was made in the ewe's abdomen, and the uterus was exposed and opened. Polyvinyl catheters were placed into the fetal carotid artery (V3, Bolab, Lake Havasu City, Ariz.), trachea, jugular vein (V4, Bolab), and amniotic cavity (V11, Bolab). Electrodes of stainless steel polytetrafluoroethylene-coated wire (Cooner, Chatsworth, Calif.) were implanted through the orbital ridge of the zygomatic bone of each eye for recording of the electrooculogram, into the nuchal muscle for recording the nuchal muscle electromyogram, and over the sternum for recording the fetal heart rate. A reference electrode was placed in the loose connective tissue around the neck. The catheters (containing heparinized saline solution) and wires were exteriorized

through the flank of the ewe, and the abdomen was closed in layers. Polyvinyl catheters (V11, Bolab) were also placed in the maternal femoral artery and vein. At the time of surgery 800,000 IU of sodium penicillin G and 250 mg of streptomycin were injected intramuscularly to ewes and 1,000,000 IU of sodium penicillin G was injected into both the fetal jugular vein and the amniotic cavity. This antibiotic was administered daily until the experiment ended. All catheters were filled with sterile heparinized saline solution and flushed daily. Postoperatively, animals were maintained in individual cages suitable for continuous monitoring with food and water available. Ewes were also maintained on a 12-hour light-dark cycle and were allowed at least 4 days to recover from surgery before experiments began. Animal care followed the guidelines of the Canadian Council on Animal Care.

Physiologic measurements. All animals were studied during a 24-hour control period, an 8-hour experimental period of either sustained hypoxemia (hypoxia group) or normoxemia (control group), and a 40-hour recovery period. Continuous recording was obtained for fetal electroocular and nuchal muscle activities, tracheal pressure, carotid arterial blood pressure, amniotic fluid pressure, and fetal heart rate. Pressure transducers (Statham Model P-23 ID, Gould, Inc., Oxnard, Calif.) and a chart recorder (Model 7, Grass Instrument Co., Quincy, Mass.) were used to record pressures in the trachea, amniotic fluid, and carotid artery. Mean arterial blood pressure referenced to amniotic fluid pressure was calculated as diastolic plus 0.4 of systolic minus diastolic pressure. Electrical signals were processed with a common mode rejection preamplifier (Model 7, P51 IJ, Grass). Fetal heart rate was measured with a cardiotachometer (Model 7, 44B, Grass). Fetal electroocular and nuchal muscle potentials were displayed directly on the chart recorder after passage through a passive bandpass filter, 0.3 to 30 Hz, on the preamplifier.

After approximately 23 hours of normoxemic control period, a perspex chamber (volume 4.6 cu ft) designed to alter maternal-inspired gas concentration and to permit ewes to eat and drink was placed in the cage and perfused with air at 40 L/min as previously described.[9] For the hypoxia group, after 1 hour the gas mixture was changed to 9% oxygen, 3% carbon dioxide, and 88% nitrogen and maintained for 8 hours. Fifteen minutes before the initiation of induced hypoxemia, fetal and maternal arterial blood were sampled for blood gases, pH, hematocrit, oxygen saturation, glucose, lactate, corticotropin, cortisol, norepinephrine, and epinephrine (total 2.8 ml for the fetus, 5 ml for the mother). At 1 hour and 8 hours after the onset of induced hypoxemia, a second and third complete set of blood samples were drawn. Fetal arterial blood gases, pH, and oxygen saturation (0.3 ml) were also sampled every hour throughout the 8-hour period of induced hypoxemia to monitor fetal blood gas status. The perspex chamber was removed from the front of the cage. A fourth complete set of blood samples was taken 24 hours after the induced hypoxemia. In the control group similar procedures were followed except the ewes breathed room air in the perspex box at 40 L/min throughout the 8-hour experimental period. Biophysical monitoring was continued through 40 hours of recovery, with animals later killed and autopsies performed to examine for neuropathologic factors.

Maternal and fetal arterial blood samples were drawn into heparinized syringes and placed on ice. Arterial blood gases, pH, and oxygen and carbon dioxide concentration within the perspex plexiglass chamber were measured with a blood gas analyzer with temperature corrected to 39.5° C (ABL-3, Radiometer, Copenhagen). Oxygen content was calculated with a capacity of 1.36 ml oxygen/gm hemoglobin. Whole blood glucose and lactate measurements were made in triplicate with membrane-bound glucose oxidase and D-lactate dehydrogenase, respectively (model 23A, Yellow Springs Instrument Co., Yellow Springs, Ohio). Hematocrit was measured on a centrifuge (Autocrit Ultra 3, Clay Adams, Becton Dickinson, Parsippany, N.J.).

Blood samples for the determination of catecholamine concentrations were transferred to plastic tubes containing glutathione—ethylenediaminetetraacetic acid and centrifuged at 4° C for 15 minutes at 2000 rpm. The plasma was removed and stored at −70° C until analyzed. Blood samples for the determination of corticotropin and cortisol were transferred to plastic tubes without preservative and were similarly centrifuged and stored. Norepinephrine and epinephrine were subsequently measured by electrochemical detection after high-pressure liquid chromatography fractionation.[10] Immunoreactive corticotropin and cortisol were determined with radioimmunoassays as previously described and validated.[11]

Data analysis. Electroocular and nuchal muscle activities were assessed by visual analysis. Episodes of negative tracheal pressure were used to indicate fetal breathing movements. The minimum amplitude of breaths recognized was 1 mm Hg. Apnea was defined as an interval of >6 seconds with no episodes of fetal breathing movements. The incidence of fetal breathing movements, nuchal muscle, and electroocular activity were reported as the percentage of time spent in each 2-hour period. Fetal heart rate and arterial blood pressure recordings were analyzed every 5 minutes and reported as mean values for 1-hour intervals. Results are reported as the mean ± SEM. Data were analyzed by analysis of variance with repeated measures (BMDP 5V, BMDP Statistical Software Inc., Los Angeles).

When a significant F value ($p < 0.05$) was obtained mean values were compared by paired or unpaired t test with Bonferroni's correction. Some of the hormonal samples could not be processed because of technical difficulty. Data on the neuropathologic findings will be reported separately.

Results

Maternal blood gases and pH. The oxygen concentration in the perspex chamber was decreased from 21.0% ± 0.3% during the normoxemic control period to 9.7% ± 0.5% when measured 1 hour after the initiation of the induced hypoxemia. At the end of the 8-hour hypoxia period the oxygen concentration measured 8.7% ± 0.5%. The animals, although hyperventilating, appeared well and continued to feed and take water. For the control group the oxygen concentration in the perspex chamber was 22.5% ± 0.4% during the control period with little measured change thereafter. The maternal P_{O_2} fell significantly in the hypoxia group from 122 ± 3 to 61 ± 6 mm Hg after 1 hour, with a further fall to 46 ± 3 mm Hg by the end of the sustained hypoxemia (Table I). In spite of the carbon dioxide added to the perspex chamber, a relative respiratory alkalosis was evident through the 8 hours of induced hypoxia. In the control group there was little change in the maternal blood gases and pH throughout the period of study.

Fetal blood gases, pH, and oxygen concentrations. The mean gestational age at the time of study was 90.8 days for the control group and 89.6 days for the hypoxia group. The mean fetal weight at the time of animal death measured 980 gm and 932 gm, respectively, for the two groups. All fetuses survived through 40 hours of recovery. Two-way analysis of variance indicated a significant effect of both time and induced hypoxemia on fetal blood gases, pH, and oxygen concentrations (Table II, Fig. 1). Fetal arterial P_{O_2} decreased from 26.6 ± 1.1 mm Hg during the normoxemic control period to 17.3 ± 1.3 mm Hg at 1 hour, with a further decrease at 8 hours to 14.8 ± 1.0 mm Hg. There was a small but significant fall in fetal arterial P_{CO_2} likely caused by maternal hyperventilation because maternal arterial P_{CO_2} decreased a similar amount. Fetal arterial pH fell from 7.34 ± 0.01 during the normoxemic control period to 7.23 ± 0.03 8 hours after the induced hypoxemia; this fall can be attributed entirely to a developing metabolic acidosis, as indicated by the associated change in base excess and arterial lactate values. Fetal arterial oxygen content and oxygen saturation decreased in a manner similar to that of arterial P_{O_2} and hemoglobin values were little changed. All these measurements returned to control levels 24 hours after the induced hypoxemia. In the control group there was no significant change in any of these arterial blood measurements.

Fetal glucose and lactate concentrations. Two-way analysis of variance demonstrated a significant effect of both time and hypoxemia on lactate concentrations, but not on glucose concentrations (Table II). Fetal lactate concentration increased from 1.1 ± 0.1 mmol/L during the normoxemic control period to 9.6 ± 1.4 mmol/L 8 hours after the onset of induced hypoxemia, then decreased to 1.4 ± 0.2 mmol/L 24 hours after the sustained hypoxemia. In the control group fetal arterial glucose and lactate measured 1.1 ± 0.1 and 1.1 ± 0.2 mmol/L, respectively, with no change during the study period.

Fetal hormonal measurements. Mean fetal plasma corticotropin showed a variable response to the 8 hours of induced hypoxia, increasing fourfold or greater in four of the animals in which measurements were obtained, but with little change in the other three animals (Table III). Plasma cortisol values likewise were variably changed, increasing threefold or greater in three of the four animals in which corticotropin also increased, but

with little change in the remaining animals. None of these changes were statistically significant on two-way analysis of variance with that of the control group. Maternal plasma corticotropin and cortisol showed no significant change, averaging 44 ± 5 pg/ml and 5.3 ± 0.4 ng/ml, respectively, for the hypoxia group animals and 42 ± 2 pg/ml and 5.3 ± 0.6 ng/ml, respectively, for the control group animals throughout the period of study.

Mean fetal plasma norepinephrine was significantly increased by 8 hours of induced hypoxemia, with a subsequent return to control values when measured 24 hours after the sustained hypoxemia ($p < 0.05$) (Table III). Although fetal plasma epinephrine values increased in each of the animals over the 8 hours of sustained hypoxemia, this did not reach significance because of the limited number of samples and variable increase noted. Maternal plasma norepinephrine and epinephrine both showed a variable response but without significant change, averaging 386 ± 111 pg/ml and 69 ± 14 pg/ml, respectively, throughout the period of study.

Fetal cardiovascular and biophysical activity measurements. In the hypoxia group mean fetal heart rate increased significantly from 196 ± 3 beats/min during the last hour of the normoxemic control period to 217 ± 6 beats/min over the first 2 hours of induced hypoxia, ($p < 0.05$) then returned to 208 ± 7 beats/min by 8 hours of sustained hypoxia (Fig. 2). Fetal mean arterial blood pressure was 34 ± 2 mm Hg during the last hour of the normoxemic control period and did not change significantly during the period of induced hypoxia. In the control group mean fetal heart rate and blood pressure were 199 ± 3 beats/min and 33 ± 1 mm Hg, respectively, during the last hour of the control period and showed no significant change throughout the period of study.

Satisfactory measurement of breathing movements, nuchal muscle activity, and electroocular activity were obtained from 12 studies (7 for the hypoxia group, 5 for the control group). Fig. 3 demonstrates a typical chart recording showing that fetal biophysical activity changed little during the 8 hours of induced hypoxemia. The incidence of fetal breathing movements was 20.5% ± 0.6% during the 72 hours of total recording for the control group; this incidence was similar to that during the 24 hours of normoxemic control for the hypoxia group (23.7% ± 1.4%) (Fig. 4). Two-way analysis of variance indicated no effect of induced hypoxia on fetal breathing movements, although a small drop was noted during the first 8 hours of recovery; 11.6% ± 3.3% and 18.7% ± 1.8% for the hypoxic and control groups, respectively. The incidence of nuchal muscle activity was 69.9% ± 1.4% of the time during the 72 hours of total recording in the control group, which was not different from the incidence of nuchal muscle activity during the 24 hours of normoxemic control for the hypoxia group (65.0% ± 2.1%) (Fig. 4). The incidence of electroocular activity was 81.9% ± 1.0% of the time during the 72 hours of total recording

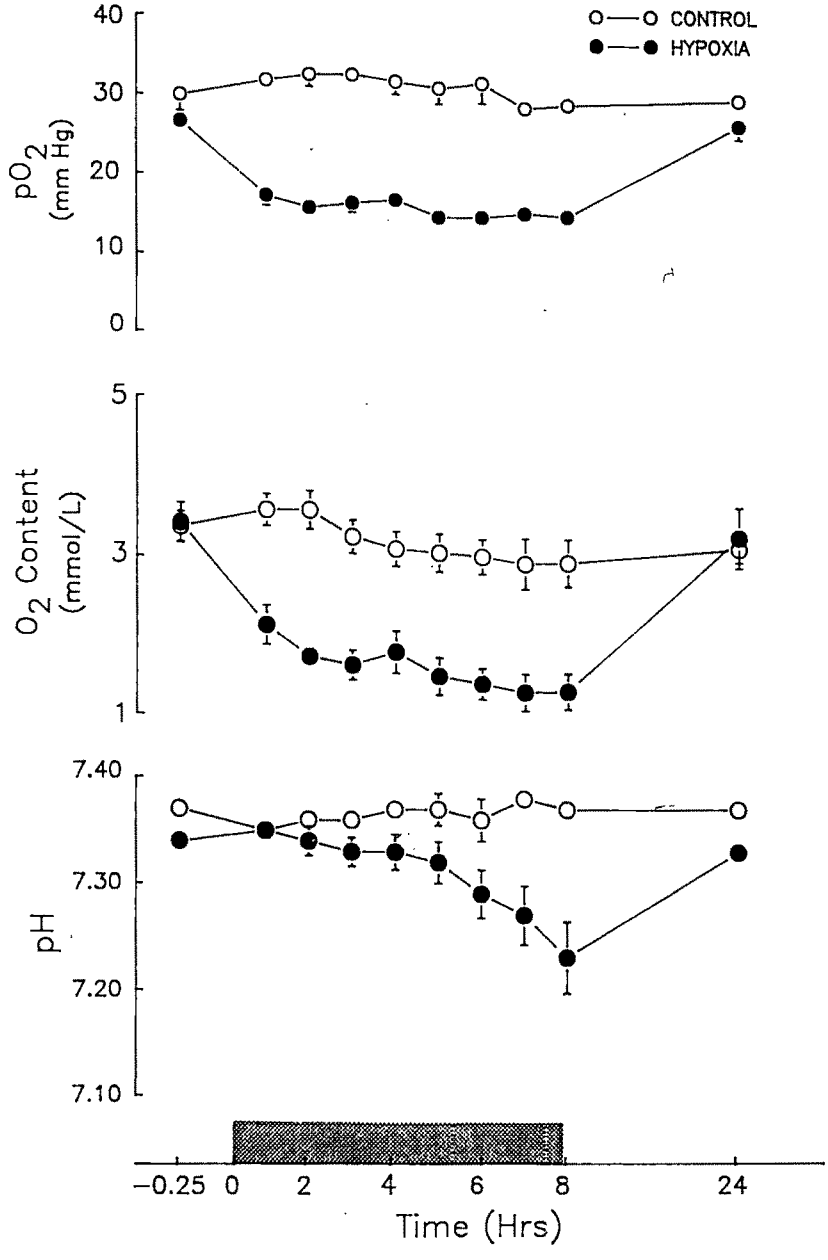

Fig. 1. Fetal carotid arterial Po_2, oxygen content, and pH (mean ± SEM) before, during, and after experiment *(shaded area)*. Induced hypoxemia resulted in significant reduction in fetal arterial Po_2, oxygen content, and pH.

in the control group, which again was not different from the incidence of electroocular activity during the 24 hours of normoxemic control for the hypoxia group (80.9% ± 1.2%) (Fig. 4). Two-way analysis of variance showed no significant effect of the induced hypoxia on either nuchal muscle or electroocular activities.

Comment

The use of the perspex chamber to lower maternal oxygen concentration allowed the animals continued access to food and water with little change in maternal corticotropin and cortisol as previously reported for animals similarly studied near term,[11] thus supporting this technique as a useful means of studying sustained fetal hypoxemia. In our study this was again induced by lowering the oxygen concentration within the chamber to 11% to 8%, with variation within this range to produce a developing metabolic acidosis as monitored by repeated sampling from the fetal carotid artery. The resultant maternal-inspired oxygen concentrations measured at 1 and 8 hours of hypoxia are similar to those we have reported for animals studied near

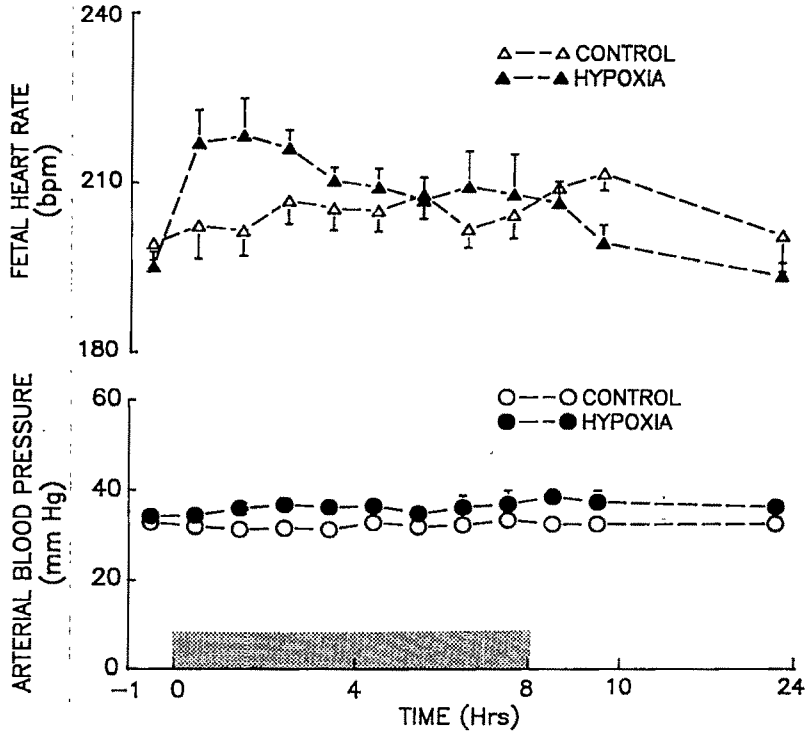

Fig. 2. Fetal heart rate and fetal carotid arterial blood pressure (mean ± SEM) before, during, and after experiment *(shaded area)*. Fetal heart rate and arterial blood pressure showed little hypoxia-induced change, although fetal heart rate increased significantly over first 2 hours of study.

term, as are the maternal blood gas and pH changes.[9]

Fetal arterial Po_2 and oxygen saturation values here measured at 0.6 of gestation under normoxemic control conditions are higher than in late gestation, a finding also noted in other studies of preterm animals[2, 12]; these higher values may relate in part to the relatively high umbilical blood flow in relation to fetal weight at this gestational age.[12] Conversely, fetal hemoglobin concentration tends to be lower in the preterm fetus[12] as also noted in our study. Fetal arterial Po_2 decreased acutely and measured 17.3 mm Hg when sampled at 1 hour of induced hypoxemia, with a further fall to 14.8 mm Hg when measured at 8 hours. Arterial pH fell after the first hour; this fall can be attributed to a developing metabolic acidosis as indicated by the associated change in base excess and arterial lactate values. Fetal arterial oxygen content also fell throughout the period of induced hypoxia, reflecting the drop in arterial Po_2 and the presumed rightward shift in the oxyhemoglobin dissociation curve with the developing metabolic acidosis. Although the imposed decrease in

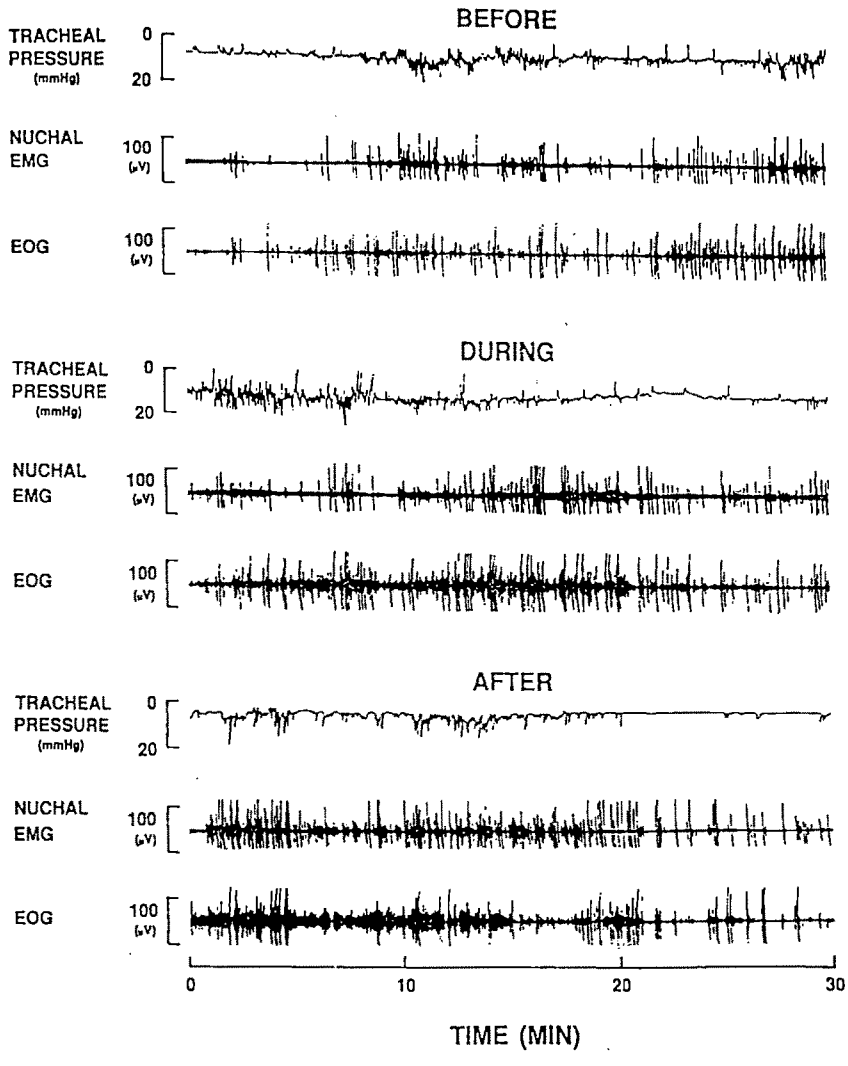

Fig. 3. Tracheal pressure, nuchal muscle electromyogram *(Nuchal EMG)*, and electrooculogram *(EOG)* 2 hours before *(BEFORE)*, 7 hours after *(DURING)*, and 24 hours after *(AFTER)* the onset of induced hypoxia in a sheep fetus at 87 days of gestation.

maternal-inspired oxygen was similar to that of animals we have previously studied near term,[9] neither the fall in fetal oxygenation nor the degree of acidemia was as pronounced. This finding of a developmental change in the fetal blood gas response to a given hypoxic insult was also noted by Clewlow et al.[2]; again, it may relate to the relatively high umbilical blood flow of the preterm fetus and thus an increased oxygen margin of safety. Fetal arterial glucose levels, which increase progressively in response to induced hypoxemia near term,[9] showed little change in our study. This lack of change may relate to the less pronounced fall in fetal oxygenation and thus degree of acidemia or an immaturity of hormonal responses to hypoxia at midgestation, including that of catecholamines as noted in our study and which are known to impact on fetal glucose levels.[13]

Fetal plasma immunoreactive corticotropin concentrations here measured under resting conditions are somewhat higher than we have reported in later gestation.[11] Although our antibody is specific and recognizes corticotropin within the region,[18-24] there may be cross-reactivity with circulating larger molecular-weight species of corticotropin at earlier gestational ages. The variable response of corticotropin to hypoxemia and the overall diminished corticotropin response compared with older fetuses[11] is consistent with reduced pituitary responsiveness to corticotropin-releasing hormone in younger fetuses.[14] At 90 days' gestation the fetal adrenal gland likewise shows decreased responsiveness to corticotropin; it is likely that much of the circulating cortisol in the fetus at this time is derived by transplacental transfer from the mother.[14]

Fetal plasma catecholamine levels here measured under resting conditions are somewhat lower than those reported by Iwamoto et al.[15] in preterm animals at 90

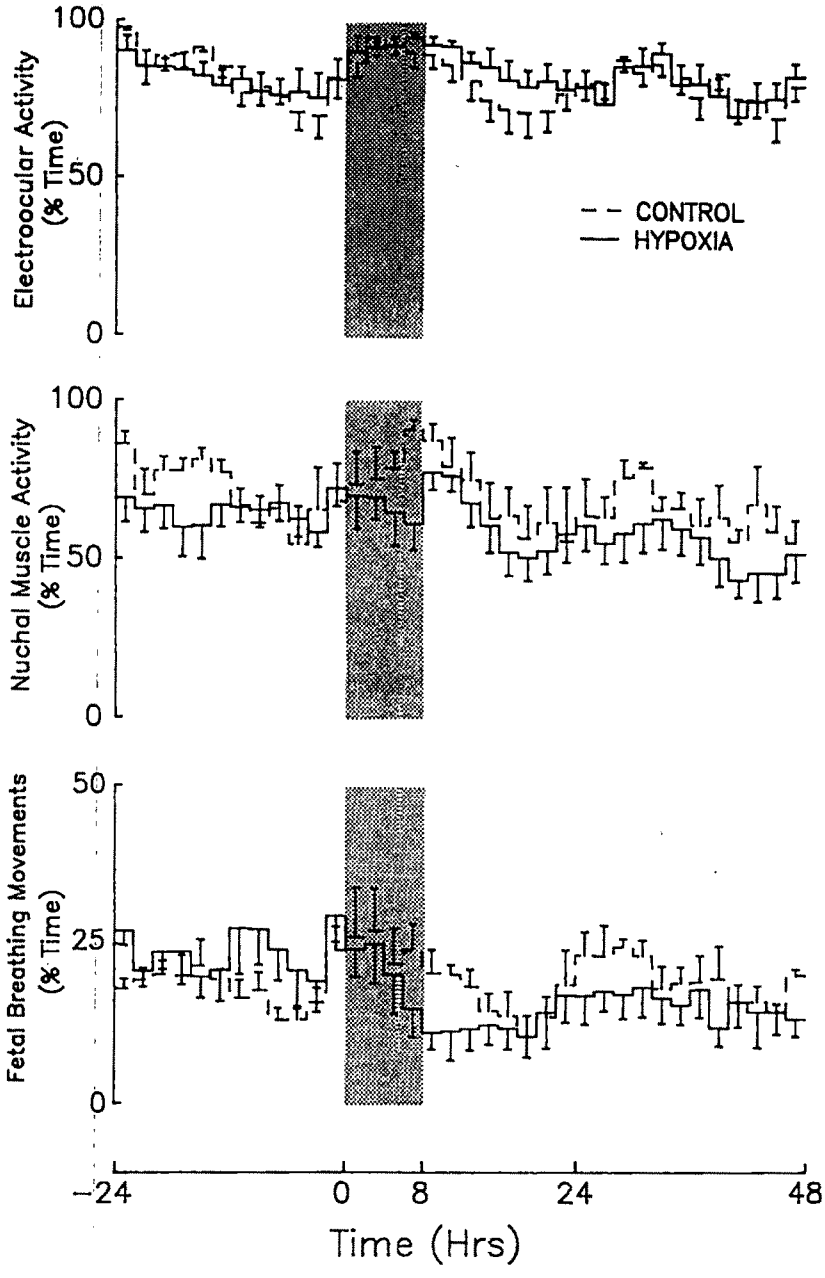

Fig. 4. Incidence of electroocular, nuchal muscle activities, and fetal breathing movements (mean ± SEM) per 2-hour interval plotted continuously from 24 hours before to 48 hours after onset of experiment *(shaded area)*. All variables showed little hypoxia-induced change.

days' gestation, although the levels are similar to those reported by Lewis et al.[16] in slightly older gestational-aged animals. In response to hypoxemia of 8 hours' duration plasma catecholamine levels were increased approximately fourfold, which is greater than the twofold increase noted by Iwamoto et al.,[15] possibly reflecting the different durations of induced hypoxemia, 8 hours versus approximately 1 hour, and the degree of associated metabolic acidemia, arterial pH 7.23 versus 7.32. This hypoxia-related increase in fetal catecholamine levels at 0.6 of gestation is nonetheless of lower magnitude, both from the standpoint of change in absolute levels and percent change from resting levels than in animals similarly studied near term[16] in keeping with an age-dependency as recently reported by Widmark et al.[17]

The mean fetal heart rate reported here is higher, whereas mean arterial blood pressure is lower than in late gestation, findings noted in other studies of preterm animals and attributed to a lower vagal tone and systemic vascular resistance, respectively.[1, 12, 18] In fetuses older than 120 days of gestational age, acute hy-

poxemia increases cholinergic and adrenergic influence on fetal heart rate, but the increase in cholinergic activity initially predominates and heart rate decreases.[19] It has been suggested by Walker et al.[19] that between 109 and 120 days of gestation the influence of cholinergic mechanisms is less than the influence later in gestation such that heart rate shows little change with hypoxemia. In our study with animals at 0.6 of gestation fetal heart rate was in fact initially increased over the first 2 to 3 hours of sustained hypoxemia, returning to control levels thereafter. Boddy et al.[1] have also reported fetal tachycardia in response to induced hypoxemia in preterm fetuses (100 days' gestation), as have Iwamoto et al.[15] and Gleason et al.,[20] which may relate to a predominance of sympathetic cardiac effects over parasympathetic effects at earlier gestational ages. Near term an increase in fetal arterial blood pressure is a well-described cardiovascular response to hypoxemia mediated through aortic chemoreceptor stimulation and α-adrenergic receptor-induced vasoconstriction.[1, 21] In our study fetal arterial blood pressure remained unchanged throughout the period of sustained hypoxemia as previously reported for the preterm fetus with short-term hypoxemia.[1, 15, 20] This developmental difference in the fetal cardiovascular response to hypoxemia may further relate to a relative immaturity of chemoreceptor function and sympathetic innervation of vascular smooth muscle; this difference may also relate to an inadequate rise in circulating vasoactive substances at earlier gestational ages, as noted in our study and as previously reported by Iwamoto et al.[15]

Fetal breathing activity during normoxic control conditions occurred 22% of the time, which is somewhat less than the time measured in animals near term.[1-5] Although comparable data are not available from other studies at midgestation, developmental changes in fetal breathing activity have been described and are clearly dependent on the means by which this activity is measured. Ioffe et al.[22] reported diaphragmatic electromyographic activity of the ovine fetus at 0.5 to 0.6 of gestation to be primarily tonic in nature with a prolonged burst duration, although periods of phasic diaphragmatic activity were also evident. With advancing gestation phasic diaphragmatic activity became more pronounced in keeping with the increased incidence of fetal breathing movements as measured by tracheal pressure change in animals near term. Bowes et al.[23] reported diaphragmatic electromyographic activity to be almost continuous at the earliest gestation studied (108 days' gestation), although no distinction was made between tonic and phasic activity, with increasing apneic modulation thereafter. Clewlow et al.[2] reported similar findings with the addition that changes in tracheal pressure were often small and difficult to detect in early gestation and were greater when the diaphragm and intercostal muscles were active simultaneously. Conversely, Dawes et al.[24] noted breathing movements to be intermittent in fetal lambs from 40 days' gestation onward delivered into a warm saline bath, and the incidence changed little as measured in chronic preparations with tracheal catheterization from 92 days until term. Although measurement of fetal breathing activity by means of tracheal pressure changes will not reflect all neurally and, in turn, muscularly generated activity of respiratory origin, a summation of this activity should be evident pending the attainment of a threshold level to overcome the resistant properties of the airways. It follows that the lower incidence of fetal breathing activity, here measured at 0.6 of gestation, will in turn reflect either a lower output of respiratory muscle activity or an increase in pulmonary resistant properties at this gestational age. Of interest, the incidence of human fetal breathing movements as measured by real-time ultrasonography is also similarly reduced in the preterm fetus occurring ~14% of the time at 24 to 28 weeks' gestation.[25] In contrast to breathing activity, electroocular and nuchal muscle activity were evident during much of the normoxic control period, a finding also reported by Clewlow et al.[2] for animals at 100 days' gestation and before the differentiation of electrocortic activity and the establishment of well-defined behavioral states.

Fetal breathing and electroocular and nuchal muscle activity, here measured at 0.6 of gestation, showed little change in response to sustained hypoxemia with progressive acidemia in contrast to the well-described decrease in such activity near term when fetal oxygenation is sufficiently compromised.[1-6] Although the degree of fetal hypoxemia and resultant acidemia was more severe in animals we have similarly studied near term,[4] fetal breathing and electroocular activity were nonetheless markedly decreased when measured at arterial Po_2 and pH values comparable with those of the present study. In animals studied at a similar age, Ioffe et al.[22] noted fetal breathing as measured by diaphragmatic electromyographic activity to be decreased with short-term hypoxemia; however, this reduction appeared to involve primarily the tonic rather than the phasic component of this activity. With advancing gestational age and increased prominence of phasic diaphragmatic electromyographic activity, a greater decrease in such activity was noted in response to hypoxemia. Likewise, both Clewlow et al.[2] and Bocking and Harding[3] report the hypoxic-related diminution in fetal breathing to be quantitatively less in younger gestational-aged fetuses (~110 to 120 days). A developmental change in the inhibitory response of biophysical activity to fetal hypoxemia is thus suggested; this change may relate to the maturation of inhibitory neural mechanisms given

the evidence for such within the brain stem at least for fetal breathing activity.[26]

For the ovine fetus near term the alterations in biophysical activity in response to induced hypoxemia appear to be a protective mechanism whereby energy expenditure and thus oxygen requirements are decreased.[7,8] This in turn provides a physiologic basis for the use of biophysical parameters in the determination of fetal health; indeed, such usage has become the mainstay in the day-to-day monitoring of the high-risk obstetric patient. In our study biophysical activity has been measured at 0.6 of gestation and close to the limit for extrauterine survival of the human fetus at a comparable gestational age. The lack of hypoxia-related change in biophysical parameters at this time in spite of the attainment of blood gas and pH levels similar to those in studies near term may indicate that the fetus remote from term requires a greater deterioration in metabolic status, possibly close to death, before such change will be evident. If the human situation is comparable this will obviously impact on the success of preterm antenatal assessment protocols. More importantly, although the oxygen margin of safety would appear to be greater for the preterm fetus, the inability to elicit a protective decrease in muscular activity may ultimately impact survival should fetal oxygenation become sufficiently compromised.

We thank Ms. E. Vollick and Mrs. P. McCallum for their technical assistance and Drs. L. Fraher, A. Bocking, and D. Penning for their interest in this work.

Intracellular calcium and the signaling mechanism of luteinizing hormone–releasing hormone in rat granulosa cells

Jian Wang, PhD,[a,b] Gillian L. Steele, MSc,[a] Kenneth G. Baimbridge, PhD,[b] Marie R. Rodway, PhD,[a] and Peter C.K. Leung, PhD[a,b]

Vancouver, British Columbia, Canada

OBJECTIVE: The purpose of these studies was to determine the source(s) of the increase in intracellular free calcium in response to luteinizing hormone–releasing hormone in ovarian granulosa cells.

STUDY DESIGN: Rat granulosa cells were cultured and loaded with fura-2-acetoxy-methyl ester, a fluorescent calcium indicator dye, and intracellular free calcium measured by microspectrofluorometry. The source of the luteinizing hormone–releasing hormone induced increase in intracellular Ca^{++} was investigated with various calcium channel blockers (verapamil, diltiazem, and nifedipine), high K^+ buffer, and perifusion with media lacking Ca^{++}.

RESULTS: All three voltage-sensitive calcium channel blockers (10^{-5} mol/L) tested were ineffective in blocking the luteinizing hormone–releasing hormone induced intracellular Ca^{++} increase. Treatment with high K^+ buffer also had no effect. Perifusion with media lacking calcium resulted in a gradual loss of the luteinizing hormone–releasing hormone response, an effect that was accelerated by repeated stimulation with hormone. Transient replacement of extracellular Ca^{++} failed to restore the response but continued perifusion with Ca^{++}-replete media allowed a luteinizing hormone–releasing hormone response 10 minutes later.

CONCLUSIONS: The luteinizing hormone–releasing hormone induced intracellular Ca^{++} increase does not appear to result from the opening of voltage-sensitive or K^+-dependent Ca^{++} channels. To the contrary, this response likely results from the release of Ca^{++}, primarily from intracellular stores. (Am J Obstet Gynecol 1992;167:541-7.)

Key words: Luteinizing hormone–releasing hormone, granulosa cells, calcium

Luteinizing hormone–releasing hormone (LHRH) is believed to directly affect rat ovarian cells[1-5] by stimulating polyphosphoinositide breakdown in the cell membrane.[6, 7] Inositol 1,4,5-trisphosphate (IP_3) is a product of phosphatidylinositol-4,5-bisphosphate (PIP_2) hydrolysis and has been proposed as a mediator for intracellular Ca^{++} mobilization.[8] Additionally, products of polyphosphoinositide metabolism may also be involved in regulating Ca^{++} entry from the extracellular fluid.[9] With the calcium indicator dye fura-2-acetoxy-methyl ester (fura-2AM) LHRH has been shown to increase intracellular Ca^{++} in single rat granulosa cells.[10] The response to LHRH was rapid and transient. However, it was unclear whether the observed increase in intracellular Ca^{++} was the result of increased entry of Ca^{++} across the cell membrane or enhanced Ca^{++} release from intracellular stores. In our study the contributions of intracellular and extracellular source(s) of Ca^{++} in LHRH-induced intracellular Ca^{++} changes were examined.

Material and methods

Animals. Female Sprague-Dawley rats (Charles River, Montreal, Canada) were injected with pregnant mare serum gonadotropin (12 IU subcutaneously, day 23) to stimulate formation of preantral follicles. The rats were killed by cervical dislocation after 48 hours, and the ovaries removed.

Preparation of granulosa cells. Granulosa cells were harvested by puncturing the ovarian follicles with a fine hypodermic needle under a dissecting microscope as previously described.[11] The ovaries were squeezed gently in minimum essential medium supplemented with Eagle's salts, 2 mmol/L L-glutamine, 100 units/ml penicillin, 100 μg/ml streptomycin, and nonessential amino acids (Gibco, Grand Island, N.Y.). The granulosa cells were recovered by centrifugation for 5 minutes at 200*g*. The cells were washed, resuspended in supplemented Minimum Essential Medium, and plated (0.1×10^6 cells/ml) onto uncoated glass coverslips (18 mm diameter) in 6-well culture dishes and incubated

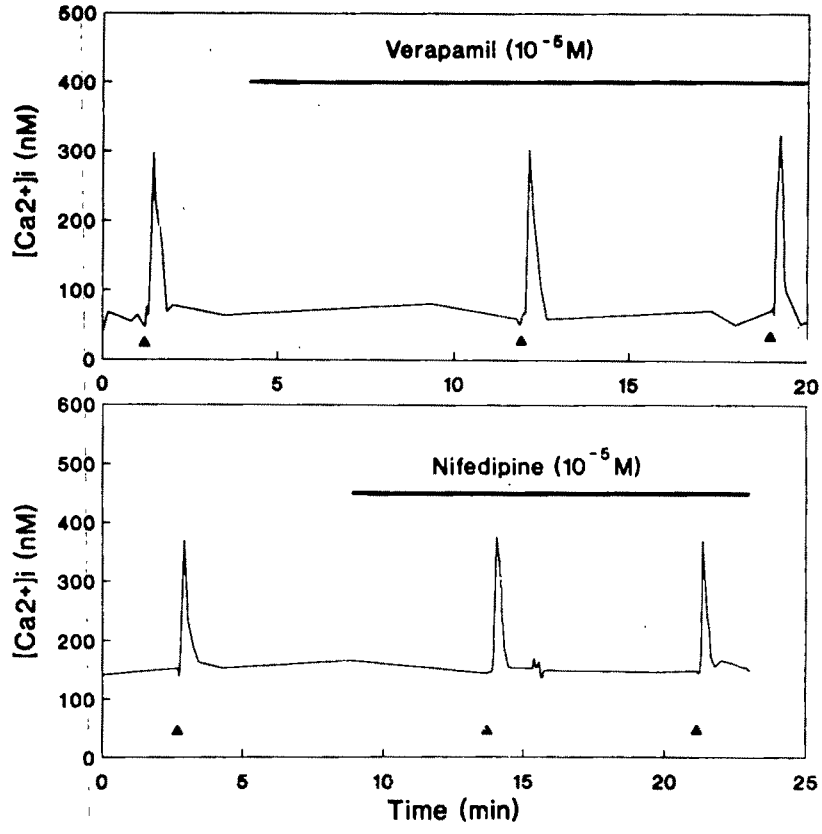

Fig. 1. Effect of voltage-sensitive Ca^{++} channel blockers on LHRH-induced intracellular Ca^{++} increase. LHRH was administered at time indicated by *solid arrow*. Verapamil *(upper panel)* and nifedipine *(lower panel)* were perifused during time indicated by *solid bar* (10^{-5} mol/L, n = 10 for each). Similarly, diltiazem (10^{-5} mol/L, n = 10) had no effect on the intracellular Ca^{++} response to 10^{-6} mol/L LHRH (results not shown).

in supplemented Minimum Essential Medium containing 5% fetal bovine serum. After 48 hours' incubation at 37° C in an atmosphere of 5% carbon dioxide in air, cells were loaded with fura-2AM (Molecular Probes Inc., Eugene, Ore.) as described previously.[10-12]

Fluorescence measurement and calculation of cytosolic calcium. Fluorescence measurement and calculation of cytosolic calcium were reported previously.[10, 12] In brief, individual coverslips were mounted in a laminar flow-through chamber (volume = 350 μl). The chamber was mounted onto the stage of a Zeiss Jenalumar microscope equipped for epifluorescence. The light, from a 200 W mercury arc lamp, first passed through one of two differential interference filters (350 or 380 nm, band widths = 10 nm) that could be rotated by a computer-controlled stepping motor. The light then passed through a 410 nm dichroic mirror, a 100× apochromat oil immersion lens (numerical aperture = 1.4), and an adjustable diaphragm, reducing the light intensity. A field diaphragm was used to reduce the area of illumination to the size of a single granulosa cell. All fluorescent light passed back through the dichroic mirror and a 450 nm band pass filter to reduce background fluorescence. The emitted fluorescence resulting from excitation at 350 nm or 380 nm was deflected either to the eyepiece or to a camera port in which was mounted a photomultiplier tube used to convert the fluorescence into DC voltage. The voltage was converted to a digital form and measurements of fluorescence ratios, corrected for background, were obtained on a 1.8- or 5-second time base.

The method for calculating intracellular Ca^{++} has been reported.[13] A calibration method with the same granulosa cells as described in a previous study[10] was used. An increase of more than 50 nmol/L in intracellular Ca^{++} was considered to be significant.

Treatment regimens. Hormone treatment was added directly to the chamber in a 250 μl volume. LHRH was consistently treated in a concentration of 10^{-6} mol/L. The cells were perifused continuously with Earle's balanced salt solution (EBSS) (or $-Ca^{++}$ EBSS) at a rate of 2 ml/minute. For the Ca^{++} channel studies, cells were perifused with channel blockers (10^{-5} mol/L) in EBSS or high K^+ buffer (50 mmol/L potassium chloride in Minimum Essential Medium) for 5 minutes before LHRH treatment.

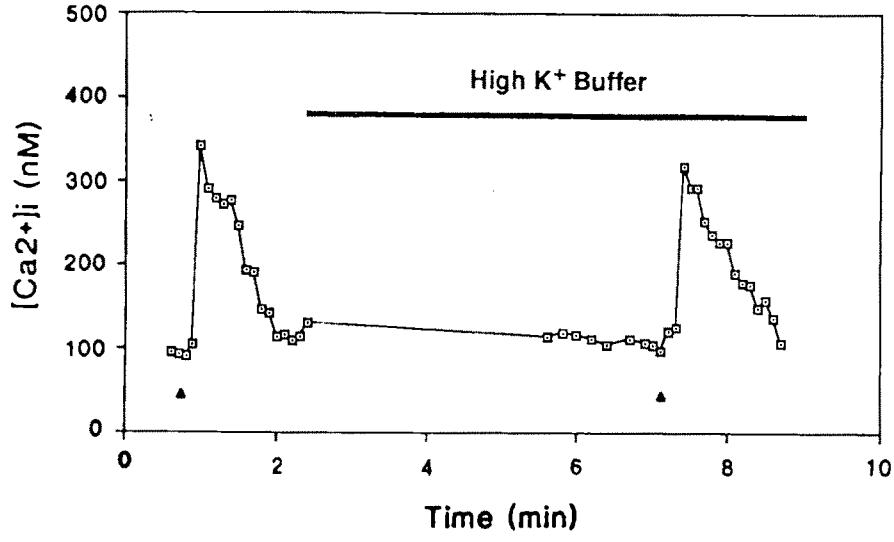

Fig. 2. Effect of high K^+ buffer on LHRH-induced intracellular Ca^{++} increase. Buffer was perifused for the period indicated by *solid bar*. This representative recording illustrates continued responsiveness of cell to LHRH (10^{-6} mol/L) in presence of high K^+ (n = 9). Note expanded scale compared with other Ca^{++} transient recordings.

Reagents. Pregnant mare serum gonadotropin was obtained from the National Institute of Diabetes, Digestive and Kidney Disease and the National Hormone and Pituitary Program (University of Maryland, School of Medicine). LHRH, Ca^{++} channel blockers, and all other reagents were obtained from Sigma (St. Louis).

Results

LHRH-induced transient increase in cytosolic calcium. Two hundred eleven rat granulosa cells from 25 different preparations were treated with LHRH (10^{-6} mol/L). The average resting level of intracellular Ca^{++} in these cells was 98.5 ± 4.8 nmol/L and intracellular Ca^{++} increased by an average of 3.9-fold in the 136 (64%) cells that responded to LHRH. Similar observations have been reported previously.[10]

Effect of calcium channel blockers on LHRH-induced increase in intracellular Ca^{++}. Calcium channel blockers of voltage-sensitive Ca^{++} channels were used in our study to examine the possible involvement of extracellular Ca^{++}. Verapamil (phenylalkylamine-type calcium channel blocker), nifedipine (dihydropyridine-type blocker), and diltiazem (benzothiazepine-type blocker) had no effect on the LHRH-induced increase in intracellular Ca^{++} (10^{-5} mol/L, n = 10 for each). Representative recordings are shown in Fig. 1.

Effect of high K^+ buffer on LHRH-induced intracellular Ca^{++} increase. High K^+ buffer was used to investigate a possible involvement of K^+-dependent Ca^{++} channels in the LHRH-induced intracellular Ca^{++} increase. Perifusion of granulosa cells with high K^+ buffer did not affect the resting intracellular Ca^{++} levels (data not shown). Furthermore, perifusion with this buffer for 5 minutes before LHRH treatment did not affect the LHRH-induced intracellular Ca^{++} response observed during perifusion with EBSS (n = 12). A representative recording of a single granulosa cell is shown in Fig. 2. The apparent difference compared with other Ca^{++} transient recordings is the result of the expanded scale.

Effect of $-Ca^{++}$ EBSS perifusion on LHRH-induced intracellular Ca^{++} increase. In order to investigate the contribution of extracellular Ca^{++} to the LHRH-induced intracellular Ca^{++} increase, the cells were perifused with $-Ca^{++}$ EBSS. Over a period of 8 to 20 minutes there was a gradual decrease and eventual elimination of the intracellular Ca^{++} response to LHRH (n = 10). Repeated stimulation with LHRH in media lacking Ca^{++} resulted in a more rapid loss of the response (i.e., within 13 minutes; Fig. 3, *upper panel*). However, after a recovery period the same cell was able to respond (albeit in an attenuated fashion) to LHRH after 13 minutes of $-Ca^{++}$ EBSS perifusion provided it was not treated with LHRH during this time (Fig. 3, *lower panel*).

After 7 minutes' perifusion with EBSS containing 1.8 mmol/L Ca^{++} the cells again showed a rapid and transient elevation of intracellular Ca^{++} in response to 10^{-6} mol/L LHRH (Fig. 4). A similar response was observed in 14 individual cells.

Effect of transient addition of Ca^{++} to LHRH-induced intracellular Ca^{++} increase. After the initiation of $-Ca^{++}$ EBSS perifusion LHRH-induced intracellular Ca^{++} changes were decreased gradually and eventually abolished at 1, 6, and 16 minutes, respectively (Fig. 5). Subsequently the cells were exposed to four

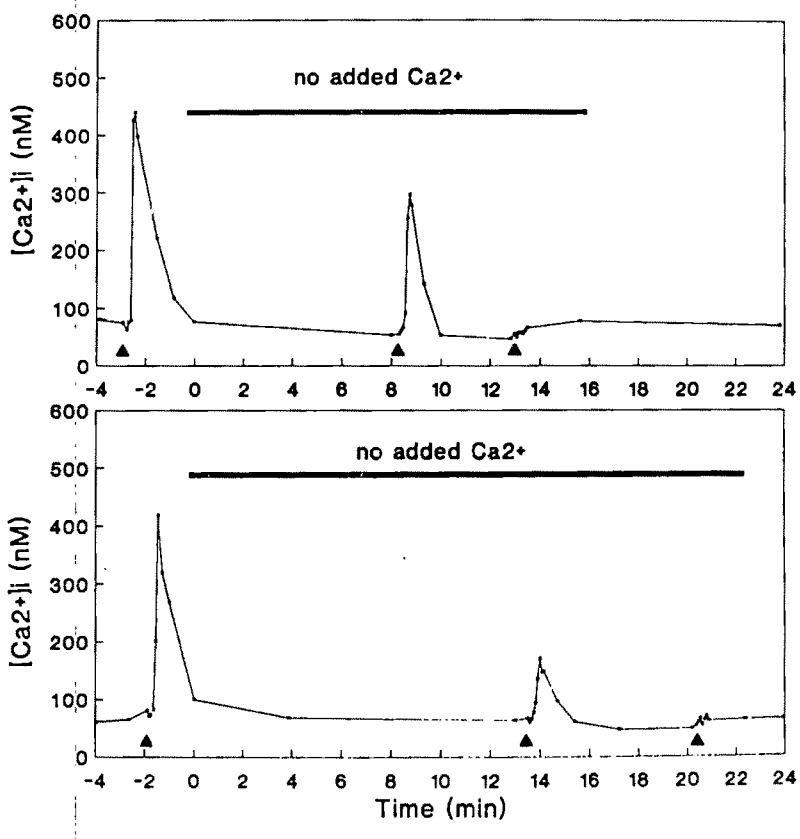

Fig. 3. Effect of $-Ca^{++}$ EBSS perifusion on LHRH-induced intracellular Ca^{++} increase. $-Ca^{++}$ EBSS was perifused for period indicated by *solid bar*. *Upper panel*, cell shows decreased LHRH response at 8 minutes, with complete loss of response at 13 minutes. *Lower panel*, same cell was tested after 10-minute recovery period in normal media. Response to 10^{-6} mol/L LHRH could be elicited after 13 minutes of $-Ca^{++}$ EBSS perifusion provided there was not prior LHRH treatment during this time.

successive injections of LHRH (10^{-6} mol/L) in EBSS containing 2 mmol/L, 5 mmol/L, 10 mmol/L, or 20 mmol/L calcium chloride, respectively. Perifusion of 1 ml of each of these solutions allowed the extracellular calcium concentration to be transiently restored or even increased. There was no observed effect of any of the four treatments on intracellular Ca^{++} ($n = 8$). However, continued perifusion with EBSS containing 1.8 mmol/L Ca^{++} for 10 minutes restored the intracellular Ca^{++} response to LHRH in the same granulosa cell (Fig. 5).

Comment

Previous studies have demonstrated that LHRH stimulates polyphosphoinositide hydrolysis in ovarian granulosa cells.[6,7] Inositol 1,4,5-triphosphate generated during polyphosphoinositide breakdown has been proposed as a mediator of intracellular Ca^{++} mobilization.[8] Inositol lipid metabolism is also believed to be involved in the regulation of Ca^{++} entry from the external environment by inositol 1,3,4,5-triphosphate.[9] In the ovary increases in intracellular Ca^{++} may serve to modulate the stimulatory or inhibitory effects of LHRH on progesterone and prostaglandin E_2 accumulation.[14-16] Calcium is required for the inhibitory action of LHRH on cyclic adenosine monophosphate and steroid production during long-term incubation of ovarian cells.[17,18] In addition, the presence of a Ca^{++} chelator, ethylenediaminetetraacetic acid, in the culture medium can diminish the LHRH-induced increase in progesterone production in short-term cultures.[19,20]

In our study the calcium-sensitive fluorescent indicator fura-2AM was used to study the effect of LHRH on intracellular Ca^{++} in single rat granulosa cells. LHRH caused rapid and transient increases in intracellular Ca^{++}, confirming our previous observation that Ca^{++} participates in the action of LHRH on rat granulosa cells.[10] Again, there did not appear to be a sustained phase of elevation after the transient increase, unlike the intracellular Ca^{++} response to gonadotropin-releasing hormone in pituitary gonadotrophs.[21] However, the precise source of Ca^{++} that contributes to this increase remained to be resolved.

The possible contribution of extracellular Ca^{++} to

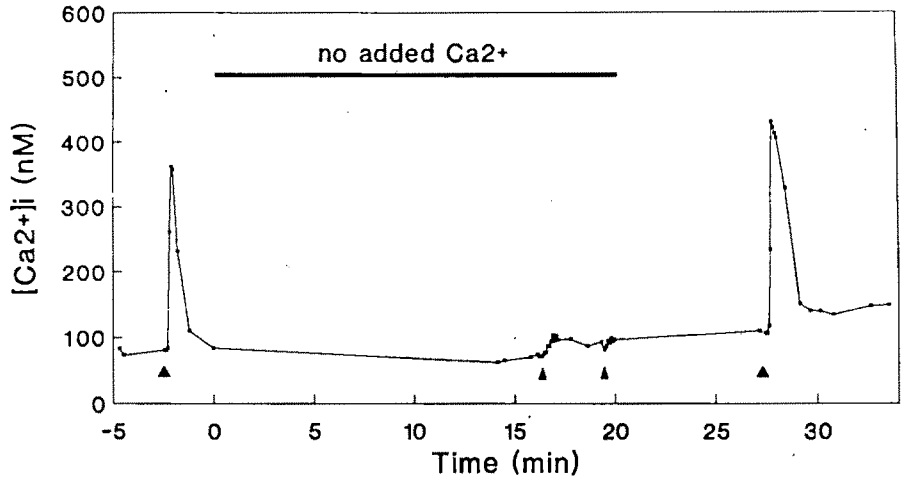

Fig. 4. Replacement of $-Ca^{++}$ EBSS with Ca^{++}-replete media restores LHRH response. Perifusion of $-Ca^{++}$ EBSS was initiated at time zero for period indicated by *solid bar*. Two sequential injections of LHRH (10^{-6} mol/L) 15 minutes later did not generate intracellular Ca^{++} response. However, replacement of 1.8 mmol/L Ca^{++} in perifusion media restored ability of cell to respond to LHRH. Similar results were obtained with 15 cells from seven experiments.

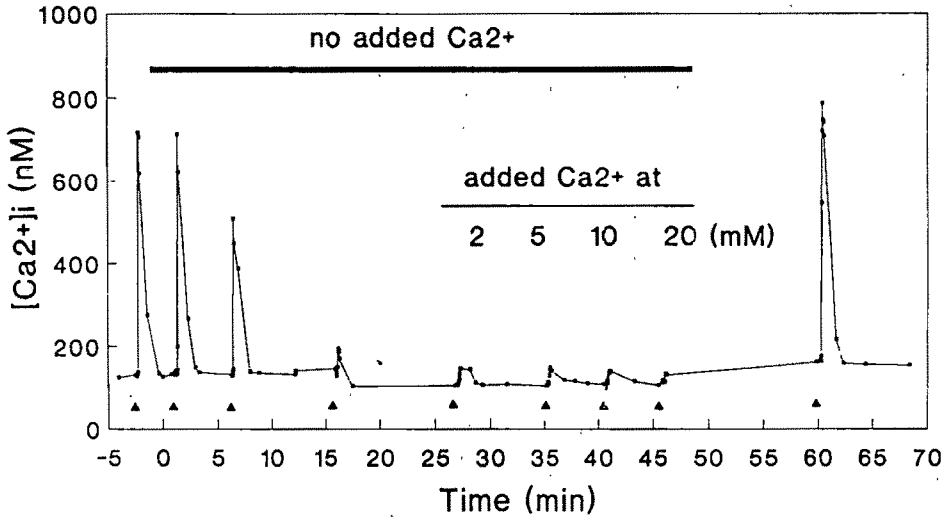

Fig. 5. Transient addition of Ca^{++} to $-Ca^{++}$ EBSS–perifused granulosa cells. Cells which had lost their intracellular Ca^{++} response to LHRH (10^{-6} mol/L) in presence of $-Ca^{++}$ EBSS did not regain responsiveness by transient addition of 2, 5, 10, or 20 mmol/L Ca^{++}. However, continued perifusion with 1.8 mmol/L Ca^{++} in EBSS allowed LHRH response 10 minutes later. $-Ca^{++}$ EBSS perifusion was for period indicated by *solid bar*. Similar observations were made in eight cells from five experiments.

the LHRH-induced intracellular Ca^{++} increase was examined with specific calcium channel blockers. Verapamil, diltiazem, and nifedipine have been shown to effectively block calcium channels at 10^{-5} mol/L.[22-24] However, these blockers had no effect on the LHRH response, suggesting that the hormone does not affect voltage-dependent Ca^{++} channels in granulosa cells. Alternatively, these channels may not exist in this cell type. The presence of both L and T Ca^{++} channels has been demonstrated in chicken granulosa cells with the technique of patch clamping.[25] The L channel was completely inhibited by 16.7 μmol/L nifedipine (dihydropyridine-type calcium channel blocker). It is known that the dihydropyridine type of Ca^{++} channel blocker prevents movement of Ca^{++} through L-type voltage-dependent channels, but is not effective on N- or T-type voltage-dependent channels or on receptor-operated channels.[26] Because verapamil, nifedipine, and diltiazem only influence L-type channels, we cannot dismiss the possibility of LHRH influencing other types of volt-

age-dependent Ca^{++} channels. However, to our knowledge these voltage-dependent channels have not been reported to exist in rat granulosa cells.

The possibility of LHRH effects on K^+-dependent Ca^{++} channels was studied with high K^+ buffer. The lack of effect of high K^+ buffer on the LHRH-induced response indicates that these channels do not contribute to the increase in intracellular Ca^{++}. Furthermore, perifusion with high K^+ buffer did not affect the resting intracellular Ca^{++} level, suggesting that these channels may not even exist in rat granulosa cells.

The involvement of extracellular Ca^{++} in the transient LHRH-induced intracellular Ca^{++} increase was also investigated with media lacking Ca^{++}. LHRH-induced changes in intracellular Ca^{++} were completely abolished by perifusion of the cells with $-Ca^{++}$ EBSS within 20 minutes. This abolition could have been caused by either the lack of an extracellular Ca^{++} source or a depletion of intracellular Ca^{++}. Support for the latter arises from the observation that complete abolishment of the LHRH-induced intracellular Ca^{++} response was a gradual process. Considering the volume of the cell chamber (350 μl) and the flow rate of the perifusion medium (2 ml/minute), an extracellular Ca^{++}-free condition should have been reached in <5 minutes. However, the response to LHRH was still observed (albeit attenuated) for 8 to 14 minutes after perifusion with $-Ca^{++}$ EBSS. Repeated stimulation with LHRH (10^{-6} mol/L) in the same cell resulted in a more rapid loss of the intracellular Ca^{++} response to this hormone under low Ca^{++} conditions (Fig. 3). We suggest that LHRH stimulation accelerated the depletion of intracellular Ca^{++} pools and that the loss of response to LHRH was the result of this effect. Indeed, intracellular stores of calcium normally require repeated stimulation in the absence of external Ca^{++} to be depleted.[27] However, prolonged efficient washing in $-Ca^{++}$ EBSS in the absence of hormone stimulation was also apparently effective in depleting intracellular Ca^{++}, which may suggest the presence of a somewhat more labile LHRH-sensitive pool of intracellular Ca^{++}.

Transient restoration of extracellular Ca^{++} during $-Ca^{++}$ EBSS perifusion failed to restore the ability of the cells to respond to LHRH (Fig. 5). Furthermore, after $-Ca^{++}$ EBSS perifusion, continued perifusion with EBSS-containing 1.8 mmol/L Ca^{++} was required for 5 to 10 minutes before the LHRH-induced intracellular Ca^{++} response was fully restored. The present data indicate that the rapid and transient LHRH-induced intracellular Ca^{++} response results primarily from the release of Ca^{++} from intracellular Ca^{++} pools. However, we cannot dismiss the possibility that extracellular Ca^{++} may be required to maintain these pools in a fashion similar to the "capacitative" model previously described by Putney and Takemura.[28, 29] In this respect extracellular Ca^{++} may play an indirect role in the LHRH-induced release of intracellular Ca^{++}.

Many studies have concentrated on the question of which intracellular pool is responsible for intracellular Ca^{++} mobilization. The site at which inositol 1,4,5-triphosphate acts has been shown to be an adenosine triphosphate–dependent, nonmitochondrial Ca^{++} pool, probably the endoplasmic reticulum.[30] Although the present results indicate that the intracellular Ca^{++} pools are probably responsible for the rapid LHRH-induced increase in intracellular Ca^{++}, the relative importance of the mitochondria and the endoplasmic reticulum in granulosa cell cytosolic Ca^{++} regulation remains uncertain.

Two phases of Ca^{++} mobilization in response to LHRH administration have been seen in pituitary cells.[31-33] The rapid and transient phase has been attributed to Ca^{++} release from intracellular stores, and the latter sustained phase has been attributed to entry of extracellular Ca^{++}.[33-35] We have seen no evidence for this sustained phase in individual rat granulosa cells. However, our observations of the transient intracellular Ca^{++} response to LHRH in the ovarian granulosa cell support the notion of an intracellular source rather than a flux of extracellular Ca^{++} through membrane channels.

In summary, our study shows that LHRH causes a rapid and transient increase in intracellular Ca^{++} in individual rat granulosa cells. Our data suggest that an intracellular pool of calcium is primarily involved in this response. The depletion of this intracellular pool appears to occur simply as a result of prolonged exposure of cells to a medium containing no added calcium. In addition, this depletion can be accelerated by stimulation with LHRH. Finally, our results support the role of LHRH as an autocrine or paracrine mediator in the rat ovary and the role of calcium as a second messenger in the action of LHRH.

Comparative analysis of normal and growth-retarded placentas with phosphorus nuclear magnetic resonance spectroscopy

Helen H. Kay, MD,[a, c] Saralyn R. Hawkins, MD,[a] John D. Gordon, MD,[a] Yuping Wang, MD,[a] Anthony A. Ribeiro, PhD,[c] and Leonard D. Spicer, PhD[b, c]
Durham, North Carolina

OBJECTIVE: Phosphorus 31 magnetic resonance spectroscopy studies were carried out on placentas from normal vaginal and elective cesarean deliveries without antenatal complications and from pregnancies complicated by intrauterine growth retardation of unknown cause to determine differences.
STUDY DESIGN: Perchloric acid extraction was performed on frozen tissue, and quantitative analysis was carried out for well-resolved resonances representing adenosine triphosphate, sugar phosphate, inorganic phosphorus, diphosphoglycerate, glycerophosphorylethanolamine, and glycerophosphorylcholine.
RESULTS: Adenosine triphosphate levels were highest in the growth-retarded group. There were significantly higher levels of sugar phosphate, diphosphoglycerate, and glycerophosphorylcholine in the placentas of the growth-retarded pregnancies compared with those from normal placentas.
CONCLUSION: These differences may represent a response to hypoxia and an increase in the amount of blood in the placenta. The results demonstrate the utility of nuclear magnetic resonance spectroscopy for studying the pathology of abnormal placentas to gain a better understanding of the pathology and represent early steps toward in vivo spectroscopic studies of the placenta. (AM J OBSTET GYNECOL 1992;167:548-53.)

Key words: Phosphorus 31 nuclear magnetic resonance spectroscopy, human placenta, perchloric acid extraction, intrauterine growth retardation

Intrauterine growth retardation (IUGR) is a complication of pregnancy affecting as many as 4% to 7% of all pregnancies.[1] The causes of fetal growth retardation include maternal hypertension, cigarette and other substance abuse, in utero infection, and chromosomal disorders. In many cases, however, a specific cause is never identified. The placenta, which serves many critical functions for the fetus, is an important organ to study in any attempt to understand the cause of idiopathic IUGR.

Very little is known about the role of the placenta in fetal IUGR. Most studies have focused on pathologic and histologic examinations. These investigations, however, tended to be nonspecific because of the many different causes of IUGR.[2] Other studies on animals have reported a decrease in glucose and amino acid transfer to the fetus.[3-5] Few studies, however, have yet focused on a biochemical analysis of placental metabolic function. Such analysis may be particularly informative in cases where the cause is unidentified.

Nuclear magnetic resonance (NMR) spectroscopy offers a unique method for studying placental metabolic function. It is a noninvasive technology that simultaneously monitors naturally occurring molecules in biologic tissue. In a previous report[6] we described the phosphorus 31 magnetic resonance spectra of fresh human placental tissues and perchloric acid–extracted tissue. We also detailed the quantitative analysis of adenosine triphosphate and inorganic phosphorus levels in the placental extracts. In the current study we extend our quantitative analysis to other metabolites easily visible in the phosphorus spectra, such as sugar phosphate, diphosphoglycerate, glycerophosphorylethanolamine, and glycerophosphorylcholine. We have focused our analysis on a comparison of placentas from idiopathic growth-retarded pregnancies and normal pregnancies to gain further insights into the cause of the growth retardation.

Material and methods

Five placentas from pregnancies antenatally identified as complicated by IUGR of unknown cause were obtained at the time of delivery by cesarean section. These were confirmed as growth-retarded placentas by neonatal weights <10th percentile with Brenner's growth curve.[7] The mean birth weight was 1253 ± 207 gm at a mean gestational age of 35.3 ± 0.9 weeks confirmed by ultrasonographic examination before 20 weeks. Thorough chart review and patient interview

revealed no specific cause such as hypertension, cigarette or drug abuse, viral illnesses, or prenatal complications, i.e., bleeding. The mean placental weight was 198 ± 32 gm, and there were no gross abnormalities such as infarctions or abruptio placentae seen on inspection. Small pieces of placental tissue were removed from multiple regions on the maternal side by sharp dissection and placed into liquid nitrogen within 1 minute and stored in a −70° C freezer for later analysis. Similarly, placentas from normal, uncomplicated pregnancies obtained from eight vaginal deliveries and eight elective cesarean section deliveries were harvested and frozen in the same fashion. Placentas in all three groups were obtained in the third trimester.

At the time of extraction the tissue was removed from the freezer and pulverized in liquid nitrogen with a stainless steel Waring blender (Dynamics Corp. of America, New Hartford, Conn.). A perchloric acid extract was performed as previously described.[6] Briefly, a 20 gm sample of finely ground placental tissue was mixed with 20 ml of 1 mol/L perchloric acid that had been precooled to −78° C in dry ice. The perchloric acid–tissue mixture was allowed to warm to approximately −10° C in the ambient air for 15 minutes during which time the metabolites were extracted. The extract was then centrifuged at 40,000*g* at −4° C for 20 minutes to separate the solid fraction from the liquid fraction. The liquid supernatant containing the extracted metabolites was then decanted into a chilled beaker and neutralized to pH 7.0 at 4° C through the dropwise addition of potassium hydroxide. The potassium perchlorate precipitated during neutralization was removed by a second centrifugation step identical to the first, and the supernatant was then passed over a Chelex-100 chelating resin (Sigma Chemical Co., St Louis) to remove divalent cations. The extract was again titrated to neutral pH with diluted perchloric acid, frozen in a vacuum flask (Virtis Co., Gardiner, N.Y.), and lyophilized to dryness. The extract was then resuspended in 5 ml of 40% deuterated water for quantitation of spectra. The extracts were placed in the outer chamber of a coaxial 10 mm NMR tube (Wilmad Glass, Buena, N.J.) with an external reference standard of 25 mmol/L hexachlorocyclotriphosphazene mixed with 31 mmol/L chromium acetylacetonate (Aldrich Chemical Inc., Milwaukee)[8] in an inner coaxial insert. Spectra were obtained with a 21 μsec pulse giving a 70° flip angle, an acquisition period of 1.12 seconds, a relaxation delay of 15 seconds (total pulse recycle time 16.12 seconds), and 160 acquisitions.

When phosphorus nuclei have sufficient time to return to their equilibrium state, i.e., fully relaxed state, their peak intensities are proportional to the concentration of the metabolite present. To assess the consequence of the pulse recycle time (acquisition time of 1.12 seconds plus variable delay) on the extent of nuclear relaxation, spectra were obtained at recycle times of 6.12, 11.12, 16.12, 21.12, 31.12, and 61.12 seconds. The hexachlorocyclotriphosphazene and β-adenosine triphosphate resonances are fully relaxed under conditions of our "standard" 16.12-second recycle time.[6] The sugar phosphate, inorganic phosphate, glycerophosphorylethanolamine, and glycerophosphorylcholine resonances, respectively, return to 93.7%, 97.4%, 95.1%, and 98.6% of their equilibrium states at the 16.12-second recycle time. The following "saturation correction factors" are then used to correct the integrated intensities of the signals obtained at 16.12 seconds: adenosine triphosphate 1.00, hexachlorocyclotriphosphazene 1.00; sugar phosphate 1.07, inorganic phosphate 1.03; glycerophosphorylcholine 1.05, and glycerophosphorylethanolamine 1.01 before calculation of metabolite concentrations.

The quantitative analysis is previously reported.[6] Metabolite quantitation was performed with the external reference standard of hexachlorocyclotriphosphazene and chromium acetylacetonate as a spin relaxation agent (Aldrich) in a coaxial capillary system. In brief, the integrated peak area of a phosphorus resonance was divided by the integrated peak area of the hexachlorocyclotriphosphazene reference signal. The ratio for the β-adenosine triphosphate resonance is then used to quantitate the adenosine triphosphate metabolite present with a calibration curve previously constructed for varying known concentrations of adenosine triphosphate. The adenosine triphosphate levels and the β-adenosine triphosphate/hexachlorocyclotriphosphazene ratio are related by the equation $Y = 0.035 + 0.088X$. After calculation of the concentration of adenosine triphosphate, the remaining peak ratios and their corresponding saturation correction factors were then used to determine the final concentration of the other metabolites.

All spectra were obtained on a 300 MHz NMR spectrometer (model GN-300 WB General Electric, Fremont, Calif.) interfaced with a wide-bore superconducting magnet (89 mm bore, 7.0 tesla field) in the Duke Magnetic Resonance Spectroscopy Center. A standard 20 mm broad band probe (General Electric) tuned to 121.4 MHz was used for ^{31}P spectroscopy. Spectroscopic data were collected at the ambient operating probe temperature (approximately 22° C) without temperature regulation. To avoid radiofrequency heating effects on the tissue and extracts, no proton decoupling was used. ^{31}P chemical shifts are referenced to phosphocreatine at 0.00 parts/million.

Statistical analysis was accomplished with a Statgraphics program (Statistical Graphics Corporation, STSC, Rockville, Md.). The means and standard deviation of each metabolite were calculated for the three

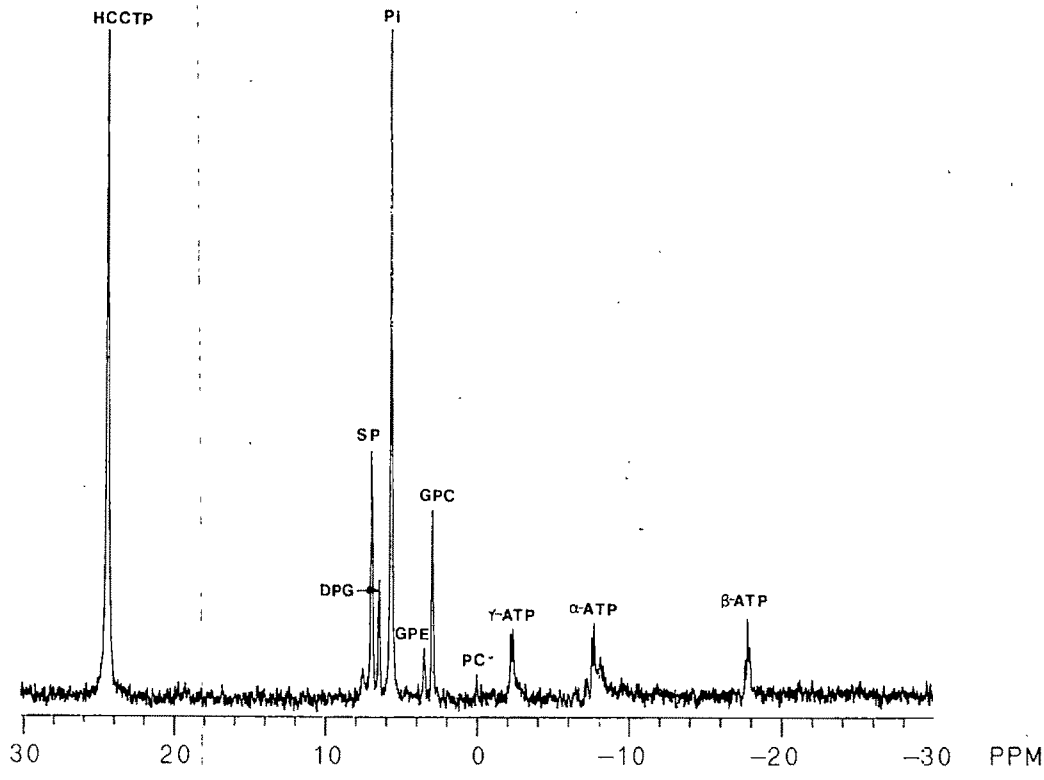

Fig. 1. Phosphorus NMR spectrum of perchloric acid–extracted placental tissue from normal vaginal delivery. Note resonances for external reference standard hexachlorocyclotriphosphazene *(HCCTP)*, diphosphoglycerate *(DPG)*, sugar phosphate *(SP)*, inorganic phosphate *(Pi)*, glycerophosphorylethanolamine *(GPE)*, glycerophosphorylcholine *(GPC)*, phosphocreatine *(PCr)*, and adenosine triphosphate *(ATP)*.

groups (vaginal delivery, cesarean section, and growth retardation). A one-way analysis of variance was performed to determine the presence of a statistical difference among the means of the three groups. A multiple-range analysis or a *t* test was performed to determine specific differences among each of the three groups.

Results

Fig. 1 shows the phosphorus spectrum from a perchloric acid extract of a normal placenta. Of note are the distinct and well resolved resonances for hexachlorocyclotriphosphazene, sugar phosphate, diphosphoglycerate, inorganic phosphorus, glycerophosphorylethanolamine, glycerophosphorylcholine, and the three phosphorus nuclei of adenosine triphosphate. Note that there is very little phosphocreatine at 0 parts/million, and there is a large amount of inorganic phosphorus.

Table I lists the placental metabolite concentrations determined by ^{31}P NMR for vaginal-delivery placentas, cesarean-section placentas and growth-retarded placentas delivered by cesarean section. The table specifically lists the mean concentration and standard deviation for each of the metabolites of the three placenta groups. The mean concentrations of the phosphorus metabolites are highest in the IUGR group, by almost a factor of two compared with the vaginal and cesarean section groups, except for inorganic phosphorus. There are no statistically significant differences among the metabolites between the vaginal and cesarean section placentas. However, there are statistically significant differences among the adenosine triphosphate, sugar phosphate, diphosphoglycerate, and glycerophosphorylcholine levels between the growth-retarded placentas and those from normal vaginal and cesarean section deliveries.

Comment

The current study is a comparative analysis of placentas from normal and abnormal pregnancies with phosphorus NMR spectroscopy. Our findings suggest that NMR spectroscopy, with its ability to simultaneously display the levels of several metabolites, can be extremely useful for in vitro and in vivo biochemical analysis. In this study the NMR analysis yields further insights into placental metabolism. Human in vivo NMR studies in diagnostic medicine are currently focused on ischemic brain injury, muscle dystrophy, and tumor response to chemotherapy.[9] With continued de-

velopments in technology, detailed analysis may someday be feasible for in vivo spectroscopic studies of the human placenta.

Our current report focuses on differences between spectra from tissue extracted with perchloric acid both for the increased resolution available to identify biochemical change and with the expectation that these differences, once established, may be visible in whole placental tissue. It is an important first step to characterize the NMR spectra of human placental extracts to facilitate the analysis of peaks in the spectra from gross tissue for relevant biochemical and diagnostic studies in the future. Our previous preliminary studies on gross placental tissue[6] demonstrated obvious resonances for sugar phosphate, inorganic phosphorus and adenosine triphosphate. The diphosphoglycerate, glycerophosphorylethanolamine, and glycerophosphorylcholine resonances were not well resolved. In addition, phosphocreatine was absent in the spectrum of gross tissue. However, with perchloric acid extraction we were able to confirm the presence of phosphocreatine albeit in very small quantities. We were also able to determine tissue adenosine triphosphate levels from the extracts.

In this study we performed further analyses on the spectra from perchloric acid–extracted tissue. We found different adenosine triphosphate levels in the three groups studied. They were lowest in the vaginal delivery group, although not statistically different from the cesarean section group. The adenosine triphosphate level is highest in the IUGR group with a statistical difference from the vaginal delivery group. Bloxam[10] also reported lower levels of adenosine triphosphate in placentas from vaginal deliveries than from placentas from cesarean section. This may, in part, be due to varying amounts of blood within the placentas. Less blood is expected in vaginal delivery placentas because blood is squeezed out of the sinuses during labor and delivery. We have previously found[6] that the blood concentration within the placentas is significant and may account for as much as 30% to 50% of the total amount of adenosine triphosphate seen. Therefore the fact that the highest level was found in the IUGR placentas is interesting and suggests that these placentas may have the largest amount of blood. This is further supported by the fact that diphosphoglycerate, which is a major component of blood, is present at the highest level in the IUGR group and is statistically different from the other two groups. This increase in blood content in the IUGR placentas may represent a compensatory increase in blood flow.

It is also possible that differences in the adenosine triphosphate levels result from varying oxidative phosphorylation requirements within the placentas at the time of delivery. Levels are likely to be lower in the vaginal delivery group because the adenosine triphosphate is used during the process of labor. The increased levels in placentas from growth-retarded pregnancies, on the other hand, could arise from a need to increase oxidative phosphorylation to maintain fetal viability because of possible uterine stresses. Although glycolysis predominates in the placenta,[10] the hypothesis that other aerobic pathways in stressed placentas may produce larger amounts of adenosine triphosphate cannot be excluded. The role of adenosine triphosphate in placental tissue has not yet been totally characterized, although it has been shown to be important in the act of ion transport in placental tissue[11] and its levels have been investigated in preeclamptic placentas.[12, 13] Without knowing the actual contribution of blood in an individual placenta we are unable to determine the true increase in oxidative phosphorylation from the tissue per se. To our knowledge there are no accurate means to determine blood content with our methodology, and other means, such as histologic examination of each placenta to compare the intervillus vascular space with the villus tissue space, are at best estimates of the blood contribution.

The most interesting and particularly remarkable finding in this study is the result that the overall phosphorus metabolite levels not restricted to adenosine triphosphate levels alone are higher in the growth-retarded placentas compared with the normal placentas (Table I). On the basis of our analysis there appear to be statistically significant differences in the metabolites of the growth-retarded placentas compared with the others in all categories, except for inorganic phosphorus and for glycerophosphorylethanolamine, where the concentration difference was close to being statistically significant with a p value of 0.0528. A statistically significant difference in the sugar phosphate levels, which includes such compounds as glucose-6-phosphate and fructose-6-phosphate, could represent enhanced carbohydrate metabolism, through glycolysis, in the growth-retarded placentas. The difference in the diphosphoglycerate levels is striking and, as previously mentioned, may be consistent with a higher amount of blood in the placenta. The differences noted in the glycerophosphorylethanolamine and glycerophosphorylcholine levels suggest a higher level of membrane phospholipid synthesis or turnover, because these are important components in cell membrane phospholipids.[14] A previous study by Noyszewski et al.[15] also reported an increase in the glycerophosphorylcholine peak intensity in growth-retarded placentas compared with normal placentas, although their results were not quantitated and were performed on pieces of fresh, nonextracted placenta bathed in a perfusate. In this current study the higher levels of nucleotide, carbohydrate, and membrane components in the growth-retarded placentas may be important indicators of increased cell damage and repair in these placentas, compared with a normal healthy placenta.

The highest levels of metabolites were found in inorganic phosphorus. Although there was no significant difference among the levels in the three groups, it was the highest in the IUGR group, which may be consistent with increased cellular metabolism because it has been suggested that large amounts of inorganic phosphate may be necessary for enzymatic function.[16]

Although the current results do not necessarily explain the cause of the growth retardation in the pregnancies studied, they do suggest that there may be placental response to hypoxia. Fox[17] and MacLennan et al.[18] have shown that human placental villi and trophoblasts in culture undergo syncytial degeneration and a marked increase in the number of cytotrophoblastic cells when exposed to hypoxic conditions. The higher levels of phosphorus-containing metabolites seen in our IUGR placentas could similarly represent repair and regenerative processes in the placenta in response to hypoxia. In these cases of idiopathic IUGR, hypoxia may exist in the placental bed but may not be recognized clinically. A placental reaction to hypoxia in these idiopathic cases of fetal growth retardation is consistent with other conditions known to be associated with IUGR, such as hypertension or infection, because these conditions can lead to hypoxia in the placental bed. Therapeutic efforts directed at correcting the hypoxia, such as with the use of aspirin to decrease thromboxane production,[19] may be further supported by these findings.

Finally, it should be pointed out that the analyses undertaken in this study could have been carried out with other traditional biochemical tools. However, the NMR spectroscopic analyses offers the distinct advantage of a simultaneous study of all phosphorus-containing metabolites in one spectrum and the prospect for using NMR as an in vivo biochemical probe. Our current spectral results, which demonstrate an overall increase in phosphorus metabolites, have allowed us the insight that clinically unrecognized hypoxia may be one of the underlying causes of idiopathic IUGR.

NMR spectra were obtained at the Duke University NMR spectroscopy center, which is funded by the National Institutes of Health, the National Science Foundation, the North Carolina Biotechnology Center, and Duke University.

Electrocortical activity, electroocular activity, and breathing movements in fetal sheep with prolonged and graded hypoxemia

Bryan S. Richardson, MD, Lesley Carmichael, BSc, Jacobus Homan, BSc, and John E. Patrick, MD

London, Ontario, Canada

OBJECTIVE: Our objective was to determine the effect of a prolonged and graded reduction in fetal arterial oxygen saturation on electrocortical activity and associated biophysical variables.
STUDY DESIGN: Fourteen unanesthetized fetal sheep were studied between 126 and 135 days' gestation with continuous monitoring of electrocortical and electroocular activity and breathing movements, during a 24-hour control period, and subsequently during 4 days of prolonged and graded hypoxemia induced by progressively lowering the maternal inspired oxygen concentration.
RESULTS: Graded reduction in fetal arterial oxygen saturation resulted in little change in arterial pH until close to 30% when metabolic acidemia was apparent. The incidence of low-voltage electrocortical activity, electroocular activity, and breathing movements were marginally decreased with hypoxemia alone; however, a significant decrease was not apparent until associated with the onset of fetal acidemia.
CONCLUSION: Hypoxemia of a chronic nature must approach the level at which acidemia becomes apparent before a marked change in fetal behavioral activity is noted. (Am J Obstet Gynecol 1992;167:553-8.)

Key words: Fetal behavior state, breathing movements, hypoxemia

It is well recognized that the human fetus near term displays a periodicity in behavioral and biophysical parameters with coincidence of such into well-defined behavioral states similar to those described for the human newborn.[1] Cyclic changes in fetal behavioral state and state-related parameters are thus characteristic of the healthy fetus and provide a basis for the biophysical assessment of fetal health.[2] However, although biophysical parameters appear to reflect fetal health at the time of study,[3] their time course for alteration when fetal oxygenation becomes restricted is unknown, which may limit their usefulness in predicting fetal compromise.

Studies with the chronically catheterized fetal lamb with short-term, induced hypoxemia show the incidence of low-voltage electrocortical activity, electroocular activity, and breathing movements to be variably reduced.[4-6] Although further supporting the role of biophysical parameters in the assessment of fetal health,

these studies do not predict the response to a slow and progressive decrease in fetal oxygenation, as might be encountered in the high-risk human pregnancy. To determine the effect of a progressive decrease in fetal oxygenation on behavioral activity, we have therefore studied fetal electrocortical activity as a measure of behavioral state and associated biophysical parameters, including electrooocular activity and breathing movements in the chronically catheterized sheep fetus with prolonged and graded reductions in fetal arterial oxygen saturation.

Material and methods

Surgical procedures. Guidelines for the care and use of animals were followed as established by the Canadian Council on Animal Care and approved by the university. Studies were performed on 14 fetal sheep of mixed breed between 126 and 135 days' gestation (term 147 days). Fetuses were prepared for study at least 3 days before initiation of all experiments. The ewes were anesthetized with 1.0% to 1.5% halothane and 50% oxygen/50% nitrous oxide, and the uterus was exposed and opened through a lower abdominal midline incision. Polyvinyl catheters were placed in the brachiocephalic trunk, the inferior vena cava, and the sagittal sinus, as previously reported.[7] Tracheal and amniotic fluid catheters were also placed as previously described.[7] Electrodes of Teflon-coated stainless steel wire (Cooner, Chatsworth, Calif.) were implanted biparietally on the dura for fetal electroencephalographic recordings and through the lateral orbital ridge of the zygomatic bone of each eye for electrooocular recordings. A reference electrode was placed in the loose connective tissue overlying the occipital bone of the skull. The catheters, containing heparinized saline solution, and wires were exteriorized through the flank of the ewe, and the abdomen was closed in layers. Polyvinyl catheters were then placed in the maternal femoral artery and vein. At the time of surgery, 1 gm of dihydrostreptomycin and 800,000 U of penicillin G were injected intramuscularly into the ewe, and after the uterus was closed 1,000,000 U of penicillin G was injected into both the fetal hind-limb vein and the amniotic cavity. This antibiotic coverage was continued daily for 2 to 3 days. Postoperatively the animals were maintained in individual cages suitable for continuous monitoring, with food and water available.

Physiologic measurements. Each fetal lamb was studied during a 24-hour normoxic control period and subsequently during 4 days of prolonged and graded hypoxemia. Strain gauge manometers (Statham model P-23 ID, Gould, Oxnard, Calif.) and a strip-chart recorder (model 78D, Grass, Quincy, Mass.) were used to record pressures in the trachea, amniotic fluid, and brachiocephalic artery. Mean arterial blood pressure referenced to amniotic fluid pressure was calculated as diastolic plus 0.4 of pulse pressure. Electrical signals were processed with a common mode rejection preamplifier (model 7 P511J, Grass). Fetal heart rate was measured by a cardiotachometer (model 7P44B) triggered from the arterial pulse pressure wave. Fetal electrocortical and electrooocular potentials were displayed directly on the chart recorder passing through a passive band-pass filter, 0.3 to 30 Hz on the preamplifier.

Continuous recordings of electrocortical, electrooocular potentials, tracheal pressure, amniotic fluid pressure, fetal arterial blood pressure, and fetal heart rate were obtained throughout the normoxic control period and the 4 days of induced hypoxemia. During this time the ewe's head was placed in a perspex chamber (volume 4.6 cubic feet) secured within the animals' cage, yet allowing for free access to food and water. Prolonged and graded hypoxemia was induced by progressively lowering the oxygen concentration within the perspex chamber with 1% to 2% carbon dioxide added as monitored by periodic measurement of oxygen and carbon dioxide gas tensions; on day 1 to 18%, day 2 to 16%, day 3 to 12% to 14%, and on day 4 to 10% to 12% with the change in maternal inspired oxygen concentration occurring at approximately 10 AM each day. Total gas flow to the perspex chamber was 40 L/min. Fetal arterial blood was sampled three times each day at ~8 AM, 12 noon, and 3 PM during both the 24-hour control period and the 4 days of induced hypoxia. At 12 noon each day a paired sagittal vein blood sample was also obtained and radionuclide-labeled microspheres were injected into the inferior vena cava for determination of regional organ blood flows.

All blood samples were analyzed for oxygen saturation, hemoglobin, oxygen content, pH, P_{O_2}, and P_{CO_2}. Brachiocephalic artery blood samples at 12 noon each day were also analyzed for corticotropin and cortisol. Fetal blood loss per day was ~4 ml from blood sampling and 4 ml for reference sampling for blood flow determinations. On completion of each daily microsphere injection and subsequent blood sampling, the fetus was transfused with 8 ml maternal blood.

Arterial oxygen saturation and hemoglobin were measured in duplicate by an OSM2 (Radiometer, Copenhagen) hemoximeter, and oxygen content was then calculated with an oxygen capacity of 1.36 ml oxygen/gm hemoglobin[8]. Blood pH, P_{O_2}, and P_{CO_2} were analyzed on an ABL-3 (Radiometer) blood gas analyzer with temperature corrected to 39.5° C. Oxygen and carbon dioxide concentrations within the perspex chamber were also analyzed on an ABL-3 blood gas analyzer.

Data analysis. Although all animals showed a progressive decrease in oxygenation, fetal arterial oxygen saturation values were nonetheless variable, averaging 57.0% ± 2.3% (SEM) on the control day (range 70.4 to 44.2) and with induced hypoxia decreasing to 46.2% ± 3.1% on day 1 (range 63.3 to 27.0), 36.4% ± 3.3% on day 2 (range 55.6 to 18.8),

†$p < 0.05$.

28.9% ± 3.1% on day 3 (range 43.8 to 15.2), and 22.4% ± 2.4% on day 4 (range 29.6 to 12.8). The time course for this decrease was also variable, with only seven of the 14 animals studied through the entire 4 days of induced hypoxemia, because four of the animals showed a developing metabolic acidosis of the third day and three of the animals on the second day of induced hypoxia with the animals put to death that same day. Results obtained have therefore been grouped according to fetal arterial oxygen saturation with a mean value obtained for each animal within a grouping for multiple values. Data are then presented as grouped means ± SEM in relationship to changes in arterial oxygen saturation. Measurements were not obtained from all animals for each oxygen saturation grouping because of experimental variability in the response to induced oxygen concentration changes within the perspex chamber and to intermittent catheter or electrode failure (Tables I and II). Electrocortical activity was assessed by visual analysis into periods of high voltage (100 to 200 μV), low voltage (<50 μV), and intermediate voltage (50 to 100 μV). Fetal breathing movements were defined as repeated negative deflections in tracheal pressure (corrected for amniotic pressure) of >2 mm Hg lasting for >30 seconds. The incidence of electrocortical states, electroocular activity, and fetal breathing movements were determined as a percentage of the recording time evident for the hour before and after each fetal blood sampling with the measured arterial oxygen saturation presumed to be representative of the fetal blood gas status for that time interval. The data reported were examined by nonpaired t test analysis with significance determined with a Bonferroni correction for multiple comparisons. Cerebral metabolic data and the regional blood flow changes will be reported separately as will the corticotropin and cortisol data.

Results

The oxygen concentration in the perspex chamber measured 21.6% ± 0.3% on the control day and with induced hypoxia decreased to 17.6% ± 0.3% on day

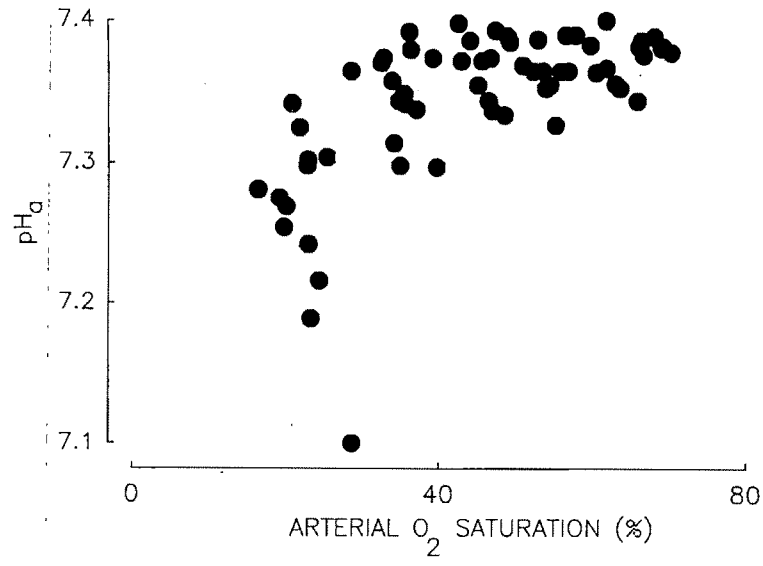

Fig. 1. Grouped and meaned arterial pH values for individual animals plotted in relationship to arterial oxygen saturation. Progressive reduction in fetal oxygenation resulted in little change in arterial pH until arterial oxygen saturation was close to 30%, when onset of metabolic acidosis was evident.

1, 15.7% ± 0.4% on day 2, 12.9% ± 0.5% on day 3, and 11.3% ± 0.5% on day 4. The corresponding carbon dioxide concentrations within the chamber were 0.9% ± 0.1% on the control day and then 1.9% ± 0.1% on day 1, 2.1% ± 0.1% on day 2, 2.5% ± 0.2% on day 3, and 2.9% ± 0.2% on day 4. The animals appeared well and continued to eat and take water. Fetal brachiocephalic arterial blood measurements from the control and study days are shown in Table I, grouped according to induced changes in fetal arterial oxygen saturation. With the graded fall in arterial oxygen saturation, arterial oxygen content and P_{O_2} also fell, whereas arterial P_{CO_2} remained little changed until terminally, when P_{CO_2} did rise in three of the fetuses. Arterial pH also remained little changed until arterial oxygen saturation was between 30% and 40%, when three of the animals began to show a developing metabolic acidosis with a related fall in base excess (Fig. 1). With arterial oxygen saturation <30% all animals except one showed a metabolic acidosis with variable falls in arterial pH noted. Fetal hemoglobin concentration showed no significant change throughout the study.

The incidence of low- and high-voltage electrocortical activity, electroocular activity, and breathing movements from the control and study days are shown in Table II, again grouped according to induced changes in fetal arterial oxygen saturation. The percent time spent in low-voltage electrocortical activity averaged 52.0 ± 1.4, with fetal arterial oxygen saturation >60%, and showed a marginal decrease with oxygen saturation between 30% and 60%. Even with fetal arterial oxygen saturation <30% and a metabolic acidosis now apparent in most animals, low-voltage electrocortical activity, although significantly decreased, was still evident 35.1% ± 4.1% of the time on average. This decrease in the incidence of the low-voltage electrocortical state with graded hypoxemia was mainly due to an increase in the incidence of the high-voltage state, because the percentage time spent in the intermediate-voltage state remained little changed throughout the study and that state was evident approximately 5% of the time on average.

The incidence of electroocular activity, which occurred almost exclusively during the low-voltage electrocortical state, was also marginally decreased with oxygen saturation between 30% and 60%; however, a marked and significant decrease was not noted until arterial saturation was <30%, with electroocular activity now occurring only 17.0% ± 4.2% of the time ($p < 0.01$) (Table II). The incidence of fetal breathing movement, which also occurred almost exclusively during the low-voltage state, was likewise marginally decreased with oxygen saturation between 30% and 60%. However, a marked and significant decrease was again not evident until oxygen saturation was <30% with fetal breathing movements now occurring only 5.7% ± 2.6% of the time ($p < 0.01$) (Table II).

Comment

In this study we have determined the change in fetal behavioral state and associated biophysical parameters in response to a progressive lowering of fetal oxygenation induced by a stepwise decrease in maternal inspired oxygen concentration. The fetal arterial oxygen saturation of all animals measured >50% at some time

point on the control day and showed a subsequent decrease to <30% over the study period. In spite of the progressive decrease in oxygenation, fetal arterial oxygen saturation values were quite variable between animals for a given day of study, as was the time course for the decrease in oxygenation. The data have therefore been analyzed according to the induced change in fetal arterial oxygen saturation rather than the day of study, to better define the relationship of fetal behavioral activity to blood gas change. Although "rate of change effects" will not be apparent with such an analysis, all animals were exposed to the same stepwise decrease in maternal inspired oxygen concentration, resulting in a graded reduction in fetal arterial oxygen saturation with the day-to-day drop no greater than 20% for any of the animals studied.

With the progressive fall in fetal arterial oxygen saturation, arterial oxygen content and partial pressure of oxygen also fell, although to a lesser extent, presumably due to the small increase in hemoglobin concentration over the course of study and the rightward shifting of the oxyhemoglobin dissociation curve with the terminal onset of metabolic acidosis. The graded reduction in arterial oxygen saturation resulted in little change in arterial pH until close to 30%, when a metabolic acidosis was apparent in most animals. At this time arterial oxygen saturation was decreased to approximately half that of normoxic control values, which averaged 62.0% ± 1.1% for all animals. Although fetal oxygen delivery (the product of umbilical venous oxygen content and umbilical blood flow) was not measured, a similar decrease would be anticipated, given the expected linear relationship between oxygen delivery and circulating oxygen levels with this animal model of induced hypoxemia.[9] This finding of metabolic acidemia as graded reductions in arterial saturation approach 50% of normal is thus similar to that with acute reductions in fetal oxygen delivery, where metabolic acidosis is only evident with reductions >50%.[9]

In this study low-voltage electrocortical activity was evident 53% of the time on average with fetal arterial oxygen saturation >60%, which is similar to that previously reported[4-6] for normoxic control study at a comparable gestational age. A marginal decrease in this activity was noted with arterial oxygen saturation between 30% and 60%. Although not statistically significant, this marginal decrease may nonetheless be biologically important and represent a protective mechanism whereby the fetus is able to change to a metabolic state with lower oxidative needs, at least for the brain, as we have previously shown cerebral oxidative metabolism to be increased during the low-voltage electrocortical state.[10] With arterial oxygen saturation <30%, the incidence of the low-voltage electrocortical state was significantly decreased ($p < 0.01$), now occurring 35% of the time, although cycling of low- and high-voltage electrocortical activity was still evident. At this time a metabolic acidosis was noted in all animals except one. The findings of the current study are thus similar to those with short-term reductions in fetal oxygenation,[4-6] where a reduction in the low-voltage electrocortical state is only seen with pronounced hypoxemia, usually in association with metabolic acidemia. However, it is unlikely that acidemia per se resulted in the reduced incidence of the low-voltage electrocortical state, because induced central nervous system acidosis by perfusion of the cerebrospinal fluid results in little change of electrocortical state.[11] It would seem rather that hypoxemia is the stimulus for the alteration in electrocortical state but must be of sufficient degree and therefore in most instances associated with acidosis before a significant change in electrocortical activity is noted, given the cyclic nature of this activity.

The incidence of electroocular activity and breathing movements was also marginally decreased with fetal arterial oxygen saturation between 30% and 60%. This may be accounted for by the decrease in the low-voltage electrocortical state, because the reductions were similar. However, a marked and significant decrease in this biophysical activity was again not evident until arterial oxygen saturation was <30%. At this time electroocular activity was decreased to approximately 40% and breathing movements to approximately 20% of that seen with arterial oxygen saturation >60%. This decrease in the incidence of fetal biophysical activity with pronoucned hypoxemia is considerably greater than that seen for the low-voltage electrocortical state (at approximately 65% of well-oxygenated values), suggesting differing mechanisms for their reduction. Alternatively, the same mechanism causes inhibition of biophysical and low-voltage electrocortical activity but with less effect on the latter. Additionally, fetal breathing movements would appear to be a more sensitive biophysical indicator for pronounced hypoxemia than would electroocular activity, at least under the current study conditions.

Previous studies in the ovine fetus with short-term reductions in oxygenation suggest that hypoxemia alone can result in a significant decrease in both electroocular activity and breathing movements.[6] However, it has become apparent that this decrease in biophysical activity in response to moderate hypoxemia shows adaptation over several hours with a return to normoxic levels in spite of the persistence of the hypoxemic insult.[12, 13] It is thus not surprising in the current study with graded reductions in fetal oxygenation over 3 to 4 days that fetal biophysical activity was only marginally decreased with hypoxemia alone. It would again seem that when hypoxemia is slowly induced it must be pronounced and thus often associated with acidosis before a significant decrease in fetal biophysical activity is noted.

Although the biophysical response to acutely induced hypoxemia has been well studied in the ovine fetus, information is limited on chronic reductions in fetal oxygenation. Worthington et al.[14] have studied the effects of reduction of placental size in sheep with resultant asymmetric intrauterine growth restriction and chronic hypoxemia without acidemia. Of interest, the incidence of fetal breathing movements was decreased to approximately 20%, a value similar to that of the current study with hypoxemia alone. This decrease in fetal breathing activity with induced intrauterine growth retardation was significant but involved 24-hour periods of observation, which would limit the effects of other influencing factors, including the diurnal nature and cyclicity of breathing activity. A progression from decreased fetal breathing activity to prolonged apnea to abnormal breathing activity has also been reported in sheep before death in utero.[15, 16] Although abnormal breathing patterns were usually only seen with associated acidemia, decreased breathing activity or apnea were evident with hypoxemia alone, as in the current study, supporting hypoxemia as the stimulus for the alteration in behavioral activity rather than any associated acidotic change. Of note, abnormal breathing patterns were not observed in the current study, suggesting these to be terminal events of short duration.

With prolonged and graded reductions in oxygenation, the ovine fetus thus demonstrates chronic hypoxemia but with little disturbance in arterial pH until oxygen saturation approaches 30%, when metabolic acidosis becomes apparent. Likewise, the human fetus with intrauterine growth restriction demonstrates variable hypoxemic change[17, 18] but is usually born without significant acidosis.[19, 20] Hypoxemia alone has a marginal effect on fetal behavioral activity that nonetheless may be of biologic significance and represent a protective mechanism whereby metabolic costs (including those of growth) are decreased over time. However, it would appear that hypoxemia of a chronic nature must approach the level at which acidemia becomes apparent before a marked change in fetal behavioral activity is noted. It is thus not surprising that the behavioral activity of the human fetus with intrauterine growth restriction is often reported to be normal and or only marginally changed.[19-21] As such, fetal biophysical assessment should be seen as a marker for moderate to severe hypoxemic change with heightened surveillance required for the extremely high-risk pregnancy, because the time course for biophysical alteration before fetal death may be relatively short.

We thank Ms. E. Vollick and Mrs. P. McCallum for technical assistance and Drs. A. Bocking, R. Gagnon, and R. Natale for their interest in this work.

An immunochemical and immunocytologic study of the increase in myometrial gap junctions (and connexin 43) in rats and humans during pregnancy

Thomas Tabb, MD,[a] Gisela Thilander, VMD,[b] Ashok Grover, PhD,[b] Elliott Hertzberg, PhD,[c] and Robert Garfield, PhD[a]

Galveston, Texas, Hamilton, Ontario, Canada, and Bronx, New York

Myometrial gap junctions are thought to play a necessary role in control of parturition. In this study we evaluated the presence of gap junctions in myometrial tissues with a specific antibody to the gap junction protein, connexin 43, with immunocytochemistry and immunoblots. Immunofluorescence of rat heart showed gap junctions were localized along the intercalated disks, but no change occurred during pregnancy. Fluorescent staining of rat myometria showed punctate staining of gap junctions between muscle cells during term and preterm birth, illustrating the tremendous increase in gap junctions during labor. Similarly, staining of human myometrial tissues was present in specimens from pregnant patients but absent in tissues from nonpregnant women. Immunoblots of myometrial tissues from rat and humans confirmed the existence of high levels of connexin 43 during term and preterm labor in rats and also during late pregnancy in humans. (Am J Obstet Gynecol 1992;167:559-67.)

Key words: Gap junctions, myometrium, uterus, connexins, parturition, smooth muscle

Gap junctions are the structural entities that allow direct cell-to-cell communication between opposing cells in various tissues.[1, 2] Both electrical and metabolic transmission of signals occur through these specialized membrane regions.[3] Contractions of the myometrium and also the heart are dependent on the underlying propagation of action potentials from pacemaker regions.[4-7] Thus the pathways for coupling between individual small muscle cells are extremely important in coordinating contractility.

In the myometrium of animals electron microscopic studies have demonstrated that the gap junctions are infrequent in nonpregnant cycling states and most of gestation.[8] However, at term and in some cases preterm the gap junction numbers and sizes increase to provide the basis for propagation of electric activity and synchronized contractility during labor.[8] Similar studies of human myometria, taken during either cesarean section or hysterectomy, demonstrate comparable changes, although the junctions are much more difficult to quantify by electron microscopy due to the larger sizes of the muscle cells.[8, 9]

Recently several studies have shown that the gap junctions exist as a homologous group of proteins that form the intercellular channels of the gap junction.[10-13] These proteins are expressed in varying amounts in different cell types. In the heart and rat myometrium a 43 kd protein, termed connexin 43, has been identified as the gap junction protein.[12-14] Some studies have used antibodies to connexin 43 in the analysis of gap junctions in rat myometrium after estrogen treatment and during pregnancy.[14, 15] However, no study has shown data from animals delivering at term or preterm when gap junctions as identified by electron microscopy[8] are known to be at their highest levels, and no study has demonstrated connexin 43 levels in the human uterus.

In this paper we used antipeptide antibodies directed to the carboxy terminal domain of the cardiac protein connexin 43 to investigate the expression of this protein in rat heart and myometrium and human myometrium by immunohistochemical and immunoblotting techniques. This study shows that connexin 43 levels are elevated in the rat myometrium during term and preterm birth. In addition, connexin 43 protein is present in human myometrial tissues taken from pregnant patients.

Material and methods

Animals and tissue processing. Wistar rats were used for all the studies. Nonpregnant animals at in-

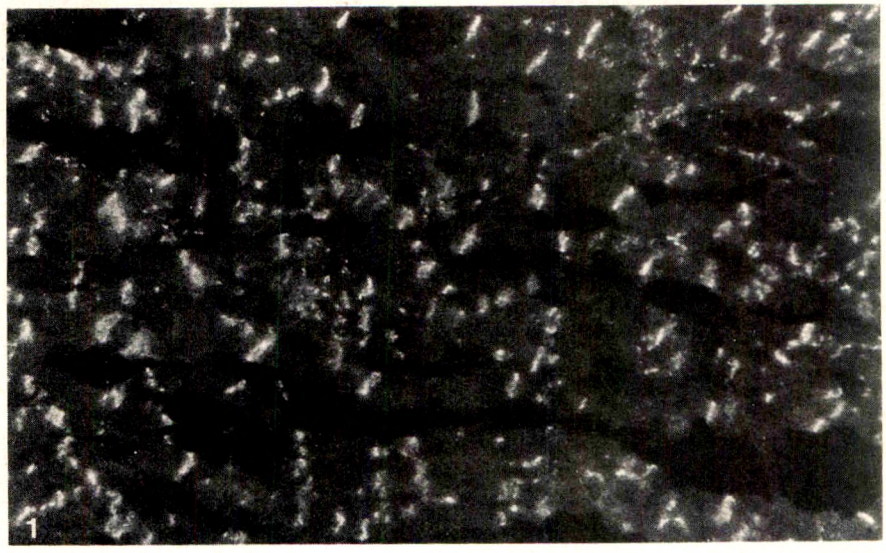

Fig. 1. Low-magnification light photomicrograph of rat heart with epifluorescence for fluorescein isothiocyanate staining with connexin 43 antibody to demonstrate gap junctions. Note muscle fibers positioned horizontally with bright fluorescence concentrated between myocardial cells along intercalated disks. (Original magnification ×380.)

determinant stages of the estrus cycle and timed pregnant rats (day 22 = day of delivery) at various times of pregnancy were used in this study. Tissues were removed from delivering rats after expulsion of two fetuses.

Rats were killed by a blow to the head, and the uterus was removed. The center of each uterus (about 1 cm^2) was pinned on dental wax and rapidly frozen in liquid nitrogen for immunohistochemistry. The remaining pieces were plunged in liquid nitrogen for preparation of microsomal fractions for immunoblotting. Rat cardiac tissues were obtained from the ventricles of the heart and handled in the same manner as uterine tissues.

The human tissue was removed at the time of elective cesarean section and at the time of hysterectomy for benign disease. This study was approved by the institutional review board and consent from each patient was obtained. During cesarean section a 2 × 1 × 1 cm strip was taken from the superior aspect of the uterine incision. Similarly, at the time of hysterectomy of nonpregnant premenopausal subjects, a piece of myometrium was removed from the fundus. The specimens were washed in ice-cold saline solution on collection and then immediately frozen in liquid nitrogen. Small portions of all tissues were processed for immunocytochemical studies and the remainder used for immunoblotting studies.

Some rats were also treated with the antiprogesterone compound RU 486 (Roussel Uclaf, Romainville, France). Timed pregnant rats were injected subcutaneously on day 16 of gestation with 10 mg of RU 486 in sesame oil. On either day 17 or 18 (between 24 and 48 hours after RU 486 treatment) of gestation during premature delivery the rats were killed and the uteruses processed. Control animals were injected with the vehicle only and subsequently treated the same.

Polyclonal antibody to connexin 43. The polyclonal antibody, raised in rabbits, that was used routinely in these studies was directed against the cytoplasmic C terminal domain (amino acids 346 through 360) of connexin 43. The antibody is similar to that used by others,[2, 14-16] and it has been previously shown by immunocytochemistry, immunoblotting, and electron microscopy to bind to gap junctions and connexin 43 protein in the heart.[17]

Immunocytochemical staining. All tissues for immunocytochemical staining were rapidly frozen in liquid nitrogen and stored at −70° C until sectioning. The microscope slides on which the sections were to be placed were coated with poly-L-lysine (10 mg/ml water) and allowed to dry for 30 minutes. The coated slides were then placed in a cryostat at −20° C. The tissue to be sectioned was mounted on a microtome chuck with ornithine carbamyl transferase embedding medium. The tissue was sectioned at 7 to 8 μm thickness. Sections of rat heart were placed on each slide to validate the staining procedure, because the rat heart consistently stains along the intercalated disks with the connexin 43 antibody (Figs. 1 through 3). The sections were allowed to air dry for 1 hour at room temperature. The sections were then rinsed in two changes of phosphate-buffered saline solution at room temperature and then incubated in a blocking solution consisting of 3% bovine serum

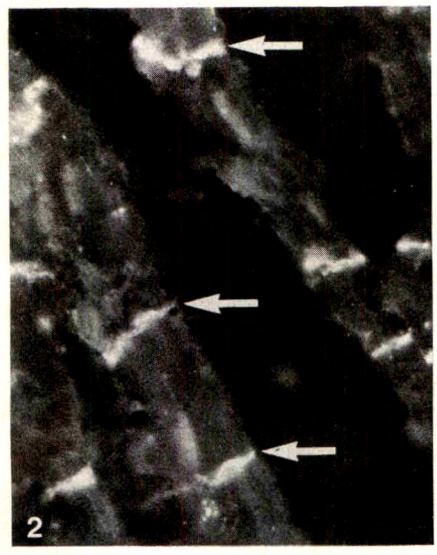

Fig. 2. Higher magnification photomicrograph of heart muscle cells as shown in Fig. 1. *Arrows*, Region of labeling with connexin 43 antibody between cells at intercalated disk area. (Original magnification ×780.)

albumin and 1% Triton-X100 in phosphate-buffered saline solution for 20 minutes at room temperature. Incubations were carried out in a humidified chamber. The sections were then rinsed in phosphate-buffered saline solution for 10 minutes (two times) at room temperature. The primary antibody (1:250 dilution with phosphate-buffered saline solution) against connexin 43 was placed on the tissue sections, which were then incubated in a humidified chamber overnight at 4° C. The next day the slides were rinsed in phosphate-buffered saline solution (6 × 10 minutes each) and then a fluorescein isothiocyanate–labeled secondary antibody (goat antirabbit immunoglobulin G) purchased from Jackson Immunoresearch Laboratories was added to the sections (1:200 dilution) and the preparation incubated for 1 hour at room temperature. Afterward, the sections were again rinsed in phosphate-buffered saline solution (6 × 10 minutes each), and then 1 to 2 drops of mounting medium (0.4% *p*-phenylenediamine in 0.1 mol/L sodium carbonate buffer, pH 9, diluted 1:1 with 100% glycerol) was placed on each slide and a coverslip applied. The sections were examined with a Zeiss light microscope (magnification ×40 to ×100) with epifluorescence and filters for maximum fluorescein isothiocyanate fluorescence. Table I shows the number of animals and sections examined by immunocytochemistry. We routinely examined negative controls such as sections of heart and myometrium after application of only the secondary antibody to demonstrate the lack of nonspecific staining. Similarly, we occasionally processed liver tissue as above and observed no specific connexin 43 staining.

Table I. Tissues examined with immunocytochemistry

Tissue	*No. of subjects*	*No. of tissues examined*
Rat myometrium		
Delivering	11	36
Day 18, day 19	4	12
RU486, day 17, day 18	4	6
1 Day post partum	3	6
Rat heart	14	158
Human myometrium		
Nonpregnant	4	7
Term		
Labor	7	16
Nonlabor	15	25

Number of animals or patients and the number of tissues examined by immunocytochemistry for connexin 43 content. Rat tissues were obtained during term delivery (delivering), day 18 or day 19 of gestation and at day 17 or day 18 after RU 486 treatment during preterm delivery.

Preparation of crude microsomal fraction. The methods used to obtain a crude microsomal fraction containing the plasma membrane proteins are similar to those used previously.[18] The myometrial tissues were minced with scissors and suspended in six volumes of sucrose-3-(*N*-morpholino)propanesulfonic acid buffer (250 mmol/L sucrose, 20 mmol/L 3-(*N*-morpholino)propanesulfonic acid adjusted with sodium hydroxide to pH 7.0) and homogenized with a polytron PT20 giving three bursts of 10 second duration each at 15,000 revolutions/min. The sucrose-3-(*N*-morpholino)propanesulfonic acid also contained phenylmethylsulfonyl fluoride (1 mmol/L), dithiothreitol (2

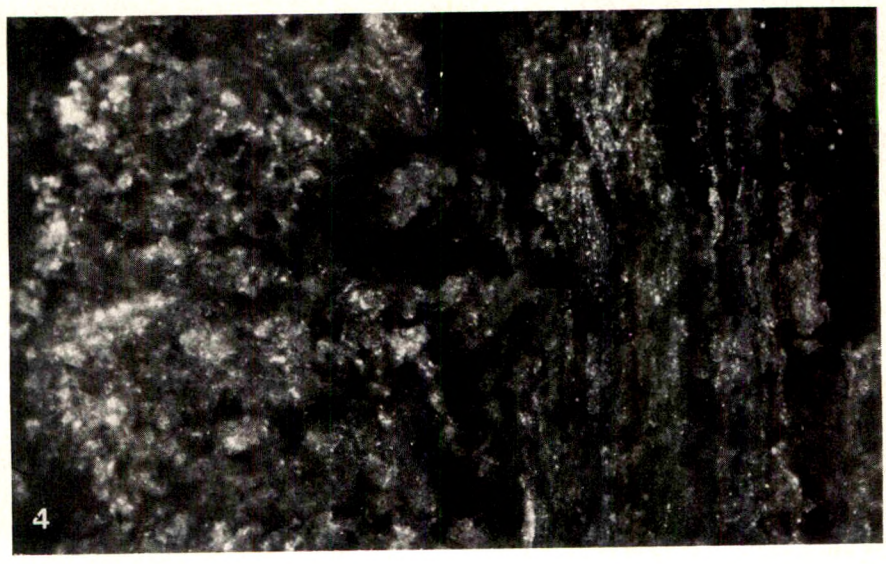

Fig. 4. Photomicrograph of uterine tissue from term delivering rat showing longitudinal (cut in cross section, *left*) and circular (cut in longitudinal orientation, *right*) muscle layers. Bright, punctate staining of gap junctions with connexin 43 antibody is evident in both muscle layers. (Original magnification ×370.)

mmol/L), and trypsin inhibitor (1 mg/ml). The homogenates obtained were centrifuged at 10,000*g* for 10 minutes in a JA20 rotor to yield a pellet and a supernatant fraction. The supernatant was recentrifuged at 115,000*g* for 30 minutes in a Beckman L5-65 ultracentrifuge (with a 60TI rotor) to give a 115,000*g* pellet and a supernatant fraction. This 115,000*g* pellet was resuspended in 8% sucrose. This was the crude microsomal fraction used for the immunoblotting studies. The pellet from the 10,000*g* centrifugation was resuspended in 8% sucrose to check for the presence of connexin 43 with immunoblots. Similarly, the supernatant fraction from the 115,000*g* centrifugation was also analyzed for connexin 43. There were only trace amounts of connexin 43 in the 10,000*g* resuspended pellet and the 115,000g supernatant fraction. Thus the microsomal fraction was shown to contain the majority of the connexin 43 protein. Similar procedures were used for cardiac tissues. Protein concentrations were determined on all fractions according to the method of Lowry et al.[19]

Electrophoresis. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis was carried out with a 12% polyacrylamide separating gel and a 4% stacking gel. The technique used was that according to Laemmli.[20] Before the samples were placed on the gel for electrophoresis, they were heated to 95° C for 5 minutes. The molecular weight markers used were bovine serum albumin (66,000 molecular weight), ovalbumin (45,000 molecular weight), and carbonic anhydrase (29,000 molecular weight).

Immunoblotting. Crude microsomal fractions isolated from rat and human myometrium were resolved in the sodium dodecyl sulfate gels and electrophoretically transferred to nitrocellulose in a BioRad (BioRad, Richmond, Calif.) apparatus at 100 V for 1 hour. The nitrocellulose was incubated with the specific anticonnexin 43 antibody and subsequently reacted with an iodine 125–labeled secondary antibody (goat antirabbit immunoglobulin G, purchased from New England Nuclear, Boston). The nitrocellulose sheets were then autoradiographed with Kodak XAR-5 (Eastman Kodak Co., Rochester, N.Y.) film. After autoradiography was completed (about 3 days), specific areas of the nitrocellulose sheets corresponding to the labeled protein-antibody complex were excised, and the radioactivity in each immunoblot was counted in a γ counter.

Immunoblots were used to determine the amount of myometrial gap junction protein present throughout gestation in the rat. Crude microsomal fractions from day 18, day 22 (delivering), and 20 to 24 hours post partum were prepared and immunoblotted. Fifty micrograms of total microsomal protein from different days of gestation were added to separate lanes of the electrophoresis gel. A preparation of rat heart (also 50 μg) was also run on each gel to act as a positive control. Counts of the radioactivity (counts/min) were used to estimate a ratio between myometrium and heart (counts/min/50 μg protein of uterine tissue ÷ counts/min/50 μg protein of rat heart) to compare the amount of myometrial gap junction protein at different gestational times. The heart tissues used as positive controls were all from rats at midgestation to minimize the possible variation at different times. However, analysis of connexin 43 levels in the heart throughout gestation revealed no significant changes.

Fig. 5. Photomicrograph, similar to those shown in Figs. 1 through 4, of myometrial tissue from rat at 18 days of gestation. Note absence of any punctate type staining as shown in Figs. 4 and 6. (Original magnification ×925.)

Fig. 6. Myometrial tissue from rat at 18 days of gestation during premature birth after treatment with RU 486. Note abundance of staining of gap junctions as compared with tissue from control animals shown in Fig. 5. (Original magnification ×925.).

Statistics. Statistical differences between mean values of various groups of data were determined by one-way analysis of variance. For comparisons of mean values between two groups, the Wilcoxon rank-sum test was used.

Results

Immunohistochemical studies. The anti-connexin 43 antibody specifically stained the intercalated disk regions of the rat heart on sections placed on all slides. Figs. 1, 2, and 3 show rat heart tissues at low (Fig. 1) and high magnification (Figs. 2 and 3). Fig. 3 is a phase-contrast image of the same fluorescent field shown in Fig. 2 illustrating that the bright fluorescent labeling is along the intercalated disk area of the striated heart cells. Findings identical to those above were found in many heart tissue samples (n = 28) from animals at various stages of gestation (Table I). There were no obvious differences in the immunofluorescent staining pattern in hearts of pregnant or nonpregnant animals.

Immunofluorescent staining of rat myometria are shown in Figs. 4, 5, and 6. The pattern of antibody staining in the longitudinal and circular muscle during delivery at term is illustrated in Fig. 4. Bright fluorescent punctate spots can be seen throughout both circular and longitudinal muscle layers. In contrast, there was little or no staining of tissues from myometrial tissues from animals at day 18 or 19 of pregnancy (Fig. 5). However, in tissues from animals delivering prematurely on day 18 of gestation after treatment with RU 486 there were enormous amounts of staining (Fig. 6), and the appearance was like that found in tissues from animals delivering spontaneously at term (Fig. 4). Tissues from numerous animals (Table I) indicated that the connexin 43 staining was elevated only during term and RU 486–induced preterm delivery.

Immunofluorescent staining of human myometrial tissues are shown in Figs. 7 and 8. In tissues from nonpregnant patients (Table I), there was little staining (Fig. 7), and thus the fluorescence was equivalent to that in the rat myometrium before delivery (Fig. 5). Tissues taken from patients at term, both labor and nonlabor groups, showed variable staining with some demonstrating high levels of fluorescence (Fig. 8) as in the rat during delivery (Figs. 4 and 6) and others exhibiting reduced amounts.

Immunoblotting. The antibody (antipeptide 346 to 360) used in the immunoblots exhibited homology with respect to the rat heart and myometrial tissues studied. When 25, 50, and 100 μg of microsomal proteins from both rat and human myometrium were added to different lanes, concentration dependent staining of the immunoblots was observed with distinct bands at about 43 kd. In some cases each band was composed of triplets.

To validate that the antibody was recognizing the connexin 43 protein in a concentration-dependent manner, different protein concentrations of the crude microsomal fraction were quantitatively analyzed after immunoblotting. Plots of the amount of membrane protein added for electrophoresis versus the amount of radioactivity (counts per minute) in the immunoblots showed linear relationships for tissues from rat heart and delivering rat myometrium and also human myo-

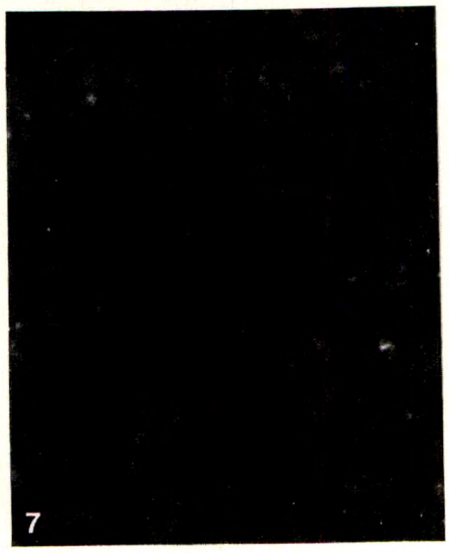

Fig. 7. Human myometrial tissue from nonpregnant patient. Note almost complete lack of connexin 43 staining as compared with myometrial tissues from rat during term (Fig. 4) and preterm (Fig. 6) delivery and also human myometrium from pregnant term patient (Fig. 8). (Original magnification ×1400.)

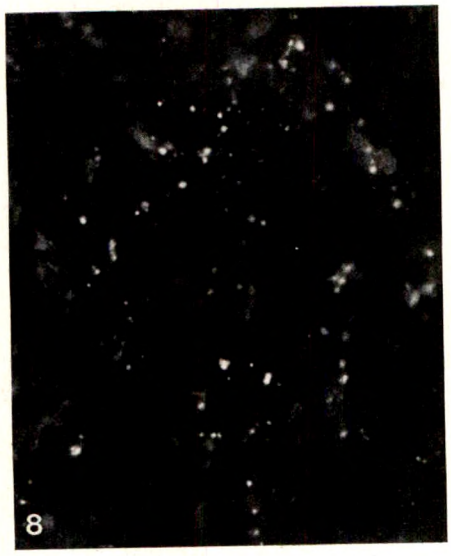

Fig. 8. Human myometrial tissue from term pregnant patient in active labor. Note abundance of staining of gap junctions with connexin 43 antibody. (Original magnification ×1400.)

metrium (Fig. 9). However, there was more radioactivity in immunoblots of preparations from rat heart and myometrial tissues than from human myometria.

Fig. 10 shows immunoblots of heart and myometria from nonpregnant and pregnant rats and humans. There was little 43 kd protein present in tissues from nonpregnant and day 18 pregnant rats compared with tissues from animals that were delivering spontaneously on day 22. Similarly, in tissues from the human uterus there was little 43 kd protein in tissues from nonpregnant patients but elevated levels during pregnancy taken from women either in labor or undergoing elective section (nonlabor). Fig. 11 shows immunoblots of rat heart and myometrial tissues taken from animals at day 18 of gestation without treatment (control) and following RU 486 injections during preterm birth. The blots were much more intense from six animals treated with RU 486 than from control animals. Again, the blots were composed of three separate bands.

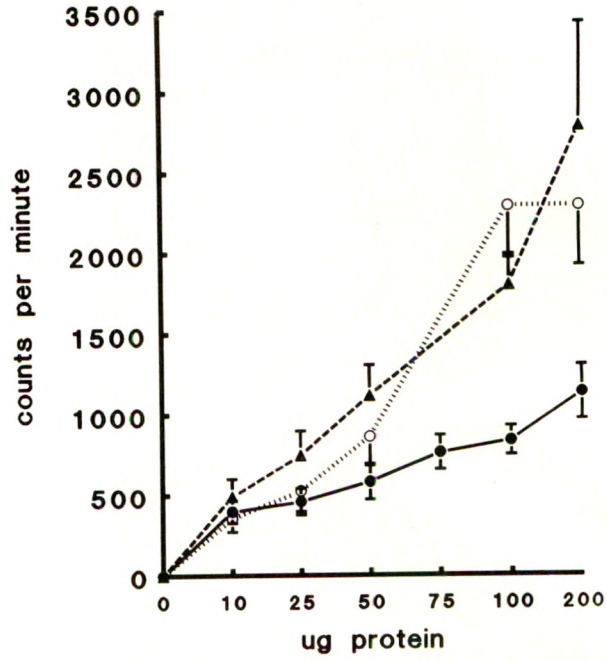

Fig. 9. Concentration dependency of methods used for analysis of immunoblots. Shown are counts per minute of blots versus amount of protein added for electrophoresis for tissues from rat heart (▲) and myometrium (○) and human myometrium (●).

Fig. 12 shows the relative amounts (ratio of connexin 43 levels, uterus/heart) of connexin 43 proteins in rat myometria at different times of pregnancy and during term and preterm birth. There was about three times as much connexin 43 protein present in the myometrium of the delivering rat uterus during spontaneous delivery as present at either day 17 of gestation or post partum. Similarly, animals delivering prematurely after RU 486 treatment showed markedly elevated levels of connexin 43. In animals treated with RU 486 and delivering prematurely, there was an approximately sixfold increase in connexin 43 as compared with day 17 of gestation.

Comment

In this study we have demonstrated through immunohistochemical and immunoblotting techniques the presence of connexin 43 in both rat and human myometrium and also have shown that there is an increase in the protein during term and preterm birth in

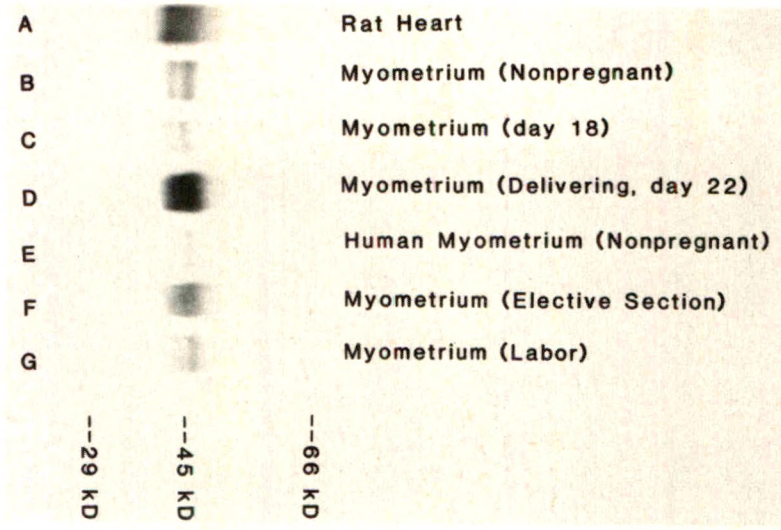

Fig. 10. Immunoblots (50 μg protein each lane) of rat heart and myometrial samples from rats (nonpregnant, day 18 of gestation, and during term delivery) and humans (nonpregnant, elective nonlabor, and labor patients).

the rat. The immunohistochemical studies clearly show the presence of the gap junction protein in the rat myometrium, which peaks during delivery. It has been previously shown with electron microscopy that gap junctions are present in low frequency and small sizes in nonpregnant and preterm and postpartum rats, with an abrupt increase in both size and frequency during delivery.[8, 9] This observation is confirmed and extended with the immunohistochemical studies presented in this study showing minimal staining in the sections at day 18 of gestation, marked staining of the section of delivering tissues, and little staining of the postpartum tissues. Similar results were obtained by measuring the levels of connexin 43 in immunoblots at different times in pregnancy. In this study a crude microsomal fraction was used for the immunoblotting technique. This preparation contains plasma membrane and cytoplasmic components reflecting not only the plasma membrane gap junctions but also the junctions during assembly and degradation. Studies were also conducted showing that this preparation gave the strongest and clearest signal for immunoblotting, far greater than the 10,000*g* pellet or 115,000*g* supernatant fractions.

The use of RU 486, which causes premature labor and increases gap junctions in the rat myometrium as detected by electron microscopy,[21] also results in an increase in connexin 43 protein. The immunofluorescent staining of tissues prepared from RU 486–treated rats appear identical to the sections from term delivering animals with respect to the amount of fluorescence. Correspondingly, the immunoblots showed that tissues from RU 486–treated rats and from term delivering rats both demonstrate high levels of connexin 43, although the former exhibited higher levels. Therefore in the event of premature labor the presence of connexin 43 appears to be the same as that of normal labor, and this confirms that the presence of gap junction is a required step in premature labor.

Each one of the bright fluorescent dots in the myometrial tissues (Figs. 4, 6, and 8) represents one gap junction between muscle cells, approximately 250 nm in diameter. The gap junctions fluoresce with great intensity because each is composed of hundreds of connexin proteins.[1, 22] However, small gap junctions may not be visible with this technique. Furthermore, because sections used in this study are relatively thick (7 to 8 μm and optimum for frozen tissues), any given area could contain many gap junctions (i.e., up to 32 throughout the section depth). It is readily apparent that the junctions are dispersed throughout the tissue and appear to be randomly positioned between smooth muscle cells with no particular region showing higher concentrations. However, this is not the case for heart cells, where the gap junctions are superimposed on each other in the section to give the image of a large unified structure in the region of the intercalated disk. That gap junctions are present in this region in heart muscle has been demonstrated by many.[13, 22]

The immunoblot studies presented support the immunohistochemical results and also provide other information. Quantities of the connexin 43 protein were estimated as normalized to heart tissue. Normalization helped minimize any error associated with the immunoblot technique. This is the first description of a quantitative analysis of the level of connexin 43 in the myometrium during gestation and term and preterm delivery in the rat. Counts of various concentrations of protein show linear relationships indicating that the blots can be used for quantitative evaluation of tissue levels of connexin 43 (Fig. 9). Although the peak values of connexin levels were present during delivery, the immunoblots generally have relatively high levels of

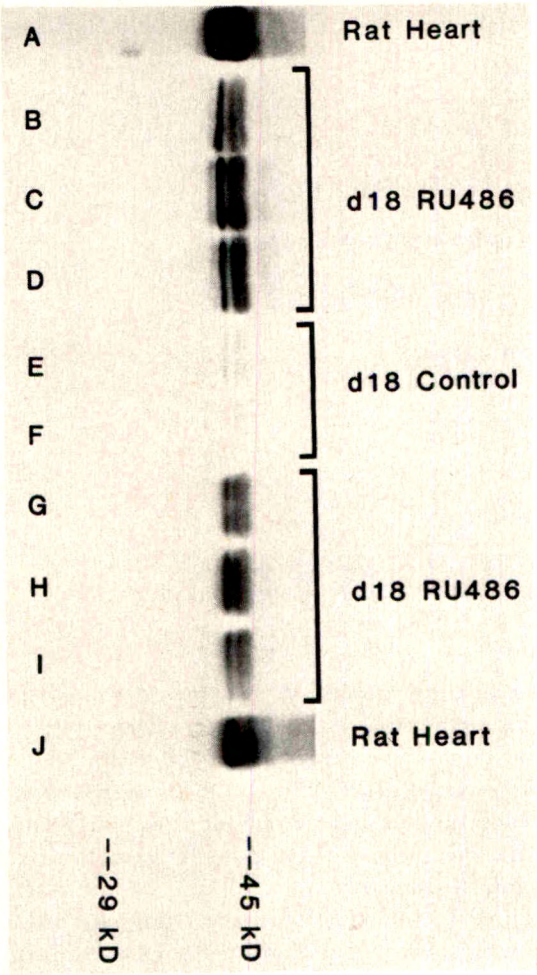

Fig. 11. Immunoblots (50 μg protein each lane) of rat heart *(lanes A, J)* and tissues from six different rats delivering prematurely at day 18 of gestation *(lanes B, C, D* and *G, H, I)* compared with tissues from two control rats at day 18 of gestation *(lanes E* and *F)*. Note distinct division of each blot into three regions.

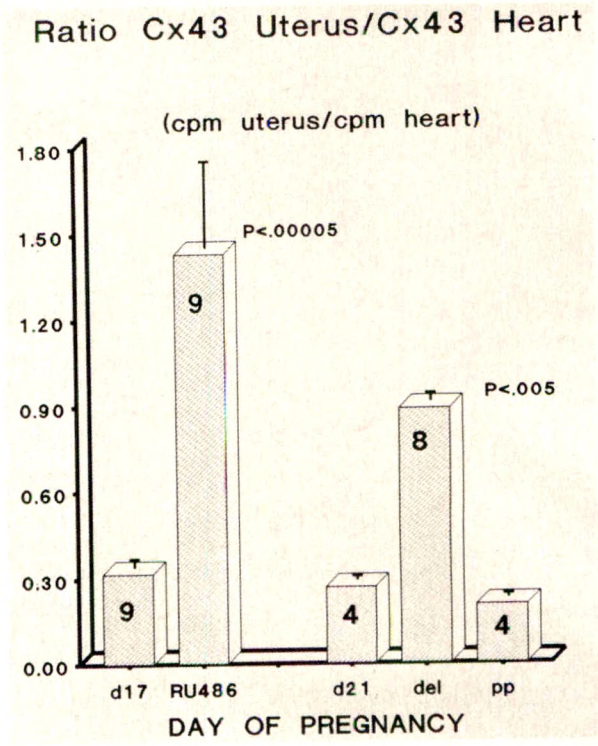

Fig. 12. Histograms showing counts per minute from immunoblots at day 17 of gestation, during delivery, post partum, and after treatment with RU 486 during preterm birth.

connexin 43 protein in tissues from rats and humans (Figs. 10 and 11) before labor and post partum. This is in contrast to previous studies with electron microscopy, which demonstrates few plasma membrane gap junctions between myometrial cells before labor and elevations in junctions during term and preterm labor.[8] Possible reasons for this discrepancy in the rat are (1) presence of binding to gap junctions in other cells besides myometrial cells, (2) presence of small but undetectable gap junctions with both electron microscopy and immunocytochemistry, and (3) binding to gap junction proteins in the cytoplasm of the myometrial cells. The last two possibilities seem the most likely because no visible binding was observed with other cells with immunocytochemistry (no. 1 above). Thus this study is useful in defining the quantity of connexin 43 proteins in the uterus at various times of pregnancy. However, this study does not clarify the exact position of the protein within or between myometrial cells. These studies are only crude approximations of myometrial gap junctions. Studies with the electron microscope still remain the method of choice in defining the presence of gap junctions between myometrial cells.

The regulation of the gap junction protein is not well understood at either the level of transcription or translation. The expression of the transcript in the rat myometrium for connexin 43 has been investigated during gestation with an approximately fivefold increase in transcript levels noted immediately before delivery.[15] This increase was suggested to be the result, in part, of a hormone-induced increase of transcriptional production rate. Posttranslational control may be through phosphorylation of the connexin 43 protein. Although it has been suggested that phosphorylation may play a role in assembly of gap junctions,[23] the possibility of a role in regulation of channel activity or aspects of connexin 43 turnover will require further study.

The observation (Fig. 11) that the anti–connexin 43 antibodies bind to multiple bands on Western blots is consistent with several studies in which it has been shown that they correspond to different phosphorylated forms of connexin 43.[23-25] Roughly equal amounts of the faster migrating unphosphorylated form of connexin 43 (apparent mobility of about 41 kd) and slower migrating phosphorylated forms (doublet with apparent mobility of about 43 kd) are present in our myo-

metrial samples. Although there are significant differences in the relative proportions of the phosphorylated and unphosphorylated forms of connexin 43 in different tissues and cell types, the basis for what must have a physiologic role is not yet understood.

With respect to human samples, this is also the first study to demonstrate the presence of connexin 43 in the myometrium. Our study suggests that there is homology between connexin 43 in the rat myometrium and heart and the human uterus. Both immunohistochemical staining (Fig. 8) and the immunoblots (Fig. 10) clearly show the presence of connexin 43 in pregnant human myometrium. The protein was present in low amounts in the nonpregnant myometrium (Fig. 10). Of particular interest is that connexin 43 was identified in myometrium from patients who had not undergone labor and those who did. The exact quantitative difference, if any, is presently being investigated. It should be noted that all human myometrial tissues from pregnant patients were from the lower uterine segment. Similar electron microscopic studies suggest an increase in human myometrial gap junctions at term.[8] However, in the present studies there was great variability between samples with both immunocytochemistry and immunoblots. Frequently there was greater staining of sections and larger blots from tissues of nonlabor patients than tissues of labor patients (Fig. 10). This may indicate that muscle from the lower uterine segment is not representative of muscle throughout the uterus during pregnancy. The tissues obtained from nonpregnant patients were all from the upper fundal and muscular portion of the uterus. Thus these tissues may not be comparable to those obtained from the lower segment of pregnant patients. In this study the nonpregnant tissues showed little connexin 43 by immunocytochemistry or in the Western blots (Figs. 7 and 10). The human nonpregnant myometrium appears to contain few gap junctions, as has been shown previously by electron microscopy for human myometrium and also in studies of nonpregnant rats.[9] Additional investigations are required to determine the presence of connexins other than connexin 43 in the human nonpregnant and pregnant myometrium.

LETTERS TO THE EDITORS

Subtherapeutic doses of magnesium sulfate do not inhibit preterm labor

To the Editors: I was disturbed by the article by Cox et al. (Cox SM, Sherman ML, Leveno KJ. Randomized investigation of magnesium sulfate for prevention of preterm birth. Am J Obstet Gynecol 1990;163:767-72.) The authors defined clinically safe magnesium concentrations as "those <8 mEq/L" and attempted to determine whether these levels of magnesium were effective in preventing preterm birth.

The design of the study appears to be inadequate in that the amount of drug administered (4 gm magnesium sulfate bolus and 2 gm per hour infusion) has been shown to be associated with subtherapeutic serum levels of magnesium. Hollander et al.[1] found that the median dosage of magnesium sulfate necessary to achieve tocolysis was 4.5 gm per hour; the mean serum magnesium level to achieve tocolysis was 6.6 mg/dl (5.5 mEq/L). Elliott[2] found serum magnesium levels of 5.1 mg/dl (4.25 mEq/L) with dosages of 2 gm per hour infusion of magnesium sulfate and 6.4 mg/dl (5.3 mEq/L) when 3 gm per hour were given. Somehow in this study the authors state that a maximum magnesium concentration of 5.5 mEq/L was achieved (page 771) or a mean magnesium concentration of 5.5 mEq/L was achieved (page 769). Which is it?

The authors state that the magnesium sulfate was discontinued in eight patients (11%) because of toxicity, mainly generalized muscle weakness (6 patients). Were these patients removed from the study or treated as failures of the drug? To stop the drug because of lethargy and then continue to include these patients in an evaluation of efficacy is not appropriate. Cox states, "The experience of these investigators [Hollander et al.] suggests that effective uterine contraction–inhibiting concentrations of magnesium must be near toxic levels to anticipate a clinical uterine effect." To the contrary, Hollander et al. state in their conclusion, "The drug appears to offer a high therapeutic-to-toxic ratio with a serum concentration response that is easy to determine." Discontinuing the infusion in at least six patients is prejudicial to the study and merely reflects inexperience with the use of the drug.

The authors also fail to mention how many patients received a second course of magnesium sulfate after the initial 24 hours. It is unrealistic to treat a patient in true premature labor for 24 hours with subtherapeutic doses of a drug and then discontinue it.

The bias of the investigators is readily apparent in the discussion, in which they selectively cite articles by Steer and Petrie, Spisso et al., Elliott, and Hollander et al. and essentially dismiss them. They cite the study by Cotton et al. and their own study as the only placebo-controlled randomized studies. In the study of Cotton et al. the dosage of magnesium was also inadequate (4 gm bolus and 2 gm per hour intravenous infusion—no option to raise the infusion rate). The number of patients treated with magnesium sulfate in that study was also totally inadequate—8 patients with *intact* membranes had magnesium sulfate versus 9 saline and 12 terbutaline. The magnesium sulfate was also administered for 12 hours and then stopped.

Apparently the authors ignored other studies (Ferguson et al., Wilkins et al.) in the literature comparing magnesium sulfate with intravenous β-sympathomimetic therapy and finding magnesium sulfate either superior to or comparable with the β-sympathomimetic drugs.

The conclusion reached in the article by Cox et al. that "magnesium sulfate infusions resulting in maximum serum concentrations of magnesium equal to 5.5 mEq/L are ineffective in the prevention of preterm birth" is absolutely true. If their goal was to avoid toxicity they certainly achieved it, but in their zeal to avoid toxicity they also fell far short of therapeutic levels of magnesium in the sera of their patients.

The only conclusion that can be drawn from these data is that magnesium sulfate in subtherapeutic dosages does not inhibit preterm labor better than intravenous hydration.

Reply

To the Editors: We take it that Elliott did not like our report concerning the lack of efficacy for intravenous magnesium sulfate in the prevention of preterm birth. Elliott has liberally referred to his own 1983 retrospective review of tocolysis with magnesium sulfate,[1] and we are compelled to do so, too.

Elliott reported in 1983 that he administered magnesium sulfate as follows: "After a 4 gm intravenous bolus of magnesium sulfate, a constant infusion was started at 2 gm/hr . . . ." The maximum infusion rate apparently used was 3 gm per hour. A total of 355 pregnancies were included in Elliott's report; 673 magnesium levels were measured subsequent to therapy for an average of 1.9 levels per pregnancy. Interestingly, only 28 magnesium levels were obtained during 3 gm per hour infusions. Does this mean that Elliott's only experience with the higher infusion rate is from approximately 14 pregnancies representing 4% of his study population? Alternatively, Elliott reported that 536 magnesium levels were obtained during 2 gm per hour infusions. Does this mean that 282 (or 79%) of Elliott's patients received 2 gm per hour infusions? Now

Elliott refers to our study and claims, "The design of the study appears to be inadequate in that the amount of drug administered (4g magnesium sulfate bolus and 2 gm per hour infusion) has been shown to be associated with subtherapeutic serum levels of magnesium." We must conclude that Elliott is far more guilty of subtherapeutic therapy than we because we used the higher infusion dosage more often than he did. Specifically, 62% of our patients received 3 gm per hour infusions. Moreover, we are mystified that Elliott claims tocolytic efficacy for magnesium sulfate when most of his patients apparently were treated with what he now calls a subtherapeutic dosage regimen.

Elliott also reported in 1983, "Clinically, we found that levels between 5.0 and 7.0 mg/dl were usually sufficient to inhibit contractions. . . ."[1] We reported a mean magnesium level of 6.6 mg/dl. Elliott now states that "The conclusion reached in the article by Cox et al. that 'magnesium sulfate infusions resulting in maximum serum concentrations of magnesium equal to 6.6 mg/dl are ineffective in the prevention of preterm birth' is *absolutely true* (emphasis added)." In an attempt to apply some logic to all this we seem unavoidably compelled to conclude that Elliott now believes his 1983 statement ". . . levels between 5.0 and 7.0 mg/dl were usually sufficient . . . "[1] is untrue. Our real bias is that Elliott unwittingly seems to agree with us, although we take it he would not like this, either.

The effect of gestational age on maternal serum α-fetoprotein levels in pregnancies with Down syndrome

To the Editors: Greenberg et al. (Greenberg F, del Junco D, Weyland B, et al. The effect of gestational age on the detection rate of Down syndrome by maternal serum α-fetoprotein screening. Am J Obstet Gynecol 1991;165:1391-3) found that maternal serum α-fetoprotein (AFP) levels were lower on average in 14 pregnancies with Down syndrome tested at 16.5 to 17.5 weeks' gestation than in 22 pregnancies tested at 14 to 16.5 weeks and in 15 at 17.5 to 21.5 weeks. Expressing levels in multiples of the median for unaffected pregnancies of the same gestation, the mean value at each gestation was 0.59, 0.74, and 0.69 respectively. However, these differences are not borne out by summarizing other published studies.

Table I updates a previous summary of the literature[1] to include all recent publications[2-5] in which individual multiple of the median values according to week of gestation are either tabulated or can be abstracted from a figure and where the serum sample was not taken after amniocentesis or chorionic villus biopsy. A total of 379 affected pregnancies between 14 and 21 weeks were available for analysis. There was no tendency for the median AFP level in any gestational week to differ from the overall median value, nor did any effect of gestation emerge when an analysis of variance of log AFP was carried out to allow for differences between the various studies included. First-trimester AFP levels have been reported in a total of 67 pregnancies with Down syndrome[6-10] and found to be similar to second-trimester levels. The geometric mean weighted for the number of pregnancies in each first-trimester study was 0.74 multiples of the median.

Table I. Maternal serum AFP levels in pregnancies with fetal syndrome according to gestational age[1-5]

Gestation completed (wk)	*No. of pregnancies*	*Median AFP (MoM)*
14	2	0.72-0.73
15	26	0.72
16	144	0.72
17	110	0.72
18	53	0.70
19	29	0.74
20	13	0.77
21	2	0.45-1.96
14-21	379	0.72

MoM, Multiple of the median for unaffected pregnancies of the same gestation.

These results have implications for screening policy in centers in which AFP is the only Down syndrome marker being measured. If the same blood sample is used for both Down syndrome and neural tube defect screening the test would need to be done at 16 to 18 weeks, the gestation at which neural tube defect detection is highest. If a separate blood sample can be used or if reliance can be placed on ultrasonography for neural tube defect screening, Down syndrome screening need not be restricted to 16 to 18 weeks. For centers using multiple markers the optimal gestation will depend on which additional markers are used.

Reply

To the Editors: We are pleased to have this opportunity to emphasize the importance of pursuing improvements in the efficacy of the maternal serum α-fetoprotein (AFP) screening test for Down syndrome pregnancies. Comparing affected with unaffected pregnancies at our center we found that for a given maternal serum AFP cut point of 0.8 weight-adjusted multiples of the median the detection rate was higher and the false-positive rate was lower between 16.5 and 17.5 weeks' gestation than at earlier or later gestational ages. This suggested to us that the optimum gestational age for maternal serum AFP screening for Down syndrome may be similar to the optimum reported previously for neural tube defect screening.[1] Wald and Cuckle's[2] previous and current synthesis of maternal serum AFP multiples of the median data from different centers focus on mean or median values in Down syndrome pregnancies. Such values relate only to detection rates and only indirectly so. Although Cuckle did not detect statistically significant differences among the gestational age–specific median maternal serum AFP multiples of the median he reported, it is interesting to note that a nadir of 0.7 multiples of the median was reported at 17 weeks' gestation in his first paper[2] and at 18 weeks' gestation in his updated table. It is possible that the nadir between 17 and 18 weeks' gestation is real, not a result of random fluctuation, and that it implies a higher detection rate for Down syndrome pregnancies in that time window. A similar pattern of maternal serum AFP multiples of the median results (with a nadir at 17 weeks' gestation) was reported by Waller et al.[3] To assess accurately whether the patterns observed by Waller and Cuckle suggest underlying detection rates and false-positive rates similar to ours would require comparable analyses allowing for variance in unaffected and affected pregnancies. We urge individual centers to periodically examine their maternal serum AFP detection rates and false-positive rates in this manner. Given the quantitative advantages and power of recent metaanalysis techniques[4] to properly incorporate center-specific variances, we recommend the application of these methods to assist policy decisions in maternal serum AFP screening. Finally, we stress the importance of appropriate tests for heterogeneity among centers before any pooling of data across centers. In assessing heterogeneity as in pooling across centers, maternal serum AFP variability in both unaffected and affected pregnancies must be taken into consideration.

An association between placental location and nuchal cord occurrence

To the Editors: A continuing prospective study named the Perinatal Umbilical Cord Project made an association between placental location and nuchal cord occurrence.[1] The number of entries into this private study has now numbered 400 cases. The purpose of this letter is to update the statistics on nuchal cord and placental location.

Four hundred pregnancies were prospectively studied over a 3-year period. Three hundred sixty met requirements of a 28-week ultrasonographic examination and manual removal of the placenta at delivery. Placental location was reviewed after delivery and compared with the occurrence of nuchal cord. Nuchal cord is defined as the umbilical cord being 360 degrees around the neck.

Table I summarizes the data.

Among 360 pregnancies the location of the placenta was recorded as follows: posterior, 37%; anterior, 38%; and fundal, 25%. The occurrence of a nuchal cord (14%) among all pregnancies is not the same for each of the placental locations; it is most common among

Table I. Summary of data

Placental location	*n*	*Nuchal cord*	*Percentage with nuchal cord*
Posterior	134	30	22.4
Anterior	137	16	11.7
Fundal	89	4	4.5
TOTAL	360	50	13.9

posterior positions (22.4%), nearly twice that for anterior positions (11.7%), and five times that for fundal location (4.5%). These differences in incidence are statistically significant (logistic regression $p = 0.0003$). The posterior placenta has a statistically significant association with nuchal cord versus other placental locations.

Menopausal patient considerations

To the Editors: The article by Sutton et al. (Sutton GP, Bundy BN, Delgado G, et al. Ovarian metastases in stage IB carcinoma of the cervix: a gynecologic oncology group study. Am J Obstet Gynecol 1992:166:50-3) presents an interesting subset of data collected as part of a large surgical staging protocol by the Gynecologic Oncology Group. The data focus on the overall incidence of ovarian metastases in patients with stage IB cervical cancer. It would be most helpful if the authors would further review their data to focus on the incidence of occult ovarian metastases in patients believed to be candidates for ovarian preservation at the time of radical hysterectomy and bilateral pelvic node dissection for early cervical cancer.

Of their 1125 patients, 135 (12%) were excluded for protocol problems and an additional 111 (11.2%) did not undergo radical hysterectomy with bilateral salpingo-oophorectomy because of extensive disease found at surgery. Of the remaining 879 patients 833 underwent radical hysterectomy (I cannot account for the other 46 patients); of the 833, 439 had a radical hysterectomy with bilateral salpingo-oophorectomy.

Of these 439 women, the authors could delete those who were postmenopausal (or >40 years old?) and those in whom incidental ovarian pathologic conditions were found. The remaining patients would be those in whom some physicians would consider ovarian preservation at the time of radical hysterectomy. The incidence of occult metastatic disease for various cell types could then be calculated to help allay our fears that ovarian preservation during surgery for early adenocarcinoma of the cervix is not as safe as has been established for squamous lesions.

Tubata et al.[1] reported that 2 (77%) of 26 cases of stage IB adenocarcinoma of the cervix had ovarian metastases; this statistic heightens our concerns.

Response declined

Daily commuting and preterm birth rate

To the Editors: In a survey carried out in two maternity units in the Paris region (1987 through 1988) we studied risk factors of preterm births among working women. The sample included 838 women who were interviewed during their stay in the hospital after delivery; among them, 61% had jobs during their pregnancy. Women who had a qualified job in professional, intermediate, or clerical occupations had a significantly lower rate of preterm births than women with less-qualified jobs in industrial, service, and shop occupations (Table I). This finding agrees with the literature.[1-3]

In addition, women whose daily commuting time was ≥2 hours with public transportation had a preterm birth rate of >2 times that of women whose commuting time on public transportation was shorter or women who used other types of transportation such as their own cars or walking. This difference appeared clearly in both groups of occupations; adjustment for occupational group was a way to control roughly for social characteristics and working conditions.[3] Women who used public transportation for <2 hours daily did not have an excess of preterm births. In our sample 33% were exposed to ≥2 hours of public transportation each day.

Kaminski and Papiernik[4] had already shown that long daily travel had to be included in a score of prediction of preterm birth from data collected in a ma-

Table I. Preterm birth rate and daily commuting in the Paris region

	Preterm births					
	All women		*Public transportation ≥2 hours*		*Other*	
	No.	*%*	*No.*	*%*	*No.*	*%*
Working women						
Qualified jobs	367	5	115	9	235	4
Less-qualified jobs	127	11	33	18	85	9
TOTAL	494	7	148	11	320	5 $p < 0.05$*

*Mantel-Haenszel χ^2 test adjusted for qualification of jobs.

ternity ward in Paris in 1969. Other French surveys conducted later on national samples or on regional samples[1] outside of Paris did not report any clear relationship between daily travels and the preterm birth rate.

Long daily travels are a consequence of the development of very large cities, which depend on urban policy and the labor market. Even if it is important that women be aware of the risks, it is probably unnecessary to recommend that they change their commuting habits. The mode of transportation they have chosen is the result of a compromise between several personal factors, and for them it is the only feasible solution. Doctors have to keep in mind that long commuting may be a risk factor for preterm birth, and all decision-makers must be aware of the health consequences of their economic choices.

Imaging of the levonorgestrel implantable contraceptive device

To the Editors: The availability of the levonorgestrel implantable contraceptive device in the United States has led to its frequent use and predictions that many users of oral contraceptives will switch to the levonorgestrel implant device (Norplant, Wyeth-Ayerst, Philadelphia).[1]

The routine removal of such a device should pose no problem in the vast majority of cases because the subcutaneous implants are palpable. However, in cases in which infection develops or the implant migrates to a deeper nonpalpable location, the identification and removal of implants may be a problem. Prompted by such a case, we attempted to identify the levonorgestrel implantable contraceptive device in a normal location with roentgenography and ultrasonography of the arm.

The implant was easily identified on an anterior-posterior projection film of the distal humerus with soft-tissue film and filming technique (55 kvp, 10 mA sec). The six fanlike projections of the levonorgestrel device are radiopaque (Fig. 1). Nonpalpable implants could be easily localized with radiopaque skin markers similar to those techniques used in mammography.

With a 10 MHz transducer and 1 cm gel pad the six arms of the levonorgestrel implant device can be identified in the transverse plane on the basis of their posterior acoustic shadowing, a characteristic often seen with high-attenuation foreign bodies (Fig. 2). The longitudinal axis can also be identified because of the posterior shadowing.

Plain film roentgenography of the arm for localiza-

Fig. 1. Soft-tissue x-ray film of the forearm shows the levonorgestrel implantable device with the fan-like configuration of its six radiopaque arms *(arrows)*.

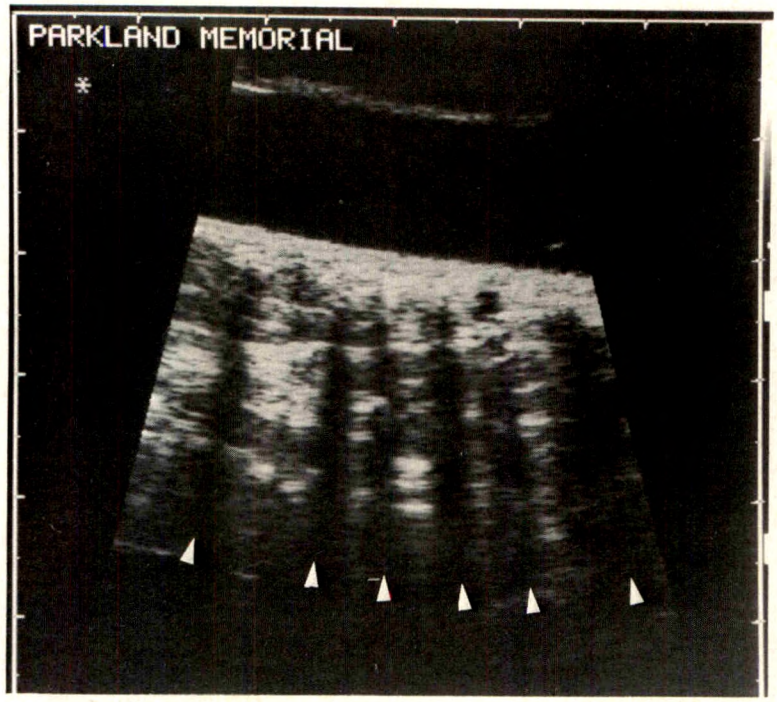

Fig. 2. Ultrasonogram of the levonorgestrel implantable device with the six arms in their axial planes shows the posterior shadowing from the high attenuation of the implant *(arrowheads)*.

tion in our case was faster, easier, less expensive; it also provided better resolution than ultrasonography. Localization for nonpalpable implants can be easily done with skin markers.

In summary, a single anterioposterior soft-tissue roentgenography of the arm can localize the radiopaque levonorgestrel implant device easily and with favorable resolution. This is recommended when palpable localization of the levonorgestrel implant device is not possible.

EOE

PERINATOLOGIST

Maine Medical Center is seeking a Perinatologist to join its busy division in Maine's only tertiary perinatal center. The center features a new labor and delivery suite and NICU as well as an established high resolution ultrasound diagnostic unit performing invasive diagnostic procedures.

Maine Medical Center is northern New England's largest teaching and referral hospital employing 3,500 people. The hospital is located in Portland, Maine, a vibrant and growing city providing the cultural events expected of a large city, but with easy access to the ocean, lakes, and mountains.

We offer an excellent salary and benefits package. Interested candidates should send their curriculum vitae to Phillip Stubblefield, M.D., Chief, Department of Obstetrics and Gynecology, Maine Medical Center, 22 Bramhall Street, Portland, ME 04102, or call (207) 871-2749. An equal opportunity employer.

MAINE MEDICAL CENTER

DEDICATED TO EXCELLENCE

Perinatologist

The Department of Obstetrics and Gynecology of the Long Island Jewish Medical Center is recruiting a third Perinatologist to join the Division of Maternal/Fetal Medicine. The Medical Center is an 825-bed institution with approximately 4,000 deliveries each year, 40% of which are "high risk". An established Antepartum Testing Unit operated by the Division offers sophisticated ultrasonographic facilities and doppler technologies for fetal blood flow assessment. Our Neonatal ICU is one of the largest and most advanced in the entire metropolitan area. Experience with invasive techniques like CVS and PUBS preferred.

Responsibilities include student and resident teaching, prenatal diagnosis, perinatal consultation and a strong interest in research.

Excellent benefit package includes competitive salary, pension plan and ample time for research and scientific meetings. Contact: Dr. Adiel Fleischer, Department of OB/GYN, Room 1100, at (718) 470-7660. Long Island Jewish Medical Center, 270-05 76th Avenue, New Hyde Park, NY 11042. *An Equal Opportunity Employer.*

University of Connecticut
Farmington, CT 06030

Two full-time positions are available in the Department of Obstetrics and Gynecology, University of California, Davis, Medical Center, Sacramento, as perinatologists on the Maternal/Fetal Medicine Service with concurrent appointments to the faculty of the University of California, Davis, School of Medicine. Applicants should be Board eligible or certified in Obstetrics and Gynecology and must have successfully completed subspecialty training in Maternal/Fetal Medicine with subsequent Specialty Board eligibility and/or certification in Maternal/Fetal Medicine. Applicants must possess or be eligible for medical licensure in the State of California. Applicants must demonstrate experience and competence in teaching effectiveness and research related activities or potential for such activities. Applicants must demonstrate experience in prenatal diagnosis, ultrasound and genetics.

Responsibilities of these positions include direction and responsibility for research activities in the division, both inpatient and outpatient case management, surgery and procedures specific to high risk obstetrics participation in teaching activities with residents, interns and medical students, development and/or participation in research activities and involvement in University and Hospital committees.

Send curriculum vitae and five references to:

R. Jeffrey Chang, M.D.
Chairman, Department of Obstetrics and Gynecology
University of California, Davis, Medical Center
1621 Alhambra Boulevard, Suite 2500
Sacramento, California 95816

These positions will be open until filled but not later than December 31, 1992.

The University of California, Davis is an equal opportunity, affirmative action employer.

THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY UNIVERSITY OF WISCONSIN MEDICAL SCHOOL

is seeking applicants for two (2) full-time faculty positions for a new women's health center and academic program at its Milwaukee Clinical Campus.

Sinai Samaritan Medical Center has recently consolidated its obstetrical and gynecological services in a redesigned facility in downtown Milwaukee. The department supports a residency program, the largest perinatal service in Wisconsin (5500 deliveries), consultative ultrasound, genetic and infectious disease programs, and reproductive/endocrine services (including an IVF program). The department is affiliated with Planned Parenthood of Wisconsin and St. Luke's Medical Center in Milwaukee.

Qualifications include a board candidacy or certification in obstetrics and gynecology and a commitment to teaching residents, medical students, and clinical research. Qualifications for the two positions for GENERAL OB/GYN can take into consideration special individual interests. Special expertise of interest for the department are:

—STATEWIDE FAMILY PLANNING
(Part-time medical director, Planned Parenthood)
—OPERATIVE LAPAROSCOPY, HYSTEROSCOPY
—UROGYNECOLOGY
—OB/GYN ULTRASOUND

Private practice opportunities are also available in an associated offsite multispecialty clinic and all faculty members participate in a group practice at the institution. Contact:

FACULTY OPENINGS IN OBSTETRICS & GYNECOLOGY FOR GENERALISTS

Full time faculty positions at the University of South Alabama, Department of Obstetrics & Gynecology. Excellent opportunity for teaching, research and clinical service. Individuals must be board eligible or certified in Specialty. The academic rank and salary will be dependent upon the training and experience of the applicant. These positions are available immediately.

CHAIRMAN

The University of South Carolina is accepting applications and nominations for Professor and Chair of the Department of Obstetrics and Gynecology. The department has eight full-time faculty and sixteen residents. It is broadly based, with particular strengths in oncology, genetics, ultrasonography, maternal and fetal medicine, reproductive endocrinology, and urodynamics. The selected individual will have outstanding credentials in clinical care, research, and academic administration. The Chair's responsibility includes residency and medical student programs in the University of South Carolina School of Medicine, Richland Memorial Hospital, the Dorn VA Medical Center, the Moncrief Army Community Hospital, and the Greenville Hospital System. The incumbent is expected to promote scholarly endeavors, provide administrative leadership to the faculty and staff and to have a national and international reputation. Applicant should submit a curriculum vitae and the names of three references to James A. McFarland, MD, Search Committee Chairman, University of South Carolina School of Medicine, Center for Cancer Treatment and Research, Seven Richland Medical Park, Suite 202, Columbia, SC 29203. The University of South Carolina is an Affirmative Action/Equal Opportunity Employer.

OB/GYN OPPORTUNITIES

Winthrop University Hospital, a major 569-bed teaching affiliate of SUNY Stony Brook School of Medicine, currently has 2 openings for BC/BE Physicians in its OB/GYN Department. This is a dynamic department which includes a full service Perinatal Laboratory and provides over 4,000 GYN procedures utilizing cutting edge surgical technologies and 4,000 deliveries per year.

General Obstetrician/Gynecologist

This full time position offers participation in resident and medical student teaching activities, research opportunities and clinical practice.

Perinatologist-*Faculty Position*

In addition to research, teaching, and consultation activities, you will work closely with The Maternal Fetal Medicine group providing chorionic villus sampling, amniocentesis, cordocentesis, ultrasonography, computerized fetal heart monitoring, and other state of the art genetic testing/fetal monitoring services.

Winthrop University provides compensation that is competitive with experience, credentials and rank, in addition to an outstanding suburban environment. Interested applicants should send CV to: **Harold Schulman, MD, Professor and Chairman, Department of Obstetrics & Gynecology, Winthrop-University Hospital, 259 First Street, Mineola, LI, NY 11501.** An Equal Opportunity Employer M/F/H/V

THE DEPARTMENT OF OBSTETRICS AND GYNECOLOGY UNIVERSITY OF WISCONSIN MEDICAL SCHOOL

is seeking applicants for two (2) additional full-time faculty positions in MATERNAL FETAL MEDICINE for a new women's health center and academic program at its Milwaukee Clinical Campus. The current faculty includes two perinatologists.

Sinai Samaritan Medical Center has recently consolidated its obstetrical and gynecological services in a redesigned facility in downtown Milwaukee. The department has the largest perinatal service in Wisconsin (5500 deliveries) and has a dedicated antenatal testing and perinatal ultrasonography unit, a midwifery, and adolescent pregnancy service. The department has an affiliation with St. Luke's Medical Center in Milwaukee for its residency program.

Qualifications include board candidacy or certification in maternal-fetal medicine and a commitment to teaching residents, medical students, and clinical research. Competitive salary package. Contact:

FRIENDLY FOLKS. BREATH-TAKING BEAUTY. AND THE BEST MEDICINE OUTSIDE MARSHFIELD, WISCONSIN.

Marshfield Clinic, a 400-physician multi-specialty practice, has remarkable practice opportunities within its network of 21 regional centers.

Practice We are seeking obstetrician/gynecologists to join our practices in west central, northwestern and north central Wisconsin. These practices are multi-specialty and range in size from 14 to 35 physicians.

Location / Lifestyle Our practice opportunities are located throughout Wisconsin, a state rich in natural beauty. The areas are surrounded by forest with an abundance of lakes, rivers and streams. Recreational opportunities are plentiful year 'round. Midwestern values in combination with professional excellence contribute to an outstanding quality of life. If these opportunities intrigue you, contact David Draves at 1-800-782-8581, ext. 7-5376.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: **Robert L. Barbieri, MD**
State University of New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty.

- Each bimonthly issue focuses on a specific clinical problem you see in your practice or on a subject area in which important clinical and research information is being generated.
- You get a complete analysis of topics such as: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, sexually transmitted diseases, pediatric and adolescent gynecology, and more.
- Each article is extensively referenced, saving you hours of library research.

Subscribe today by returning the attached order form or by calling our toll-free number!

"Smart, current, in-depth, tough, unique, charismatic, authoritative, handy, relevant, lucid, thorough, convenient, detailed, pithy, top-notch, helpful, sagacious, indispensable, comprehensive, timely, thought-provoking, incisive, straightforward, lively, astute, invaluable, concise, fact-packed, and one-of-a-kind."

Okay. So maybe we're going a little overboard. But our subscribers are an opinionated and enthusiatic bunch. Nearly one in four physicians practicing today is a Year Book subscriber and they are vocal in their loyalty.

And why not? A subscription to the Year Book gives you all the past year's most essential ob/gyn articles condensed for quick and easy reading, and expert advice to help you put the latest findings and techniques to work immediately.

Let's be honest, though, no list of two-dollar words can really convey a book's usefulness and value. *You've got to evaluate it for yourself.*

That's why we're offering you this no-risk, no-examination copy. Put it to work for a month, and if you're not completely satisfied for any reason, just send it back and owe nothing.

But we hope you might want to send us a few adjectives of your own instead–extraordinary, versatile, and revolutionary are still available.

❑ Yes! Please send my 30-day free approval copy of the *1992 Year Book of Obstetrics and Gynecology* (22636) according to the service terms described below. If I decide to keep the book I'll pay just $59.95 (plus shipping, handling, and state sales tax where appropriate).

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboernbolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of an increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1970's. Current clinical recommendation involves the use of lower estrogen dose formulations and a careful consideration of risk factors. In 1989, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the use of oral contraceptives in women 40 years of age and over. The Committee concluded that although cardiovascular disease risks may be increased with oral contraceptive use after age 40 in healthy non-smoking women (even with the newer low-dose formulations), there are also greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception. The Committee recommended that the benefits of low-dose oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take an oral contraceptive which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and individual patient needs. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert.**

ADVERSE REACTIONS: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis.

OVERDOSAGE: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.
